Acerca de este libro

Esta es una copia digital de un libro que, durante generaciones, se ha conservado en las estanterías de una biblioteca, hasta que Google ha decidido escanearlo como parte de un proyecto que pretende que sea posible descubrir en línea libros de todo el mundo.

Ha sobrevivido tantos años como para que los derechos de autor hayan expirado y el libro pase a ser de dominio público. El que un libro sea de dominio público significa que nunca ha estado protegido por derechos de autor, o bien que el período legal de estos derechos ya ha expirado. Es posible que una misma obra sea de dominio público en unos países y, sin embargo, no lo sea en otros. Los libros de dominio público son nuestras puertas hacia el pasado, suponen un patrimonio histórico, cultural y de conocimientos que, a menudo, resulta difícil de descubrir.

Todas las anotaciones, marcas y otras señales en los márgenes que estén presentes en el volumen original aparecerán también en este archivo como testimonio del largo viaje que el libro ha recorrido desde el editor hasta la biblioteca y, finalmente, hasta usted.

Normas de uso

Google se enorgullece de poder colaborar con distintas bibliotecas para digitalizar los materiales de dominio público a fin de hacerlos accesibles a todo el mundo. Los libros de dominio público son patrimonio de todos, nosotros somos sus humildes guardianes. No obstante, se trata de un trabajo caro. Por este motivo, y para poder ofrecer este recurso, hemos tomado medidas para evitar que se produzca un abuso por parte de terceros con fines comerciales, y hemos incluido restricciones técnicas sobre las solicitudes automatizadas.

Asimismo, le pedimos que:

+ *Haga un uso exclusivamente no comercial de estos archivos* Hemos diseñado la Búsqueda de libros de Google para el uso de particulares; como tal, le pedimos que utilice estos archivos con fines personales, y no comerciales.

+ *No envíe solicitudes automatizadas* Por favor, no envíe solicitudes automatizadas de ningún tipo al sistema de Google. Si está llevando a cabo una investigación sobre traducción automática, reconocimiento óptico de caracteres u otros campos para los que resulte útil disfrutar de acceso a una gran cantidad de texto, por favor, envíenos un mensaje. Fomentamos el uso de materiales de dominio público con estos propósitos y seguro que podremos ayudarle.

+ *Conserve la atribución* La filigrana de Google que verá en todos los archivos es fundamental para informar a los usuarios sobre este proyecto y ayudarles a encontrar materiales adicionales en la Búsqueda de libros de Google. Por favor, no la elimine.

+ *Manténgase siempre dentro de la legalidad* Sea cual sea el uso que haga de estos materiales, recuerde que es responsable de asegurarse de que todo lo que hace es legal. No dé por sentado que, por el hecho de que una obra se considere de dominio público para los usuarios de los Estados Unidos, lo será también para los usuarios de otros países. La legislación sobre derechos de autor varía de un país a otro, y no podemos facilitar información sobre si está permitido un uso específico de algún libro. Por favor, no suponga que la aparición de un libro en nuestro programa significa que se puede utilizar de igual manera en todo el mundo. La responsabilidad ante la infracción de los derechos de autor puede ser muy grave.

Acerca de la Búsqueda de libros de Google

El objetivo de Google consiste en organizar información procedente de todo el mundo y hacerla accesible y útil de forma universal. El programa de Búsqueda de libros de Google ayuda a los lectores a descubrir los libros de todo el mundo a la vez que ayuda a autores y editores a llegar a nuevas audiencias. Podrá realizar búsquedas en el texto completo de este libro en la web, en la página `http://books.google.com`

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

Abnormal lamp breakage.... N 234
Accumulator, Biographical sketch of the Khotinsky, Capt. A de Khotinsky. *A 293, 308, 446, 473, 491, 519
  “ Elieson.... *A 442
  “ Tommasi multipolar.... N 297
Accumulators in central stations Tudor, Paul Schoop.... *A 465
Acheson's lamp decision.... L 18
Acme Storage Battery Mfg. Co.... T N 308
Adjustment of standards of resistance and the determination of temperature co-efficients, E. G. Willyoung.... *A 591
Air compressor works, Clayton.... T N 280
Alexander, Barney & Chapin.... N 282
Alleged stealing of electric current in St. Louis.... L N 65, 66
Alternating current practice, A departure in.. E 429
  “ currents, experiments with.... *Ax 224
  “ “ Siemen's experiments with high-tension, W. J. Hammer.... *A 450
  “ plants, efficiency of.... L 579, 629
Aluminum-Iron, magnetic properties of.... Ax 29
American Association for the advancement of science.... N 42, 201
  “ Electro-Enamelite Co.... T N 185
  “ Electro-Therapeutic Ass'n.... N 278, 302
  “ Institute of Electrical Engineers.... N 275, 326, 436, 509, 606, 632
  “ Society of Mechanical Engineers.... N 582
  “ St. Ry. Ass'n, Annual meeting.... A 405
  “ type telegraph.... *A 89
America's greatest railroad.... T N 186
Ammeter, Cutler non-inductive.... T N 464
Annunciator drop, Hard.... T N 487
Antimony in electrolytic copper.... N 252
Apparatus for demonstrating curves of electric current flow in conductors under different conditions.... *Ax 111
Application of destructors, particularly to the electrical lighting of Edinburgh.... Ax 227
Arc lamps for optical projection, R. S. Dobbie.... *A 541
Armature reactions, method for balancing.. Ax 547
  “ Insulation—Micanite.... *Ax 625
  “ “ Vital importance of.... E 622
Arnot, H. W.... N 158
Aspen, Colo. electrical development.... T N 357
Association of Edison Illuminating Co.'s at Toronto.... A 152
Atmospheric electricity.... N 468
Auburn Electric Motor Co.... T N 536
Aurora Borealis.... N 166
Auroral and earth currents, D. B. Grandy.... A 220
  “ “ “ W. Finn.... A 250

B

Badge of the American Institute of Electrical Engineers, Proposed.... N 632
Balances for very heavy currents, Lord Kelvin's.... *A 80
Balch and his unipolar critics.... L 459
Ball dynamos and how they are made, L. W. Collins.... *A 522
  “ Electric Light Co.... T N 44
  “ Engine Co.... T N 69, 95, 96, 140, 161, 438, 464
  “ & Wood Co.... T N 187
Baltimore Illuminating Co.... T N 358
  “ notes.... T N 24, 635
  “ & Pikeville Electric Railway Co.... N 181
Barnes friction clutch pulleys.... T N 635
Battery and bell, “Hard.”.... T N 462
  “ Circulating.... N 594
  “ Coleman storage.... T N 558
  “ Fuller.... T N 162
  “ Wright combination primary.... T N 329
Batteries, variation of E. M. F. of secondary. Ax 88
Beacon lamps.... T N 561
  “ Vacuum Pump and Electrical Co. in Canada.... T N 116
Bericht uber die Verhandlungen des Internationalen Elektrotechniker Congress zu Frankfurt am Main.... R 85
Berliner, J.... 634
Bernard adjustable cleat.... T N 486
Bicyclist lamp trimmer.... *A 252
Billings & Spencer Co.... T N 45, 304
Biographical review of the Khotinsky accumulator, Capt. A. de Khotinsky, *A 235, 264, 293, ... 308, 446, 473, 491, 519
Bishop cable selected for Thunder Bay.... T N 358
Blackening of incandescent lamps, E. E. Carey,.... A 118
Bliss & Co., Limited.... T N 327
Block signals of the present and what is required for the future.... Ax 88
  “ system, Strom automatic electric safety,.... *A 178
Boiler Auxiliary, Sloane.... T N 303
  “ pitting cured by graphite and oil.... T N 211
  “ New York safety sectional water-tube,.... T N 536
  “ plant of Curtis Davis & Co.... T N 560
Boilers, McLauthlin, safety.... T N 162
Bolte automatic time keeper.... T N 415
Bonding electric railway track, H. K. McCay.. A 482
Borst, Jeremiah, (*obituary*).... 19
Boston West End Street Railway Co.'s international report.... N 182
Bradley hydro-carbon burner.... T N 185
Brain electric tramway system.... *A 294
Brakes for electric cars, Genett.... T N 329
Brass manufacturers, consolidation of.... E 313
Brill, J. G. Co.... T N 561
British Ass'n meeting, Units at, H. S. Carhart,.... A 166
  “ postal telegraph figures.... N 431
Brixey and Kerite.... T N 327
Brooklyn Eagle's new house.... N 113
  “ Institute of arts and sciences.... N 533
Brotherhood of electrical workers.... N 583
Brush Electric Co., Decision restoring territory, Supplement.... 335
  “ plant at Geneva, N. Y.... T N 44
  “ storage battery decision, Supplement.. 336
Burner, Iona safety pendant.... T N 385
Buffalo, Electrical Society.... N 606
  “ station, Fire in.... T N 634
Burke cable relay and transmitter.... *A 539

C

C. & C. apparatus for the World's Fair.... T N 358
Cable, buying submarine, abroad for the government.... A 229
  “ relay and transmitter, Burke.... *A 539
  “ required for Lake Huron, submarine.. N 275
  “ ship “Mackay-Bennett”.... N 577
Cables, Importation of submarine.... L 356
Camden Horse Railroad Co.... N 181
Canadian Electrical Association, first annual convention.... A 15
  “ General Electric Co.... N 433
  “ notes.... T N 188, 257, 306, 328, 360, 488, 612
  “ patent law.... P N 150, 196, 533
  “ power transmission project.... L 254
Car, Ford-Washburn storage battery.... *A 287
  “ of the Combination Car Co.... N 205
Carbon, Hazeltine double-plated.... N 544
Carbons.... Ax 88
Card Electric Motor and Dynamo Co.... T N 538
Carhart-Clark standard cells.... T N 438
Carpenter Elec. Heating Mfg. Co.... T N 359
  “ Enamel Rheostat Co.... T N 207, 296

THE
Electrical Engineer.

VOL. XIV. JULY 6, 1892. No. 218.

THE DUPLEX DYNAMOS AND MOTORS.

ELECTRIC lighting in its struggle for victory over oil and gas has not only been dependent upon improvements in lamps but upon the evolution of the dynamo; and each new stage in the larger utilization of electricity for light and power has been marked by the production and popularity of forms of machines that were not asked for during the earlier periods of development. A feature of this later work, moreover, has been the attention it has commanded at the hands of engineers and concerns who have entered the field of dynamo building just as they might have entered that of engine building—not with the object of keeping within the strict and narrow limits of a "system" but solely, as manufacturers and engineers, to construct the best apparatus that the needs and knowledge of the hour would permit. This is an altogether healthy and encouraging sign, since it places dynamo building in line with the other mechanical industries of greater age, in which the success of apparatus has come to depend upon merit, rather than upon accidental and adventitious conditions.

Among those who have steadily forged ahead in the creation of a standard series of dynamo machines is the Duplex Electric Co., Ltd., of Corry, Pa., who are now building machines adapted for both generators and motors ranging in capacity from 50 to 135 h. p.

Recognizing the desirability of avoiding the use of countershafting as much as possible, the new type of machines are constructed on the multipolar plan, the general outline of the magnetic field being shown in the engraving Fig. 1. The machine complete is shown in perspective in Fig. 2. The armature is of the Gramme ring type, and as an example of the methods adopted in the construction of these machines we give below the figures relating to the No. 10 dynamo:

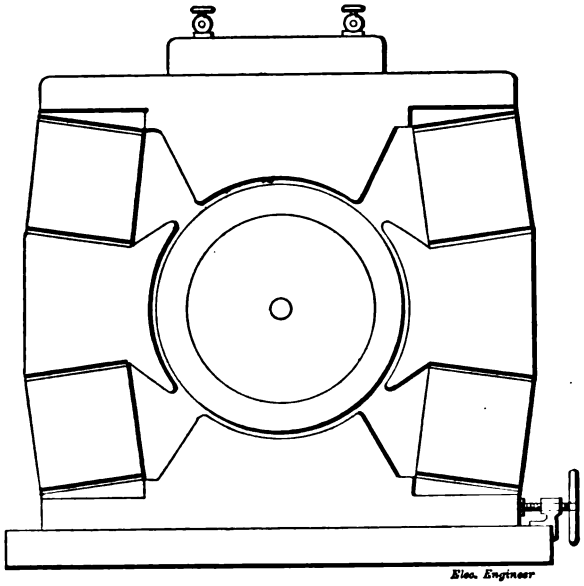

FIG. 1.—MAGNET FRAME OF DUPLEX DYNAMO.

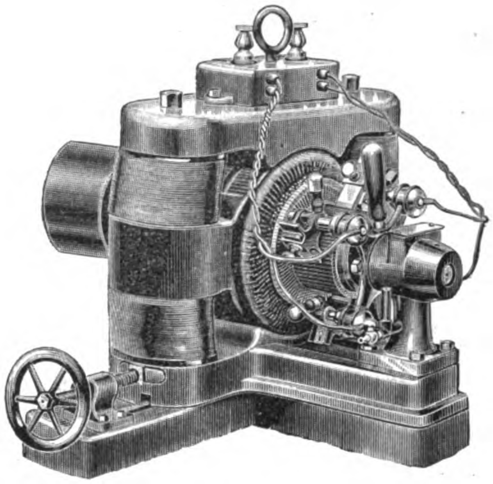

FIG. 2.—THE DUPLEX DYNAMO MACHINE.

Incandescent lamp capacity	500
Current capacity	275 amp.
E. M. F.	110 volts
Electric power	27,500 watts
Power required for driving	40 h. p.
Resistance in shunt field	23.7 ohms
" " series "	0.0066 "
" " armature	0.0078 "
Speed	750 r. p. m.
Weight	3,500 lbs.

The machine, as will be noted, is compound wound and hence regulates automatically throughout its entire load, no rheostat being required.

With the construction adopted involving so high a ratio in the field and so low a resistance in the armature and series winding, an electrical efficiency of over 95 per cent. is attained with a commercial efficiency of over 92 per cent.

THE DIAMETER OF FULGURITES.

WHEN a bolt of lightning strikes a bed of sand, says an exchange, it plunges downward into the sand for a distance, less or greater, transforming simultaneously into glass the silica in the material through which it passes. Thus, by its great heat, it forms at once a glass tube of precisely its own size. Now and then such a tube is found and dug up. Fulgurites have been followed into the sand by excavations for nearly thirty feet. They vary in interior diameter from the size of a quill to three inches or more, according to the bore of the flash. But fulgurites are not alone produced in sand; they are found also in solid rocks, though very naturally of slight depth and frequently existing merely as a thin glassy coating on the surface. Such fulgurites occur in astonishing abundance on the summit of Little Ararat, in Armenia. The rock is soft, and so porous that blocks a foot long can be obtained, perforated in all directions by little tubes filled with bottle-green glass formed from the fused rock.

WHAT AN ELECTRICAL DICTIONARY MIGHT BE.

BY

Edwin J. Houston

UNDER the above title Mr. Park Benjamin has described in the issue of THE ELECTRICAL ENGINEER, of June 22, 1892, the lines along which, according to his judgment, an electrical dictionary should be written. Although he says the article referred to was not written as a review of the second edition of my "Dictionary of Electrical Words, Terms and Phrases," yet, as I have prepared such book along the exact lines he thinks should be avoided, it may interest the public generally if I explain why I believe such lines to be eminently those along which a practical book should be written; for, what I have at least aimed at, although I may have fallen short of the mark, has been to prepare a live book, for use at the present time, and not one "whose practical value will be inversely proportional to its age."

While I quite agree with Mr. Benjamin in some respects as to the possible advantages which may be derived from a dictionary such as he believes the electrical dictionary of the future should be, yet I submit that such a dictionary would not reach the principal class for which dictionaries of all kinds are prepared; namely, the great reading public; as well as the great army of workers in the many electric and co-ordinate industries.

Mr. Benjamin has described a dictionary which would unquestionably be of great use to that limited class, the scientific expert, of undoubted value to that equally limited class, the philologist, and of unquestionable value to that rapidly increasing class, the expert electrician; but, to the great majority of busy workers, and of general readers, it would prove, what I fear some of the large dictionaries of to-day prove to the busy inquirer of knowledge, viz., one perpetual conundrum as to what such words mean to-day. For my own part, when I wish to know the exact meaning of a word as used during a certain age, I go directly to dictionaries of that age. But this cannot be done as regards electrical terms, for there were no electrical dictionaries in the early history of the science, and the glossaries of terms were exceedingly limited, and, as a rule, quite unsatisfactory.

Mr. Benjamin has pictured to himself the electrical dictionary of the future as any other distinguished expert, such as he is, would delight in. This book is to contain all the evidence required in great patent suits ready at hand, and accurately recorded, so as to avoid those researches into electrical literature, that are at the same time so laborious to the expert and expensive to his client. Such a book would, undoubtedly, be of great value, but it would hardly be a dictionary in the modern sense of the term.

As regards Mr. Benjamin's statement that, "The general public can find all the electrical terms it needs set forth, with sufficient fullness, in existing text-books, and in the great dictionaries, such as the 'Century,'" I would respectfully suggest that the general public are not so fortunate as Mr. Benjamin, who is in possession of one of the most complete electrical libraries in the country, and, even if they were, there are comparatively few who have either the time to consult such works, or the necessary knowledge to find the information desired.

As regards the latter part of the statement as to the sufficiency of the existing great dictionaries to correctly interpret electrical literature as found to-day in the leading technical journals, I feel sure that although such dictionaries are fairly complete, any one would be convinced of the contrary, if he made an actual trial. A technical dictionary is necessary correctly to interpret technical literature; especially, technical popular literature.

Mr. Benjamin assumes that the modern dictionary of electricity should be written for the electrical expert. So it undoubtedly should; but by no means for the electrical expert alone. Its principal province is to meet the wants of the vast army of electrical artisans, mechanics, linemen, station men, trimmers, engineers, firemen, motormen, electroplaters, electrotypers, electro-chemists, telegraphic and telephonic operators, and numerous others, and especially for that still greater class, the general business public, to whom an exact knowledge of the meaning of electrical words, terms, and phrases is a necessity of their business life, and to whom, with all deference to the great dictionaries already existing, such dictionaries are insufficient, as indeed owing to the technical character of the words contained, they must be.

In view of the various classes for which the modern as well as the future electrical dictionary is to be written, there should, in my opinion, of absolute necessity, be inserted cuts of all articles, even including "a Wheatstone bridge or a typical resistance coil." A definition of a Wheatstone bridge might be given that would be sufficiently exact to give some idea of the thing itself, but would necessarily be too labored and extended for practical use. Insert a good cut describing the thing as it actually appears, and, after all, it is only another kind of language, —and how much clearer the definition becomes!

It is the province of a dictionary to define words, terms and phrases correctly, and any means which will throw light on each definition and so prevent ambiguity must necessarily make such a work better as a dictionary. Indeed it appears to me that the dictionary of the future must necessarily be encyclopædic in character in order to avoid some of the other objections which Mr. Benjamin thinks he sees in the dictionary of to-day.

As regards encyclopædias, so far as my own experience goes,—after wading through an immense mass of uninteresting, unnecessary and irrelevant details, in which I am not interested, in order to get at the precise meaning of a certain thing, I either find such information carefully concealed, or exasperatingly vague,—I am decidedly of the opinion that the encyclopædias of to-day would be greatly improved if in all cases they were expected to give in concise language just what certain things are, or do mean, and then to add such explanatory or descriptive matter as seems to be required.

The vast increase in the sum of human knowledge would, it seems to me, render it more and more necessary for the future electrical dictionary to be constructed along lines exactly opposite to those described by Mr. Benjamin.

Of course there can be but one criterion for a correct definition, and this is to be found in the "general consensus of opinion." For this, the opinion of no single person or authority can, or should be, accepted; but, after all, the consensus of opinion must be formulated by some one, and the modern as well as the future dictionary must contain such formulated opinions, unless the dictionary is to become a complete library in itself.

It would seem to me that the words, terms and phrases embodied in the modern as well as the future electrical dictionary should be defined practically along the following lines, namely:

(1.) Such definitions should start with a concise definition of the word, term or phrase, giving the meaning generally accepted during the present time. These definitions, though given by a single mind, will by no means be of necessity only what the framer of such definition understands the words, terms or phrases to mean, but the significance which he believes that all who employ such words, terms or phrases, give to them.

(2.) There should then follow such full descriptive matter of the scientific principles or of the apparatus involved in the definition as the space of the work will permit. If such a method intrench on the province of the encyclopædia it will by no means impair its value as a dictionary but on the contrary will greatly enlarge the sphere of its usefulness.

(3.) Cuts of the things described should by all means be annexed. I believe all lexicographers are agreed in this respect. Mr. Benjamin will find the latest dictionaries filled with cuts describing the things defined.

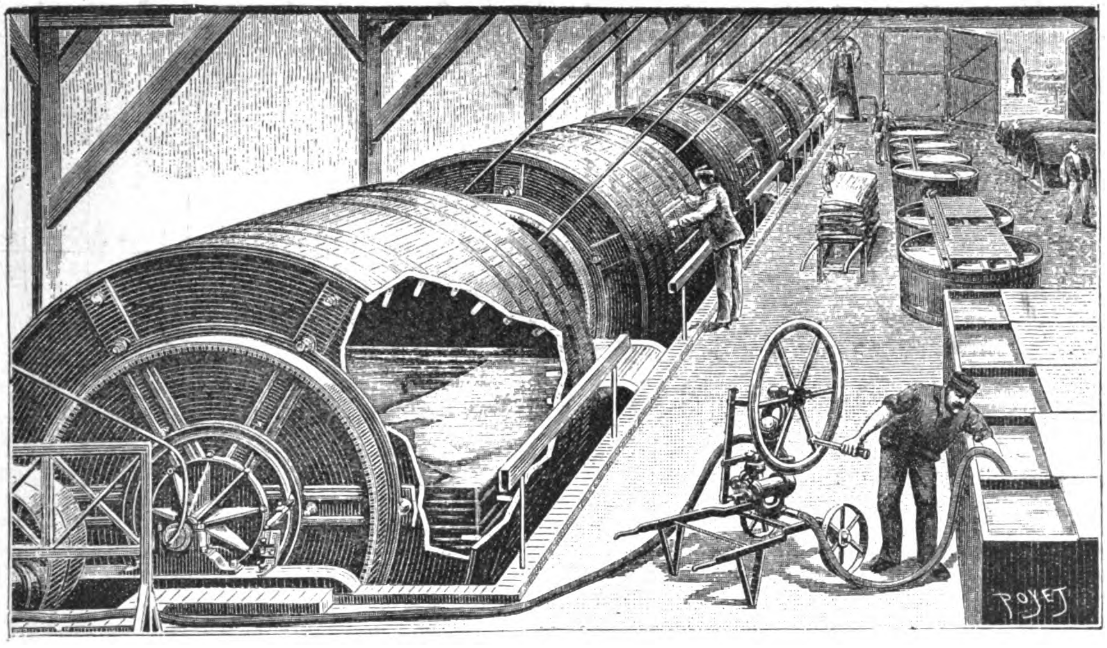
(4.) The existing meaning of the word, term or phrase being thus disposed of, there should then follow a statement of the different senses in which such word, term or phrase has been employed during different periods and such differences as herein pointed out should, if the space permit, be supplemented by extracts from contemporaneous literature.

As to the statement of Mr. Benjamin that "a dictionary which sets forth the views we take to-day, becomes inaccurate to-morrow and perhaps wrong next year," there can be no contention, but I will ask whether it is only of the electrical dictionary that this can be asserted?

Franklin Institute, Philadelphia, Pa.

TANNING BY ELECTRICITY IN PARIS.

Some time ago we drew attention to the process of electric tanning, which had been brought out in France, and in which the method of Messrs. Worms & Balé was employed.



Electric Tannery in Paris, France.—Worms & Balé Process.

Since that time a number of tanneries have been fitted up with the electric system, and in a recent number *La Nature* describes and illustrates that of Messrs. Brion & Dupré, in Paris. The process, it will be remembered, consists in the employment of electricity in connection with rotating drums which place the skins in direct contact with the tanning liquors. By this combined action of electricity and rotation a continual renewal of the surfaces is brought about, and the tanning process is greatly expedited.

The principal point was the adaptation of revolving cylinders with suitable means for obtaining a regular and continuous passage of the current, and it was for the lack of such means that former attempts at the solution of this problem failed. Messrs. Worms & Balé have solved the problem by attaching to the periphery of the drum two metallic rings, connected with circular conductors placed on the interior of the drum, as shown in the accompanying illustration. These conductors receive the current by two elastic brushes bearing against the two rings of the drum and connected to the poles of the dynamo.

The inventors make no secret of their formula. Into each rotating drum there are introduced 500 litres of filtered water for every 100 kilograms of skins to be tanned, one kilogram of bark extract at 20° Beaumé per kilogram of skins, and, finally, the necessary quantity of skins to be tanned in proportion to the figures given above. Whatever be the tanning substance employed, either in the form of liquor or bark extract, as soon as the drum has received the proper quantity it is hermetically sealed and started into rotation, and the current turned on.

The time of working is the following, according to the nature of the skins to be tanned: Ox, cow and steer hides, ninety-six hours; horse and heavy calf skins, seventy-two hours; medium and light skins, forty-eight hours. The importance of the results obtained will be apparent when it is considered that there is accomplished in ninety-six hours, by the electric method, what would require from seventeen to eighteen months by tanning in a vat, and from five to six months by the process of agitation. The electric operation is accomplished without the generation of any bad odors, and almost without noise, and with remarkable precision and regularity. The skins obtained have shown themselves, according to good authority, at least equal to those obtained by the old method.

The nature of the action going on in the electric process is quite simple.

Prof. Silvanus P. Thompson considers that the skins act like accumulator plates; that is, they constitute, as it were, enormous porous electrodes upon which the gases are liberated and which are susceptible of absorbing the gases arising from the electrolysis which takes place. At the same time the well-known phenomena of osmose take place; the capillarity of the cells of the skins being modified or interrupted, the cells are emptied of the liquors which they contain and these liquors are replaced by the tanning liquors which, placed in contact with the interior of the skins at innumerable points, produce a transformation of the hide with remarkable rapidity. The electric process is being worked not only in France but also in England, Portugal, Brazil, Argentine Republic and the United States.

The Denver Electrical Association has been incorporated for educational and technical purposes by W. J. Barker, C. K. Heasley, F. Sturges, W. D. Tyler and C. F. Hart.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY—VIII.[1]

BY

A. E. Kennelly

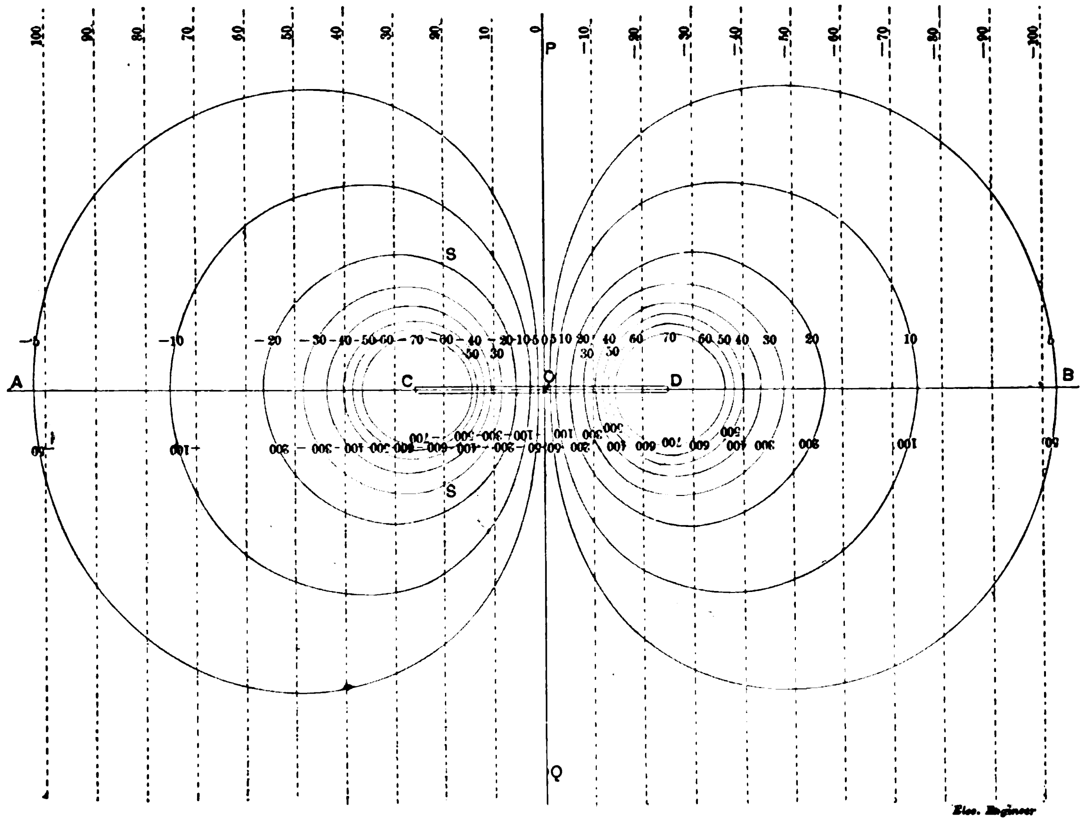
THE INFLUENCE OF IRON IN AND ON THE MAGNETIC CIRCUIT—*Continued.*

If we next consider circuits partly composed of non-magnetic material, and partly of iron, we have to add one more link to the chain of consequences, and take into consideration the demagnetizing influence of the iron on itself. The M. M. F. induced in the iron establishes its own local magnetic circuit independent of the prime system, and its flux on the returning path that completes this local circuit, entering the iron in the reversed direction, tends to neutralize the excitation of the prime flux. The induced M. M. F. reached in the iron at each point is such that it is just $\mu - 1$ times the resultant of the prime and induced counterflux.

Figs. 16 and 17 represent the effect of placing in a uniform flux, a soft-iron bar 50 cms. long, and 20 π square cms. in cross-section. The prime distribution of equipotential parallel planes is indicated by the dotted lines 10 cms. apart, and since the gradient is 10 ergs-per-unit-pole in this distance, $B = 1$, from left to right. The bar C O D is now introduced with its axis parallel to B. If the value of μ for the iron composing it, with $H = 1$, happened to be 2001, the induced distribution of potential would be approximately that indicated by the closed curves to the scale of inverted numbers. The external potentials are indicated only from + 700 to — 700. By rotating the diagram about the axis A O B, these curves will generate the corresponding equipotential surfaces. Within the bar the equipotential surfaces would be planes perpendicular to the axis with $B = 2001$ from left to right. Outside the bar the flux completes the local magnetic circuit of the induced system by curved diverging paths from right to left.

The induced system would be similar to the straight solenoid or helix in Fig. 4 discussed in Chapter III, and the bar with this distribution could be replaced by a solenoid of the same dimensions without iron, and having $\frac{2000}{4\pi}$ current-turns per cm. or $\frac{100000}{4\pi}$ current-turns in all. But the bar could never attain this distribution, owing to the counteracting influence of its own external return flux. There is no magnetic insulator which will keep this return flux outside the bar, and it penetrates the iron with an influence equal to that of prime flux with the same intensity. Thus where the surfaces of 700 and 300 ergs cut the bar, they are rather less than 5 cms. apart. The mean value of B in this length will be $\frac{700 - 300}{5}$, or, 80, due to the external flux, or 80 times more powerful than the prime flux to which it is opposed. This demagnetizing influence would be most active near the extremities of the bar, where the external fall of potential is most rapid, and least near the centre. The result will be that the flux induced in the bar instead of taking the value $H(\mu - 1)$ which we know it would assume if there were no counteracting return flux—that is, if the bar formed the core of a closed circular solenoid—rises to the value at which it is $\mu - 1$ times the local H or resultant of the prime and induced distributions. Even if the prime flux be uniform, the induced return flux will generally vary from point to point, and the value of μ corresponding to their resultant or combination, will also be in general a variable, so that the induced system in the iron usually becomes very complex.

In the case of Fig. 16, we may, for the sake of illustration, waive all attempts at accurately depicting the resulting induced system left in the bar under the combined



Scale, ¼ Full Size

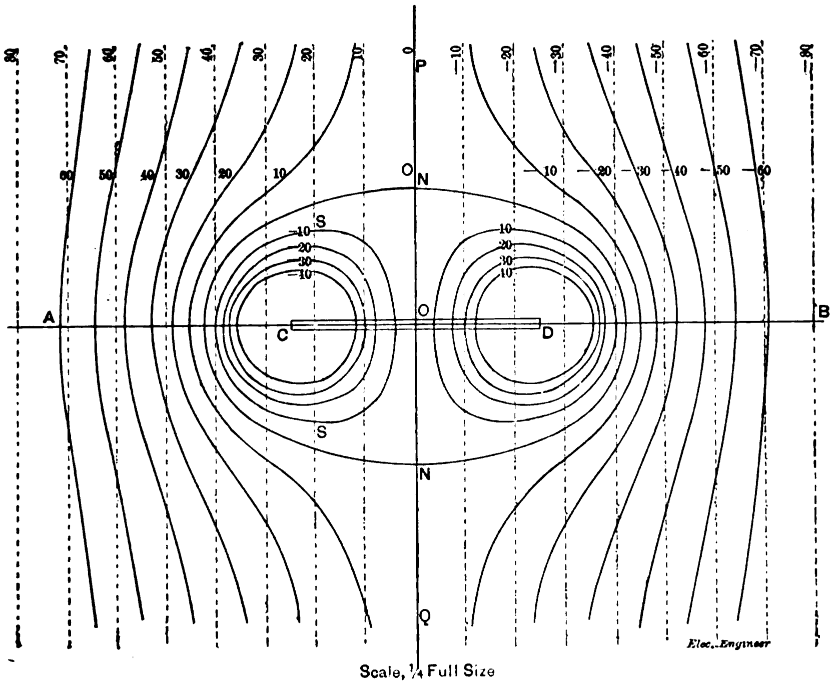
Fig. 16.

---

[1] *Copyrighted, 1892, by A. E. Kennelly.*

influences of the prime and its own return fluxes. We may assume that the relation of μ to varying values of H, as determined by experiment, may be such that the modified potential is everywhere 10 times less than the unmodified potential would have been, in which case the same distribution of equipotential surfaces here indicated will apply, the scale being altered to the upper numbers. This is the final condition of the induced system, and is independent of, although superposed upon, the prime system. If we add together at all suitable points the potentials of the prime and final induced systems, we obtain a new series of equipotential surfaces represented in Fig. 17. For instance, the points S S situated on the prime plane of + 20 and the induced surface of — 30 will have a resultant potential of — 10, and the surface of — 10 in the resulting system passes through them. Here the dotted lines still indicate the prime equipotential planes, and the curved lines the resultant system.

Notwithstanding the arbitrary manner in which we have simplified and chosen the final induced system, this diagram fairly represents the general effect of introducing a bar magnet or rod of soft-iron into a uniform field.



Scale, ¼ Full Size

FIG. 17.

Broadly, the prime equipotential surfaces are displaced, as an elastic medium might be, by the introduction of a wedge. The flux is intensified along the line of the axis, and weakened in the neighborhood of the equatorial plane. The surface of zero potential has two sheets, one in the equatorial plane, and the other an ellipsoid enveloping the bar. At their intersection N N a neutral circle is formed, obtained by revolving the radius O N round the axis A O B. At all points on this circle the flux vanishes, and a small compass needle would not assume any selective direction. That is to say, on this circle, the prime flux from left to right just balances in intensity the return flux of the local or bar circuit, from right to left.

In the above instance we have considered the case of a long, straight and narrow bar placed lengthwise in a uniform flux; but the removal of these restrictions, while it may add numerical complexity, brings no additional intricacy of process. In all cases we have first to determine, from the currents and their geometrical arrangement, the elements of the prime system with the iron removed. Then introducing the iron into the circuit, the final induced system has to be found, such that at every point the induced M. M. F. is (μ — 1) times the value of the resultant intensity due to prime and induced distributions, μ being a function of the intensity experimentally determined. We might consider the iron as divided up into bundles of rods arranged everywhere parallel to the flux, and find the distribution round one rod at a time as though that existed alone, and then superpose the successive distributions from neighboring rods, extending the process until every rod had its influence compounded. Or it might be possible to deal with the iron in mass by some more comprehensive method that would render this long summation unnecessary; but the final induced system, however arrived at, when superposed upon the prime distribution would yield the resultant system actually developed in the circuit.

On the removal of the prime system, the induced system is left active, but the iron, no longer submitted to the prime excitation is exposed solely to its own return flux tending to reduce the residual M. M. F. The demagnetizing influence will vary from point to point, depending upon the distribution of potential and flux in the induced system; but wherever the demagnetizing flux exceeds a certain intensity depending upon the quality of the iron, a process of decadence will set in. The induced system may be destroyed in a small fraction of a second, or it may be sustained nearly complete for an indefinite period according to the range of μ in the iron, and the form of its circuit, which latter regulates the intensity of the demagnetizing return flux.

These conditions of magnetization in iron are readily apprehended qualitatively, but they are numerically so complex that the elements of a magnetic circuit partly composed of iron, cannot in general be computed. They have in fact only been determined in a few simple cases, and usually on the assumption that μ has a constant value.

It is evident that from the standpoint of magnetic circuits, a magnet is equivalent to a particular form of active solenoid. A piece of magnetized iron is physically very different from a conductor carrying a current, but magnetically it is a particular aggregation of small magneto-motive forces and as such the corresponding arrangement of conducting loops must always exist.

Ewing's theory is the most recent and comprehensive hypothesis accounting for the magnetic behavior of iron. According to this view, every molecule of iron may be regarded as an elementary independent magnet, free to set itself in any direction under the influences of magnetic flux. Each molecule has a separate magnetic circuit, in which the M. M. F. is inherent and fixed. The flux from any one molecular magnet, while extending over the whole system, will be practically confined in its action to those molecules in closest proximity. The result of all the mutual actions will be an aggregation of magnetic circuits in all directions and degrees of complexity, so that the resultant M. M. F. in any one line is zero. The iron is then neutral. If a gradually increasing flux is brought to bear upon the system from an exterior M. M. F., at first only a few molecules in balanced or unstable equilibrium will be affected and turned into alignment with the flux. Gradually molecules in firmer mutual association will be separated from the configurations they had naturally assumed, and brought into more or less direct alignment with the impressed flux. There will be a certain strength of flux which will suffice to destroy a large majority of all the groups. At this stage μ will reach a maximum value. Beyond this point only the more powerful and enduring arrangements will remain to be reduced, as well as the more perfect alignment of those already mastered, while a few of the most powerfully united groups will require comparatively great intensities to resolve them. At an indefinitely great intensity, every molecule will be brought into parallelism. In this condition, the M. M. F. induced in the iron will have reached its maximum, and be equal to the sum of all the molecular M. M. F.'s in any one line. At any intermediate stage, the induced M. M. F. would be the sum of the M. M. F.'s now more or less dispersed, resolved along this line, the components at right angles to the flux disappearing in the aggregate by cancellation.

Besides offering explanations for a variety of magnetic phenomena, this theory accounts for the observation that μ does not merely depend upon the magnitude of the prime intensity H, but also upon the manner in which this magnitude has been reached; for the molecular disengagements will generally differ if this value be attained by steady increase, by reversals, or again by overreaching and descent, so that the condition at any moment involves the previous history of the iron, or gives evidence of what has been termed its "magnetic memory." We shall return to this subject at a later period.

In most electromagnetic machines, the magnetic circuit is principally of iron, and consequently approximates to the type of a closed solenoid with iron core. This greatly facilitates the computations, for although there is some return flux, whose influence prevents an accurate determination from being arrived at, unless experimentally, yet the demagnetizing flux is generally small compared with the prime excitation, and a sufficiently close approximation to the resulting magnetic circuit is usually available to meet practical requirements. It is only when the circuit has a lesser proportion of iron and larger air-gaps, that the numerical difficulties in determining the resulting system become formidable.

A USEFUL INCANDESCENT LAMP DIAGRAM.

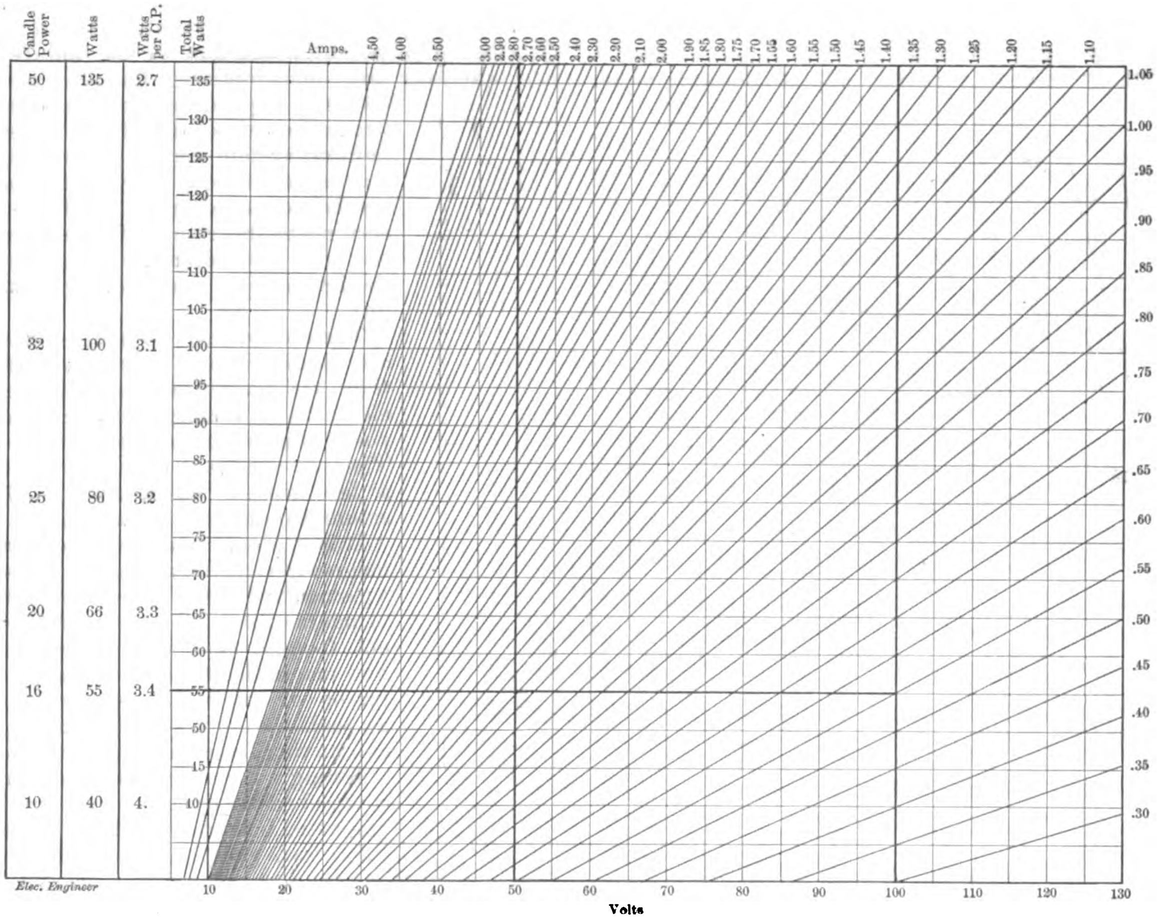
BY

E. V. Roberts

THE accompanying diagram devised by the writer will be useful when considering lamps and also for other purposes.

The first vertical column gives the candle power; the second, the total watts taken as the standard for such candle power, the third, the watts per c. p. for such a standard; the fourth column, the total watts.

In order to obtain the amperes corresponding to any total watts for any desired voltage the line indicating the total watts is followed horizontally until intersection is made with the vertical line indicating the desired voltage, and the diagonal line intersecting at such point gives the amperes. Heavy lines are drawn through 55 watts (the standard taken for 16 c. p.) and 50 and 100 volts. Of course the total watts for a given c. p. will often not be in accordance with the standard shown, 16 c. p. lamps being ordered of from 50–65 watts.



ROBERTS' INCANDESCENT LAMP DIAGRAM.

Example No. 1 —Given a 54-volt 55-watt lamp, what "C" will it take?

Answer.—Follow the 55-watt line to 54 V. The diagonal is almost half-way between 1 and 1.05; hence 1.02 ampere.

Example No. 2.—Lamp, at c. p. desired, 110 volts; 85 amperes. Find the total watts.

Answer.—Intersection of .85 ampere and 110 volt lines gives 93.5 watts.

ELECTRICITY IN BITUMINOUS MINING.[1]

BY ELMER A. SPERRY.

MANY a traveling Englishman on this side turns his eye-glass upon a swift succession of passing trains laden with barely a day's product from some unheard-of Western colliery, and thinks that he instinctively recognizes pit coals from Northumberland or Lancashire. He supposes "all coals come from Newcastle;" nor is this surprising. The average Eastern men may be said to be almost unaware of the existence of bituminous fuel. To him anthracite is coal, and Pennsylvania is the place of its nativity. Yet last year 150,000,000 tons of bituminous coal were mined in the United States, principally in the West.

The problem of replacing manual labor in coal mining has engrossed the labors and thought of the ablest engineers of the age. Some of the earliest patents granted by the English monarchs were for mechanical mining devices with an avowed object of superseding manual labor. These machines were driven by animal or hydraulic power, and more recently by steam and compressed air. They sawed, scraped, cut and plowed, but principally struck a blow. Many, even to a recent date, swung a pick provided with the ordinary transverse handle or power connection. Few if any of these machines have been successful under the severe duties required, and none have withstood the test of time. Machines generally employing cutting or scraping devices are of limited application. They are worked with success where the vein is clear; but this, however, is the exception. The presence of iron pyrites or other foreign substances in the strata quickly dulls the knives and requires such heavy driving powers as to preclude commercial use. I have witnessed the operation of this type of machine in strata excellently adapted for machine mining except for a frequent deposit of sulphur about the thickness of a silver dime. The cutters being made of the finest Mushet steel, the entire set required changing every 40 square feet undercut. The current readings would show a power consumption on an average of 27 h. p., whereas in clear coal 10.5 h. p. only were required, and one change of cutters for each 250 square feet undercut.

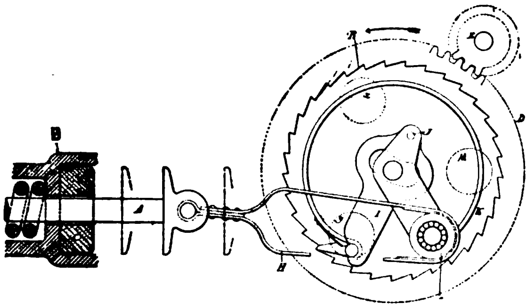


FIG. 1.—SPERRY DIRECT BLOW MINING MACHINE.

The author then described the usual methods employed in mining bituminous coal, and then proceeded to describe the machines designed to carry out these methods.

I have thus briefly pointed out the methods employed that the conditions may be better understood in the discussion now to follow of electrical machinery as adapted for use in such mines. A diagrammatic outline of the direct-blow machine is shown in Fig. 1, the completed machine being shown in Fig. 2. In this form of machine a bi-wheeled truck furnished with handles at the rear, is provided with a continuously operating electric motor of about four horse power, connected by gearing to a catch or retractor, a longitudinally moving heavy projectile with a pick secured to its outer extremity is surrounded by a driving spring of about 125 pounds per inch compression. The line of movement is practically through the centre of inertia of the machine. These springs are preferably made in sections, and initial pressure is given of about 500 pounds. A retraction then takes place of from 6¼ to 7½ inches to a pressure of 1,375 pounds, whereupon it is released and allowed to make a vigorous forward stroke. This process is repeated from 160 to 225 times per minute. The mean effect of this type of machine is 935 pounds when allowed to strike the cushion, and when striking the work at a distance of one inch from such cushion giving 1,000 pounds mean effect. This is shown in the spring curve diagram Fig. 3. The mean effect in air machinery employed for the same purpose is between 400 and 450 pounds, a 3½ inch cylinder being the largest employed. The current required for the operation of this machine is between 10 and 10.2 amperes at 220 volts. The projectile weighs between 100 and 150 pounds in the different sizes of machines.

Early in the development of this machine it was found that under the action of the intense concussion resulting from the percussive blows and shattering strains throughout the machine, a motor to last under such conditions must be essentially different in its organization from the ordinary commercial machine. After working along various lines it was at last found that by mounting the driving pinion loosely upon the armature shaft, providing it with wing-like projections between which and the armature shaft elastic cushions such as blocks of rubber could be inserted, the trouble could be averted, and when adopted it was found that the repairs on armatures were reduced to a small percentage of their former value. An elastic medium was also employed in the commutator to allow for the difference in expansion of the insulated copper segments and the steel commutator shell. Numerous driving keys or fins, consisting of rawhide, were set in the periphery of the armature and allowed to protrude for the purpose of securing the coils against circumferential displacement. The fields were not found to give trouble. With this construction of armature a large number of machines have been made and run successfully in mines in Illinois, Indiana, Ohio and Kentucky. In most instances these machines are run constantly night and day.

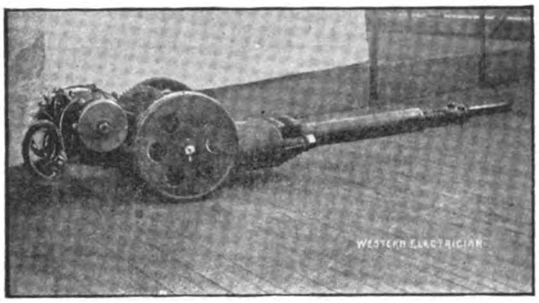

FIG. 2.—SPERRY DIRECT BLOW MINING MACHINE.

A detailed report of each day's work of these machines has been kept from the very first, stating the exact nature of any repairs, the name of the "machine runner," the number of feet undercut, hours' work, etc. These reports are kept on file, and have been of great value in aiding to eliminate the troubles developed. In Ohio alone these reports show that upward of 550,000 square feet of coal strata have been undercut by this type of machine. A somewhat larger amount than this has been excavated in Illinois. In the States of Indiana and Kentucky the operations have not been of so long duration, but at present the daily cutting in the latter States exceeds those in the former. Besides the elasticity introduced in the armature gear, elastic cushions have also been introduced between the retracting device and the main gear which is found to still further reduce the shock to the machine.

At an early date it was found that a machine capable of storing in each stroke of the heavy projectile as great an effort as is required for rapid and effective cutting must of necessity be heavy to be capable of backing up the blow without serious recoil, yet the machine on the other hand should be light for easy handling and direction by a single operator. With a light machine it is found impossible to allow the cutter to strike the work sufficiently back in the stroke for its required penetration, without serious effects from recoil. The operator would complain bitterly of the machine running back upon him, jerking him about upon the floor of the mine, making accuracy of direction impossible, and yet lightness of the machine is important. To combine both qualities I devised a cycle of operation shown in the diagram, Fig. 3, the object being to immediately start upon the act of retraction at the moment the projectile had been arrested by the

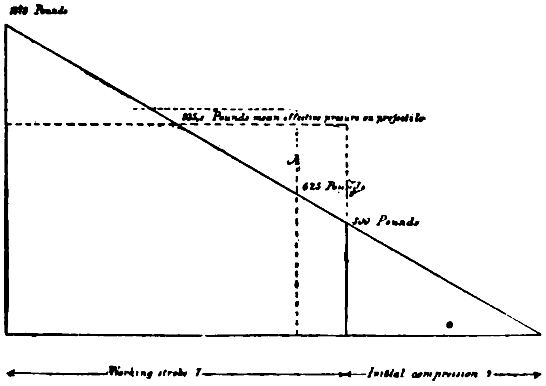

FIG. 3.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 6, 7 and 8.

work. no matter at what point in the stroke, eliminating thereby the time element necessary for overcoming the inertia of the body of the machine and starting it backward in recoil by the intense backward spring pressures. The details are simple and will readily be understood. The projectile *A*, Fig. 1, is forced forward by the spring *B*; a cushion *C* relieves the shock when the projectile is not otherwise intercepted. A gear wheel *D* is constantly driven in the direction of the arrow by the motor pinion *E*; this wheel is provided with internal ratchet teeth *R*. A crank *G* is mounted entirely free from the wheel and co-operates with a long slotted pitman *H* connected with the projectile for retracting the same. A light steel crank arm is pivoted entirely free of the wheel *D* and an auxiliary arm *I* provided with a dog co-operating with the ratchet teeth *R*, is pivoted to the main crank arm at point *J* and connected with the crank arm through the circular steel spring *K K*. When the crank *G* reaches the back dead centre at point *m* a reversal of the strains and a free forward movement occurs in the direction of the rotation of the wheel, but very much faster under the impetus of the heavy compression of the driving spring *B*, the pitman and both portions of the crank moving forward together. Suppose now that the forward stroke was intercepted at point shown in dotted line near the letter *A*; at this moment the crank *G* would be found in the position *X* also shown in dotted lines, but its momentum and the slot in the pitman would instantly allow it to take up position *Y* also shown in dotted lines, being at an equal angle on the opposite side of the centre. Its further progress would be intercepted by the remote end of the pitman and at this instant the dog would instantly fall in the next tooth in the revolving wheel *D* immediately commencing its work of retraction without the necessity of the full stroke of the pitman being accomplished. The work of the percussive blow is fully accomplished before full retardation, and while being intercepted. Nothing is accomplished by standing and pushing against the face so that its immediate retraction is not found to interfere in the least with its effective operation, but on the other hand is found to eliminate entirely the serious effects of recoil upon the operator, allowing a light machine to be easily and completely directed while at work. Modifications of the details have been employed, but the general principle has been found to work extremely well in practice. The machine efficiency from the current on the one hand, and the blow of the pick upon the other has been found to be in excess of 70 per cent.

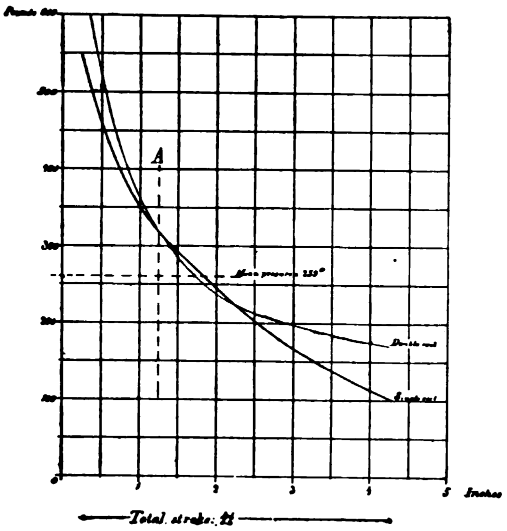

FIG. 4.

Another form of the direct-blow machine has been constructed operating upon the solenoid plan; two and three solenoids have been employed in various combinations. It has been found that the return of energy was extremely small until an approximately closed magnet circuit was reached. Another point found was that the effectiveness of the blow was materially decreased if the magnetic circuit was closed beyond a certain point, the reciprocation of the solenoid core being dependent upon the non-closure of the magnetic circuit. Diagrams were submitted, showing the various mathematical functions of the machine.

The pressure obtained in case of both single and double coils are shown in Fig. 4. Fig. 5 indicates the general arrangement of the solenoid machine. The total weight was about the same as the weight of the spring-actuated machine, and the energy absorbed somewhat in excess. The mean effective pressures, however, are not nearly as great, as diagram Fig. 4 indicates; especially is this the case when the work was intercepted, say one inch from the end of the stroke, as at point *A*, in this diagram; the mean effective pressure falls from 259 to 210, decreasing, instead of increasing, as in the case of the spring machine. It was possible to recover in the solenoid machine nearly 10 per cent. of the energy expended during the first few minutes, but the heating effect was found to seriously interfere with its protracted operation.

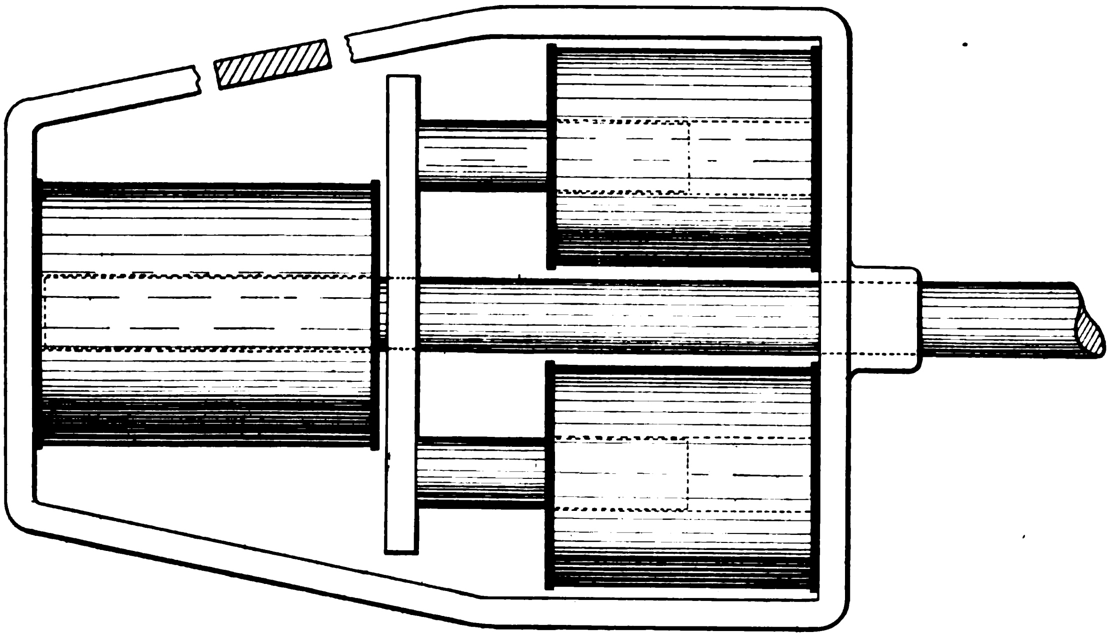

FIG. 5.—SPERRY SOLENOID COAL MINING MACHINE.

In drilling holes for blasting, an auger machine is used, as shown in Fig. 6. In this case the auger is driven by a single-reduction motor, the rod holding the auger being provided with a featherway for driving and a screw-thread for the feed. An automatic attachment is placed upon the nut of this screw feed, by means of which, when sulphurs or other foreign substances are encountered the feed is automatically relieved, the progress being inversely to the density of the strata. The machine is made light, and is usually fastened from roof to floor. One machine will drill about fifty holes 6 feet deep per shift of nine hours. The speed of its penetration in ordinary coal is about 3½ feet per minute. It requires about 3½ amperes at 220 volts. Both this and the pick machine are provided with a starting rheostat combined with or located interior to a cable reel which accompanies each machine. The flexible cable reaches back from the machine to the wires in the entries. The core of this cable is small, and although insulated clamps have been persistently shipped, secured to the ends of the cable for its attachment to the entry wires, it has been found that the miners almost invariably cut them off and prefer to simply bend the end of the cable in the form of a hook, and hang it upon the entry wire. This allows of their being readily pulled off upon the completion of the work without the necessity of going back to the mouth of the room, and at the same time seems to provide all the contact required.

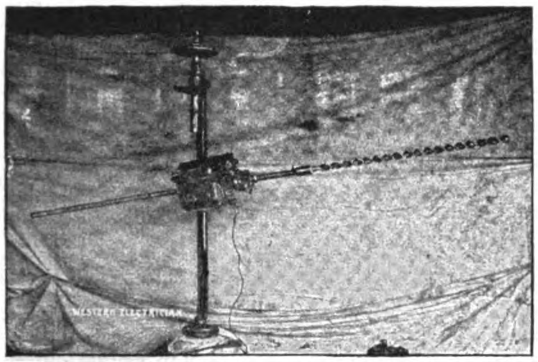

Fig. 6.—Sperry Electric Mine Drill.

As to other machines it may be stated that they are divisible into two general classes—the revolving cutter and the chain machine. In the former the cutters are secured to a revolving bar, which is forced against the substance to be cut. In the latter the cutters are inserted in a chain running over suitable sprocket wheels fastened to a frame, which extend under the coal supporting the entire cutting organization. The chain as it passes out from the coal goes around a driving sprocket from which the power is obtained. Many attempts at the construction of the former class of machines have been made, which have resulted in entire failure.

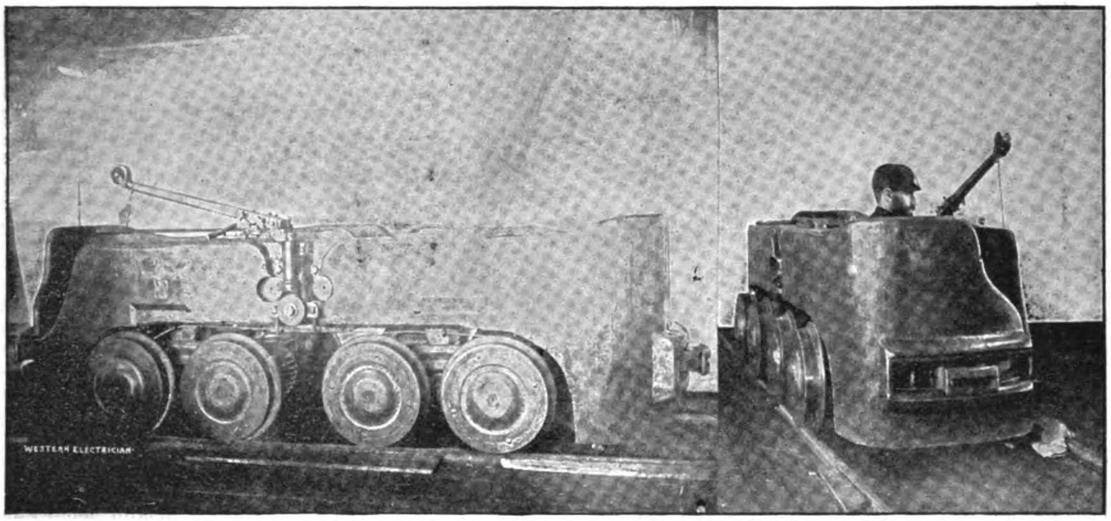

Fig. 8.—Sperry Coal Mine Electric Locomotive.

The extremely small amount of room between face and props in the longwall mines sometimes precludes the possibility of even using a very short reciprocating machine. I have therefore resorted to another form of machine, Fig. 7, to be used in connection with this style of mining, consisting of a mechanism about 5 feet in length, about 20 inches wide and 18 inches high, from the side of which protrudes a cutting device operated by an electric motor forming part of the machine. This is organized to travel along the face and undermine to a depth of three feet, usually working in the strata below the coal known as "fire-clay."

A number of these machines are in daily operation in the northern district of Illinois. A single machine has repeatedly undermined as high as 1,500 feet per nine hours. The machine weighs somewhat over a ton and travels upon a rail located at one side, which at once provides support for the machine, means for providing against the twisting strains of the lateral cutting device and providing at the same time for feeding in either direction. These rails are in sections, and are taken up after the machine has gone over them, are passed to the front over the machine on rollers provided for the purpose and are laid ahead. The pintles used to connect the rails form, with the other pintles, members of a series by means of which the feeding along the rail is effected in a simple manner, and one that has proven successful in actual work extending over a considerable period of time. These machines have been in use upward of two years. They require 22 to 35 amperes for their operation at 220 volts. Flexible cable of 150 feet is provided, which, being attached to the live wires ahead, allows the machine to cut 300 feet before readjustment is required.

After the product has been loaded and the cars massed in trains, their transit to the surface is a problem that has received considerable attention from the mining engineer. After describing the various methods of hauling, by means of cable, and difficulties encountered the author continued:

Electric haulage has been looked upon by the foremost operators as the coming system, and one which is destined to solve the problem of economical transfer of the heavy product in mines.

After considering the problem I have designed several motors, one of which is shown in Fig. 8. A number of plants containing this motor are now in daily operation in Ohio, Indiana, Kentucky and in this State (Illinois). Two of these plants have been installed in one mine in Illinois. Profiles of the entries in which these cars are in operation show grades as high as 7 per cent., 5 per cent. being not unusual.

In designing the locomotive I have employed eight drivers grouped in two swiveling trucks free to turn on the shortest radius curves—as short, in fact, as 9 feet radius, measured from the centre of the track. A single powerful motor constituting the frame of the car is coupled to all eight of these drivers, the coupling being simple and of such character as not to be interfered with in the least by the change of alignment between the truck and the car body upon irregular track or in making curves. This, while being rather a difficult problem, has been successfully worked out, as shown by the fact that none of the locomotives have ever required repairs as to this portion of their mechanism, although the first has been in operation about two years. Fig. 9 illustrates the central feature. Steel tires of a special grade are employed on all the drivers, and the fact that they are driven from a single motor insures absolute uniformity and harmony in their peripheral speed. It is to this fact, as recently stated in a paper before the Chicago Electric Club, that I attribute the extremely satisfactory results in traction which have been observed,

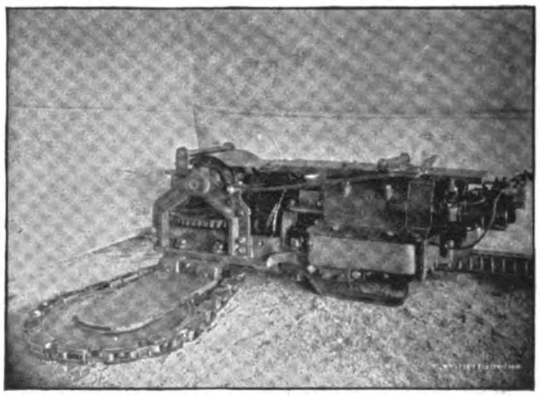

Fig. 7.—Sperry Coal Cutting Machine.

it being demonstrated both in shop tests and other conditions of actual service that two motors without mechanical coupling do not show results that are at all comparable. In regular service as high as 25 per cent. of the weight of the entire machine may be depended upon for draw-bar pull, and considerably over one-half of such weight has repeatedly been shown on the dynamometer. The wheel base is entirely flexible, distributing equal portion of the total weight upon each driver under all conditions of irregular track. The trains hauled by these locomotives frequently have as high as 200 wheels upon the track. The pit car wheels are constantly oiled, distributing an excellent lubricant from one end of the track to the other, and I have found for rapid acceleration work on heavy grades, and quick action of the brakes that sand is almost as indispensable as the current itself. In using the rails as return the sand is found to seriously interfere with the proper electrical connection to the rail, especially where four wheels only are employed. It is the usual practice in this case to use sand upon one side only, giving a torsional working strain which tends to seriously rack the frame, increasing the flange friction and giving uneven wear upon the drivers. With eight wheels, however, I have found it preferable, and in fact this practice is followed in all installations, to sand upon both sides and obtain the "bite" upon the rail through the silicates from at least six drivers out of the eight. The sand, by the time three wheels have passed over it on either side is sufficiently broken up to allow the fourth pair to get a fairly good contact with the rail for electrical conductivity. This is an accidental feature in the use of the eight-wheel car which is of great value. The machines themselves are low and narrow, the height being between 34 and 36 inches, accommodating themselves thereby to the lowest entries. Three sizes have been built, namely, eight, ten and twelve tons, Fig. 8 showing the latter. The motor of the largest of these is of 125 h. p. capacity; 250 volts is the highest that has been used in connection with the machine. The temperature of the machine is very low, not exceeding 60 degrees above the atmosphere on a ten-hour run. These machines have been operated on as low a rail section as 10 pounds with fairly good results. The heaviest rail that has ever been employed in connection with them is 20 pounds. This makes an extremely inexpensive track, not only eliminating entirely the *light track* argument used against electricity by advocates of rope haulage but "sees them one better" in that a single track with the most abrupt curves serves better purpose than double track with rope. In Streator No. 3 shaft of the Chicago, Wilmington & Vermillion Coal Co. a round trip on a haul of 7,000 feet, including switching at both ends, has been repeatedly run in 8½ minutes, part of the entry being a 3 per cent. grade against the loads. Thirty-seven pit cars of about two tons gross weight have been handled on this grade. The controlling mechanism is extremely simple, a single hand wheel serving the purpose of start, stop, acceleration and reverse. A rheostat and series fields are used. The rheostat is of most durable construction consisting of iron and asbestos. The trolley wire is upon the roof and follows the line of the track at a distance of about six inches outside of the gauge line of one of the rails. Excellent results have been obtained by the use of an elastic medium located between the trolley wire and the solid mine roof, one form used being among the exhibits. The elasticity prevents concussion of the rapidly moving trolley, obviating thereby the serious sparking often, and most easily observed in mine entries where nothing but the most intense darkness prevails. To my mind the extreme facility with which electric power can readily be transmitted by the mere contact between conductors, has no parallel in any branch of physics. I have often observed the simple contact between trolley wire and wheel while 160 h. p., namely 480 amperes, were being transmitted to the motor, each of the eight drivers slipping vigorously on the sanded track, throwing fire which illuminated the surrounding mine walls, while the trolley with the exception of slight infrequent scintillations was perfectly dark and of extremely innocent appearance.

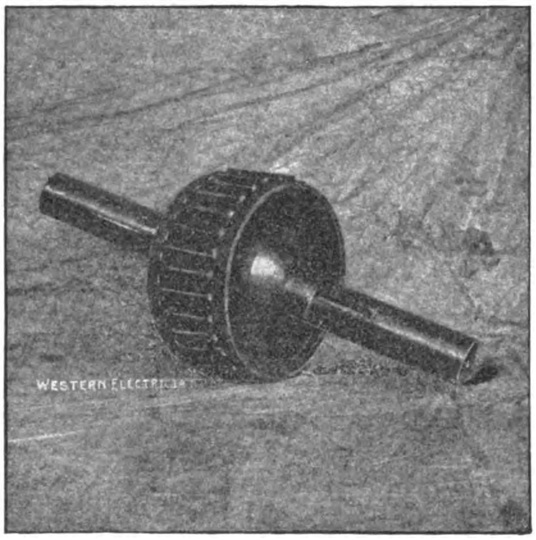

Fig. 9.

A number of special and automatic devices have been employed in connection with the system with excellent results. Powerful electric headlights are used in each end of the locomotive, and in the twelve-ton type (see Fig. 8) the end is carried out, providing a cab which entirely surrounds the motorman with high walls of metal 2 to 3 inches thick, entirely protecting him against collision, piling up of cars, falls of rock, etc. I have operated this motor on tracks which if seen by daylight would be adjudged unsuitable entirely for even the roughest mule service, handling heavy trains at a rate of speed of 2,700 feet per minute, being somewhat over 30 miles an hour. The perfect flexibility of wheel base of the motor is doubtless responsible for these excellent results. Compound-wound dynamos of about seven tons weight are used to furnish current for the machine. These are designed for sufficient excess of capacity to operate other devices in connection with the mine. In one mine at the South we have coupled to a single dynamo and engine, one of our eight-ton haulage cars, electric lights at all partings and switches, and on top in engine-room and at a store, electric mining machines of the direct-blow type, and an electric drill for blasting, by means of which machines the entire product of the mine is taken out. The mine which was formerly ventilated by a furnace, at present has its air moved by a fan driven by a powerful electric motor, and an electric pump is at present being installed, all of which are operated from the same feeder. In Kansas a mine pump raising water about 800 feet and two very extensive endless rope hauls are operated from the same dynamo as our electric excavating machinery. The pumps are of simple construction, the motor being geared to the plungers by spur gearing. It has been found with the pumps, longwall machines and drills as well as in the case of the percussion machines, that mounting the pinion loosely upon the armature shaft and driving it with cushions, located between it and the armature, has worked a decided economy in repairs, showing its adoption to be along the line of good engineering.

THE LOCKPORT CANAL.

About a year ago an association was organized in Lockport, N. Y., for the purpose of securing the construction of a hydraulic canal, 200 feet in width and 20 feet in depth, to connect Niagara River with Lake Ontario. The right to make, use, sell and transmit water, electrical and other power, and the right to furnish water to the city of Lockport, and other places, was secured, as also were written contracts for the purchase of over 2,250 acres of land. A special law was obtained authorizing the city of Lockport to contract with any persons or company which shall build the canal, for water for domestic and other purposes, at a yearly rental of $50,000. A detailed and accurate survey of the proposed canal has been made by competent engineers, showing the route, length, depth of cutting, quantities of earth and rock to be removed, bulkheads, dams, bridges, etc., necessary for obtaining upwards of 100,000 h. p., and maps and drawings have been made.

The details of the construction of the canal, as laid down in the engineer's estimate, are as follows:

Number of acres for right of way, 792; earth excavation, cubic yards, 6,250,000; rock excavation, 2,438,360; rip-rapping, yards, 91,734; bridges to be built, one double track, 80-foot span; one single track, 80-foot span; one single track, 2 spans 64 feet each; dams (four), cubic yards of mason work, 5,129; coping, cubic yards, 220; highway bridges, 80-foot span, 8; highway bridges, different lengths, 13; culverts, 2 large, 10 small; one guard lock and three bulkheads.

The total length of the canal to the head of the convenient natural gulf about a mile west of Lockport, is twelve miles, and the length of the gulf about two miles. From the gulf to Lake Ontario it is twelve miles, and a large stream which only will have to be deepened and widened in various places, connects the two, so that very little expense would be necessary below the gulf.

This gulf is midway between the river and the lake. It is from 500 to 600 feet in width, with gently-sloping sides, and from head to foot—about two miles—there is a fall of 220 feet. It is thought that four falls of about 50 feet each would best distribute and give the greatest force to the water, which is the plan indicated by the engineers, but by carrying water along either side of the gulf by raceways or pipes a fall of any depth under 200 feet can be secured.

The latest reports are such as to encourage the belief that action of a definite character is being taken looking to a speedy consummation of the plans above outlined.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, JULY 6, 1892. No. 218.

It is not in human sagacity to foresee prior to experience, what simple occurrence or what neglect in arrangement may interfere with the result of an experiment.—Joseph Henry.

THE FRANKFORT-LAUFFEN EXPERIMENTS.

IT is now just ten years ago that Marcel Deprez demonstrated, in a practical way, the possibility of transmitting energy electrically with a degree of efficiency over long distances heretofore unattainable by other methods; and though the total amount of power received at Munich from Miesbach, 37 miles off, was barely half a horse power, the experiment served to show that the method, as a method, was feasible. The last ten years have more than confirmed the estimate of the results then obtained, but it remained to show how far the progress made in the modern applications of high potentials could be applied to this same problem of long-distance transmission. There were not a few who shook their heads at the thought of using 30,000 volts on a line over 100 miles in length, and subject to the many adverse conditions under which overhead lines labor. Again, the probable loss in the line itself due to its electrostatic capacity was a matter of conjecture by no means favorable to a successful issue. Again, while few doubted the possibility of constructing transformers capable of standing a pressure of 30,000 volts, the fact remained to be demonstrated. But the success of the experiments is confirmed by the official report of the testing committee, part of which is now given to the public. Taking a few representative figures among the tests, we find that with 78 h. p. applied to the dynamo by the turbine, 53.5 h. p. or 68.5 per cent. was delivered by the secondary transformer at the distant end 109 miles off; with 150 h. p. at Lauffen, an efficiency of 75.3 per cent. was reached, and with 197.4 h. p., 73.9 per cent. These experiments were carried on in all sorts of weather, and though the potential employed is not given in the tables thus far published, it is safe to say that it was probably not below 15,000 volts. Considering the fact that the transmission included two transformations in converters, together with the loss in the dynamo and in the line, the result obtained is excellent proof of the high order of construction embodied in the apparatus employed and reflects credit on both parties to the undertaking, the Allgemeine Elektricitäts-Gesellschaft, of Berlin, and the Oerlikon Maschinenfabrik, of Oerlikon, Switzerland.

WORLD'S FAIR LIGHTING.

IT is gratifying to learn that the Grounds and Building Committee of the Columbian Exhibition accepted the bond of $500,000, offered by Mr. Westinghouse on Monday, June 27, and that the contract for lighting has since been executed between the Westinghouse Electric and Manufacturing Co. and the authorities of the Exhibition. The sureties on the bond are August Belmont, Chas. Francis Adams, Brayton Ives and Marcellus Hartley, in addition to the signature of the Lawyers' Surety Co., of New York. Mr. Westinghouse is to be congratulated upon this result of the pluck and persistency which he has shown throughout in the competition and negotiation. The managers of the Exhibition have done well in securing the desired service at so low a cost.

Since Mr. Westinghouse's tender was published some weeks ago, there has, naturally, been some speculation and some expression of opinion, among electrical people touching the probability of profit or loss to the bidder on the contract. The price was something of a surprise, no doubt, in view of the much larger figures previously submitted by several bidders; but it is well to point out that the question of profit or loss properly concerns the contracting company, more than it does others or the general public. The consummation of the contract lends an element of strength to the position of the Westinghouse Company.

ELECTRIC MOTORS AS SUBSTITUTES FOR STEAM LOCOMOTIVES.

IN commenting upon the recent presidential address of Mr. Frank J. Sprague before the American Institute of Electrical Engineers, we draw attention to the very conservative attitude assumed by that gentleman in his estimate of the limits to which the electric motor was confined on the great steam roads. Mr. Sprague showed that, for the present at least, the general substitution of the electric locomotive for the steam direct was out of the question, but that there were certain well-defined conditions within the bounds of which such substitution was even at the present time feasible and economical.

In an article appearing in the *Railroad Gazette*, Mr. Arthur T. Woods discusses the same problem from the steam railway engineers' standpoint and, we are glad to note, arrives, in the main, at the same conclusions as Mr. Sprague, thus emphasizing our contention that competent electrical engineers are fully aware of the nature of the electric railway problem, and that the profession as a class ought not to be held responsible for the loose statements of individual cranks and visionaries.

COMING DEVELOPMENT OF ELECTRIC RAILWAYS.—IV.

(*Concluded.*)

BY FRANK J. SPRAGUE.

Among the roads which are ripe for the electrical engineer, and on which, in the near future, I hope he will demonstrate he has a most legitimate claim, are the New York Elevated and Chicago Elevated, the handling of the trains on the New York Central and Harlem roads below the Harlem River, the long-talked-of rapid transit road of New York, the Metropolitan underground road of London, the proposed tunnel roads in London, Paris and Berlin, and, coming more immediately home, suburban service such as that of the Illinois Central Railroad—a most ideal track for the electrical engineer; and last, and as it will prove, one of the most important, the operation of terminal and warehouse systems for the interchange of freight on the lines entering a city situated like Chicago.

Taking this last, we have here a definite problem, now performed in a more or less satisfactory way by steam service. It is a problem large enough of itself. It has little connection with electric trunk-line service, and the present impracticability of the latter has little bearing upon the thorough practicability of the former. Eighteen hundred, or more, switch engines, many of them on duty twenty-four hours a day, a large portion of the time standing idle, puff their foulness into your overburdened atmosphere, because from 80 to 90 per cent. of all the freight that comes into the depots of this city ought never come inside its limits, and would not, were there a practical way provided to distribute it from one railroad to another outside the city limits. It has been suggested, and it seems to me a most feasible plan, that there shall be established a vast system for interchanging freight on the various railroads by a great six-track crossing belt road, which shall form a common zone of transfer either by itself or in combination with freight warehouses or storage yards. Undoubtedly there are many difficulties in the way, but from an electrical standpoint there is absolutely no question but that such a system of belt line is practicable.

With such unsolved problems, such abundant fields, I deem it unnecessary now to attempt to build electric locomotives to pull trains of great weight 100 miles an hour, or to develop a system of conductors for trunk-line service which is not possible for yard duty, or to consider a central station or track equipment for a duty never required. This problem is in a measure an experimental one, which, being carried to a certain measure of success, will clearly point the way for future development and outline its limits.

I may be pardoned, perhaps, if I take radical views in some matters of railroad practice. I have fortunately, or otherwise, been thrown into direct touch with all the larger work which is to be done in this country during the coming year, and it gives me pleasure to announce, what many of you know from the current news of the day, that there will probably be in operation in the United States, within twelve months, not less than five locomotives varying from 700 to 1,200 h.p. and from 45 to 80 tons in weight. The character of the work done will vary. In that work which I am most concerned with from a personal standpoint, a 700 electric locomotive will be built for experimental work, and to attempt to solve, as far as may be, the various problems which are involved in railroad practice in Chicago. If my judgment is followed, there will be an experimental section of track in the form of a loop about thirteen miles long, with eighteen miles of rail, and with every variety of single and double track construction and simple and compound crossings and switches.

On this I hope to see erected such varieties of overhead construction as may be found best to meet the various kinds of service, and where the railroad problems on track jointly operated by steam and electricity can be developed in the most satisfactory manner. On this track there will be not only this locomotive but also one of equal rated capacity supplied by one of the larger manufacturing companies.

The duty demanded of these machines will be severe. They will be required to haul a train of not less than 450 tons at 30 miles an hour up a grade of 26 feet to a mile. They will probably be required to develop their full rate of capacity at all speeds between 30 and 60 miles per hour, and if there is sufficient track-room they will be driven at speeds of at least 75 and perhaps 100 miles per hour for short distances. The potentials used will be nearly double that at present obtained in street railway practice.

A still larger problem so far as power goes, although not in the variety of conditions which will have to be met, will be that recently taken for the operation of the belt line tunnel now being constructed in Baltimore to avoid the necessity of boat transfer at Locust Point. The duty of the motor here will be to propel the train with engines coupled on but not in operation through a tunnel about 6,000 feet long. The conditions require the motors which will weigh about 80 tons, and have a capacity of about 1,200 h. p. to propel a 1,200-ton freight train up a grade of 42 feet to the mile at a speed of 15 miles per hour. Passenger trains of of 450 tons weight must be regularly started from rest twice in the tunnel on this grade, and in an emergency the motors must start the freight train. The draw-bar pull under regular duty, and when not starting, may be as high as 32,000 pounds.

Perhaps the traffic from New York to Philadelphia affords as good an example as any of what may be done on regular passenger service, provided the track is clear enough. For this, I some three years ago, and again in *The Forum* of September, 1891, outlined an electric express service with a method of supply through a rod carried above the car and a return circuit through the rails and earth. The current was to be supplied from one or more central stations equipped with high-class triple-expansion engines driving multipolar dynamos directly coupled. What the electrical engineer and the railroad men as well needs to know is whether the electromotice force required on the line and the number of stations necessary would be prohibitory.

No attempt was made for an excessive speed, but I confined myself to the average speed of a mile a minute for a distance of 90 miles, and considered a through service only. I assume a total weight of copper of only about two-thirds that which exists on the long-distance telephone line between New York and Boston. The trains were to be two-car units leaving every ten minutes.

I found with these conditions the stations and potentials would be about as shown in the following table:

Stations.	Miles apart.	Potential.	
		Two-wire.	Three-wire.
1	—	3,600	1,800
2	45	1,800	900
3	30	1,200	600
4	22½	900	450

If the three-wire system is used, that is, the rails as a compensating conductor between two trolley roads, then with only two stations 45 miles apart it is seen that the potential is less than 1,000 volts, and this we undoubtedly can handle.

I am not prepared to say that we may not use even a higher pressure, because I believe whatever is demanded in the interests of economy, all things being considered, will be used; but if we can reduce the potential to perfectly safe and reasonable limits by multiplying the number of stations, then those stations should be increased so long as the increase does not seriously affect the general expense of working. On a service of this character, where I have made the conditions, distributed work and the dispatching of units at brief intervals—which conditions, I repeat, are absolutely necessary if we are to consider long-distance transportation by electricity—such increase of stations as is advisable will not increase the cost of central station operation.

Such is the work before you, a work well meriting your best efforts, yet it is well to temper your enthusiasm with prudence. Limit your attempts to the solution of those problems which will prove of practical benefit. Do not chase rainbows. They are beautiful and poetic, but they have small place in the world's economies. Remember that neither sentiment nor ignorance, but lessened costs of operation for equivalent duty and increased returns on invested capital, are winning cards.

All this is said in no spirit of discouragement, for I yield to no man in my confidence in the future of electric traction. No new field is so rich, none more pregnant with great possibilities; but the growth of the work will be more expeditious and healthy if we separate the visionary from the real, the impracticable from the practicable.

A DYNAMO INDICATOR, OR INSTANTANEOUS CURVE-WRITING VOLTMETER.[1]

BY PROF. GEORGE S. MOLER.

IN connection with the work in dynamo and motor testing in the physical laboratory of Cornell University, it was found desirable that some method should be devised which would enable the student experimenting to very quickly explore the field of a machine, so that he could study some of the changes which might take place even in a few seconds. The double-brush method of Dr. S. P. Thompson, and the single-brush method of Mr. W. M. Mordey, are in use and give excellent results, but either of these methods requires a few minutes at the very shortest to obtain the data for a single curve.

To attempt to meet this want the writer devised the instrument which is the subject of this paper. It is intended to be used in tracing those curves which show the changes in potential of the two ends of a single coil of the armature, and also those showing the changes between one brush and one of the commutator bars, as the armature revolves. The instrument consists in the main of a very rapidly vibrating needle of a voltmeter, and a smoked cylinder against which the pointer is made to press at the required moment. The curve is traced during a single revolution of the armature and is then easily transferred to paper, and is thus placed in a permanent form to be studied at leisure. The voltmeter, which is inclosed in the body of the instrument, is of the permanent magnet form. The needle is of soft iron, and is very short, and held at zero by being placed between the poles of a powerful steel magnet. The pointer is made of aluminum and is quite short. It is shaped so as to be as light as possible, and so that the air cannot offer much resistance to its motion. The cylinder is of metal and very smoothly finished, so that it will offer little resistance to the movement of the pointer. It is mounted upon a short shaft and is arranged so that it can be slid to several different positions; a spring dropping into notches holds it at each place. The stationary pivot at A, Fig. 1, is made with a spring so that the cylinder can be quickly removed for smoking or for transferring the curves. This short shaft is connected with the driving shaft of the instrument by projecting pins at B, so that it will always maintain the same relative position with the pin at C. The pin C is attached to a sliding sleeve which is pushed toward the point of the shaft by a spring. A hole or a pin in the end of the armature shaft is to engage with the pin C, so that the cylinder will always have the same relative position with the armature. To operate the instrument two insulated wire hoops or bands are to be wound around some convenient part of the shaft or commutator, and one is to be connected to one commutator bar and the other to one of the adjacent ones. Small brushes are to be made to press upon these bands, and they are to be connected to the binding screws at D. The cylinder is then lightly smoked by removing it and revolving it over a candle or gas flame; then it is placed in position. The sleeve carrying the pin C is pulled back and latched in the notch E. Then the point is pressed into the centre hole in the end of the armature shaft; this will put the drum in motion; then by letting the projecting knob strike the finger the sleeve will be unlatched, and will spring forward and engage with the pin in the end of the armature shaft. Then pressing the button F closes the circuit, and pressing G brings the pointer against the drum. H is a reversing switch. The base line of the curve is drawn by pressing G only. Another form of curve will be obtained if one of the terminals of the indicator is attached to one of the permanent brushes of the dynamo, and the other to one of the brushes pressing upon the band connecting with one of the commutator strips. Also a temporary exploring coil may be wound upon the armature, and its terminals may be connected to the indicator.

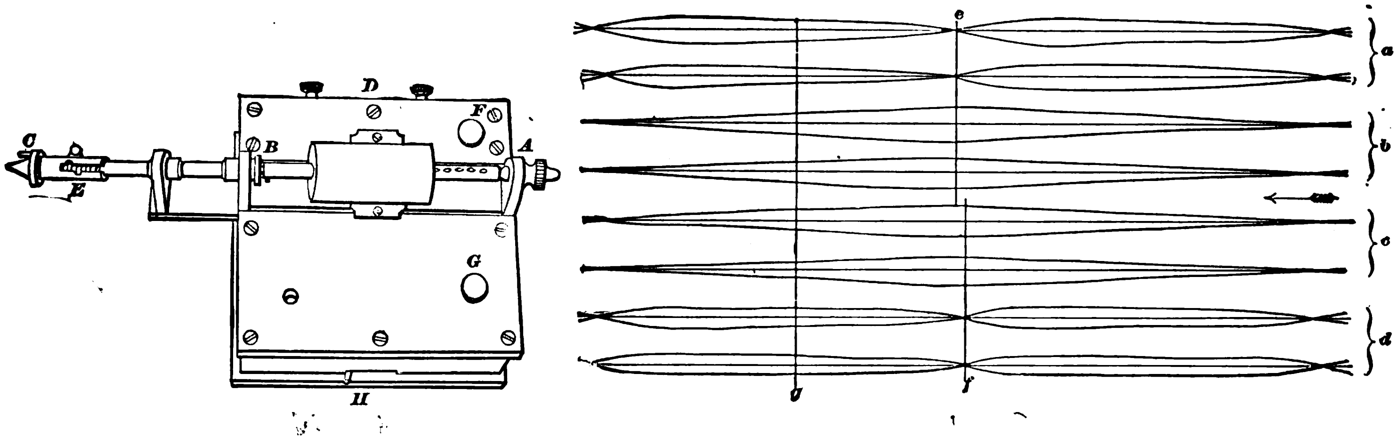
---

[1] A paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 6, 7, and 8, 1892.

The voltmeter of the indicator is necessarily one of low potential, so that the changes in a single coil will produce a suitable deflection. For greater changes of potential a resistance must be used in series with it. The curves are transferred from the smoked cylinder by dampening a sheet of paper and then rolling the cylinder over it. Three distinct copies have in this way been made from one set of curves. One of these instruments has been built and has been tested in various ways and is found to give very satisfactory results. The rate of vibration of the needle was determined while the pointer was in contact with the revolving drum and was obtained as follows: A current was applied so as to produce a deflection, then while the drum was revolving at over a thousand revolutions per minute the needle was brought in contact with it and the circuit was then broken, making a wavy line extending part way around the drum before it died out. The average rate of oscillation as determined from over 40 measurements was 103 per second, and the damping effect was so great that in .04 of a second the needle was brought to rest. It was also observed that the deflection was not changed by bringing the pointer in contact with the revolving drum.

One of the desirable features of the indicator is the rapidity with which the curves can be made. The cylinder full of curves, 18 in all, with their base lines, was made in 78 seconds, so it is seen we can explore the field many times while a dynamo is charging up just after being started, or while any great change in load is being made.

In Fig, 2 are shown some of the curves produced by exploring the field of a 20-ampere shunt-wound dynamo of the consequent pole type The dynamo was driven at a speed of 1,075 revolutions per minute, and had an automatic regulator, which held it at 115 volts, with slight variations. The curves *a* and *b* were made while 20 amperes were flowing in the main line, and *c* and *d* while the outside circuit was broken. The curves *a* and *d* show the changes in potential of the two ends of a single coil. The line *g* shows the position of the centre of the pole-piece, and the arrow the forward direction of the curves. The double curves upon each base line, were made by reversing the terminals by means of the switch H. The line *e* is the position of the neutral point when 20 amperes were flowing, and *f* its position when the line is open. The difference in shape of the curves shown at *a* and those at *d* is very marked. The curves *b* and *c* were made by connecting one terminal to one of the dynamo brushes, and the other to one of the brushes connected to one end of a coil. These also show the change of the neutral point, and a change in shape for open and closed circuit.



Figs. 1 and 2.—Moler Instantaneous Curve Writing Voltmeter.

The instrument is calibrated by comparison with a standard voltmeter. For each reading on the voltmeter a line is drawn around the drum. When the pointer is not in contact with the drum some of the effects of inertia can be noticed, but when contact is made they seem to almost disappear, and corrections may be applied to compensate for the lag on that account.

To test the reliability of the instrument one of the 20-ampere curves for half a revolution and similar to *a*, Fig. 2, was taken at random, and the data taken by two students, over which to obtain they worked at least an hour, and had to contend with fluctuating speed and voltage. These two curves were drawn to the same scale and are shown in Fig. 3, the heavier and most fluctuating line being by the experiment. The agreement is about all that can be expected, so it seems that the instrument is capable of giving reliable results.

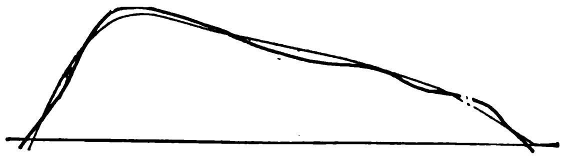


Fig. 3.

CRANFORD AND SOUTH SIDE TELEGRAPH UNION.

This society, organized last year, has now seven stations and a line 1½ miles long in the village of Cranford, N. J. The president is S. J. Cox, Jr., and F. W. Ells is secretary and treasurer. The line is governed by an executive committee composed of a representative from each station elected annually by the union. The president is chairman of this committee, which has power to impose fines, levy assessments, purchase supplies and transact all the other business connected with the line.

It has been proposed to consolidate the union with the Cranford Telegraph Association, a similar organization in the same town, which would give it a total of 3½ miles and 20 stations, taking in the entire village. The two associations have a complete code of fire, burglar and emergency signals, and, though not yet consolidated, are connected and act together for the common good.

ELEVENTH ANNUAL MEETING OF THE RAILWAY TELEGRAPH SUPERINTENDENTS' ASSOCIATION, AT DENVER, COL., JUNE 15 AND 16, 1892.

The 11th annual meeting was held at the Hotel Albany, Denver, Col., June 15 and 16. The following members and guests were in attendance:

C. S. Jones, Ill. Central, Chicago; A. R. Swift, C., R. I. & P. R. R., Chicago; C. Selden, B. & O. R. R., Baltimore; O. C. Greene, No. Pac. R. R., St. Paul; C. M. Dugan, Ill. Central R. R., Jackson, Tenn.; P. W. Drew, Wis. Central R. R., Chicago; M. Magiff, Central Vt., St. Albans, Vt.; H. C. Hope, C., St. P. M. & O., St. Paul; G. L. Lang, N. Y. and N. E. R. R., Boston; M. B. Leonard, Ches. & Ohio R. R., Richmond, Va.; C. A. Darlton, R. & D. R. R., Atlanta, Ga.; J. L. Orbison, C. H. & D., Cincinnati, O.; J. C. Ford, C., St. P. and K. C., St. Paul; G. R. Kimball, B. & O., Newark, O.; G. T. Williams, N. Y. C. and St. L., Cleveland, O.; L. B. Folley, D. L. & W., New York; J. T. Gibbons, D. L. & W., New York; K McKenzie, M. & O., Jackson, Tenn.; H. C. Reed. M. L. S. and W., Milwaukee; J. B. Stewart, West Shore, New York; W. W. Jackson, N. Y. and N. E. R. R., Providence, R. I.; R. J. M. Danley, C. H. & S., Columbus, O.; W. B. Ward, B. C. R. & N., Cedar Rapids, Ia.; W. D. Vincent, B. & O., Pittsburgh; S. K. Bullard, M. K. & T., Sedalia, Mo.; U. J. Fry, C. M. & St. P., Milwaukee, Wis.; W. J. Holton, C. & W. I., Chicago; D. H. Caldwell, N. Y. C. & St. L., Fort Wayne; G. C. Kinsman, Wabash R. R.; Decatur, Ill.; H. C. Sprague, K. C., Ft. S. and M., Kansas City; C. H. Corty, U. P. R. R., Omaha, Neb.; C. G. Sholes, A., T. & S. F. R. R., Topeka, Kan.; A. R. Lingafelt, C. R. I. & P. R. R., Topeka, Kan.; W. P. McFarlane, F. E. & M. V., Omaha, Neb.; C. S. Rhoads, C. C. C. and St. L., Indianapolis, Ind.; F. M. Duncan, D. & R. G., Denver, Col.; W. W. Ryder, C. B. & Q. R. R., Chicago; Geo. B. McCoy, Ill. Central, Memphis, Tenn.: J. J. Dickey, Supt. W. U. Tel. Co., Omaha, Neb.; R. B. Gemmell, A. T. & S. F., Topeka, Kan.; E. R. Adams, P. & R., Reading, Pa.; J. J. Burns, D. & R. G., Pueblo, Col.; E. W. Hammond, Missouri Pacific, St. Louis, Mo.; E. E. Rittenhouse, Col. Midland, Pueblo, Col.; J. W. Lattig, Easton, Pa.; S. S. Bogart, New York; W. S. Logue, New York; H. F. Houghton, Decatur. Ill.; J. B. Shaw, Jamestown, N. Y.; Ralph W. Pope, New York; T. D. Lockwood, Boston; T. J. Smith, New York; H. R. Wilson, Chicago, Ill.; D. C. Matheson, Flint, Mich.; T. R. Taltavall, New York; G. W. Crook, Valparaiso, Ind.; A. P. Willoughby, Chicago; C. P. Mackie, New York; M. C. Gilham, Kansas City.

The first session was called to order at 10:30 a. m. June 15, by President C. S. Jones.

The following officers were elected to serve for the ensuing year: President, L. B. Korty, Omaha, Neb.; vice-president, U. J. Fry, Milwaukee, Wis.; secretary and treasurer, P. W. Drew, Chicago, Ill. It was voted that the next meeting be held at Milwaukee, Wis., June 20, 1893.

Mr. S. S. Bogart read a paper on batteries in which he called attention to the adaptability of the Edison-Lalande battery for electric railway signal work. Its internal resistance was but $\frac{1}{10}$ of an ohm, it was perfectly constant, would not sulphate and was not affected by low temperature. He believed the time had arrived when they should discard the sulphate of copper battery. He was using it for block signals in preference to all others. He used four cells in series, on closed circuit with a resistance of 10 ohms. There is tapped out of it a sounder, alarm bell and annunciator, the last two on the same cell.

At the close of Mr. Bogart's paper the meeting was visited by Governor Routt of Colorado, who delivered an address of welcome which was responded to by President Jones.

The afternoon session on Tuesday was called to order at 2:45 p. m. A paper by Mr. Edison on Insulation was read by Mr. M. B. Leonard.

Mr. T. D. Lockwood stated that he was pleased to note the statement that pure water was not a conductor, although in practice we could neither get pure water nor keep it pure if obtained. In New York City it was very difficult to maintain insulation on account of the steam pipes, and some cables after being laid were found weak in spots. It was found that very small particles of water were moved along by the heat. Condensation accumulated the moisture in one spot and made a leak. In reply to an inquiry by Mr. Gemmell, as to the practical use of oil insulators, Mr. T. J. Smith said that they were now made in this country but there had been little demand for them. They had however been highly spoken of by those who had used them.

In the absence of the author Mr. C. A. Darlton read a paper by Prof. W. A. Gardner on "The Government Time System in its Relations, Practically to Railroad Matters."

Mr. Lockwood then gave a blackboard talk on "The Galvanometer and its Uses" which was devoted to a popular explanation of the handling of that instrument especially for telegraph work.

At the opening of the morning session on Wednesday, Mr. Chas. Selden read a paper upon "Electricity in its Relation to Transportation." [1]

Mr. Lockwood said that the railroad community at large owed a great debt to the Baltimore & Ohio R. R. Co., for its advance step in experimenting with the electric motor for use in tunnels, although it was not really an experiment. He did not look for the immediate application of electricity to trunk lines, but electricity was no exception to the rule that tall oaks from little acorns grow. He took the plan of Dr. Adams with a grain of salt in his proposed electrical air line between St. Louis and Chicago, yet he believed that for suburban traffic electricity would yet be found to have advantages over steam. Mr. Selden said that the actual available horse power of the locomotive was but 30 per cent. of the theoretical and under unfavorable conditions fell to 10 per cent. and that it was impossible to get as good results from a locomotive as from a stationary engine.

Mr. J. B. Stewart then read a paper entitled, "The Block Signals of the Present and What is Required for the Future." [4]

Mr. Selden said that in Maryland the law required that either a flagman or signal must be placed at each crossing. He had made arrangements to substitute bells for flagmen. They now paid $18,700 per year for service that could be performed at a cost of $2,000 by the use of bells. The worst accidents they had had, occurred when the watchman was asleep. In Philadelphia they had 20 crossings guarded by bells, and the only accident they had had was the killing of a horse. In this case the owner wished to have him killed as he needed a new horse, and he got one.

Mr. Hammond stated that they had had similar accidents on the Missouri Pacific, but had not been able to prove that the bell was ringing when they occurred.

At the afternoon session on Wednesday, the following committees were apointed: Messrs. Selden, Greene and Gemmell to revise the constitution; Messrs. Swift, Ford and Sholes, to prepare a new form of service card; Messrs. Reed, Fry and Ford, on arrangements for the next meeting; Messrs. J. B. Stewart, Gemmell and Adams on Topics, and Messrs. Selden, Leonard and Darlton on acknowledgment for courtesies extended by the C., R. I. & P., the Denver & Rio Grande, the Union Pacific, the Atchison, Topeka & Santa Fé, the C. B. & Q., the Manitou & Pike's Peak Railroad Companies, the Colorado Telephone Co., the Commercial and Athletic Clubs, Wyckoff, Seamans & Benedict, and many others.

The formal business of the meeting being finished, the retiring President Jones called President-elect Korty to the chair, and in transferring the gavel, said that he desired to express his satisfaction at the most splendid success they had achieved at this meeting, which was of course due to the large attendance of members and their enthusiasm. President Korty in reply, said that he was deeply sensible of his inability to fill the position. but would do his best. The meeting then adjourned to June 20, 1893.

Friday was devoted to a trip over the Clear Creek Division of the Union Pacific R. R., which embraces the famous Georgetown loop. The Mendota silver mine was also visited. Saturday the members were the guests of the Denver and Rio Grande Co. and the Manitou & Pike's peak R. R., and were taken over this famous cog-wheel line. Upon their return the Colorado Midland R. R. Co. ran a special through Ute Pass and return for their entertainment, and on Sunday the Denver and Rio Grande gave them a trip through the Royal Gorge to the Hanging Bridge. One of the most interesting events of the trip was the presentation of a solid silver salad bowl, fork and spoon to Mr. and Mrs. Swift in remembrance of the thoughtful preparations for the trip and their watchful attention to all who had the pleasure of enjoying the many courtesies extented to the association during its visit to the Centennial State.

EXHIBITS.

Distance did not interfere with the enterprising exhibitors, who in their efforts to show the merits of their various exhibits added much to the interest and importance of the meeting.

The Leonard train order signal and the Leonard block signal were exhibited by the Electric Secret Service Co. Working models of these signals were shown in combination with the automatic selective apparatus of the Electric Secret Service Co. Other applications of the latter were shown adapted for telegraph, electric light and power service.

A working set of the Edison phonoplex was shown in actual operation, being connected with the line to Cañon City. Current was supplied by the Edison-Lalande battery, various sizes and forms of which were also on exhibition.

The Dulaney self-winding clock operated by two cells of gravity battery attracted much attention, it being in practical use on the C. B. & Q. R. R.

The Gill-Alexander Electric Manufacturing Co. was represented by M. C. Gillham who had arranged a working exhibit of the system of selective apparatus manufactured by that company.

The iron gravity battery manufactured by the Standard Battery Co., 324 Dearborn street, Chicago, was shown by Dr. A. P. Willoughby. In this battery an iron electrode is substituted for the zinc as ordinarily used. A secret compound is used for starting it. The battery is now being tested by various companies.

The "Excessive Current Protector" invented by I. N. Miller of

---

[1] See page 15.

Columbus, Ohio, was on exhibition and was explained by Mr. Leonard.

Samples of insulating fibre were shown by the Laminar Fibre Goods Co., of Boston.

FIRST ANNUAL CONVENTION OF THE CANADIAN ELECTRICAL ASSOCIATION, HAMILTON, JUNE 14, 15 AND 16, 1892.

The first annual convention of the Association was opened at the Board of Trade Building, Hamilton, Canada, on the afternoon of June 14. A business meeting of the executive committee was held previously, at which thirty-four new members were admitted.

After the opening of the regular session, President Wright delivered his address, in which he referred to the flourishing condition of the association, whose membership includes representatives of every branch of electrical industry. The object of the organization was to promote the interests of those engaged in electrical pursuits from both a commercial and scientific standpoint. He suggested the appointment of a committee to collect and compile statistical information, such as, for instance, the number of electric lights in use in the different cities and towns of Canada; particulars as to their operation under various conditions, the cost of operation and condition of electric lighting plants operated by municipalities, etc.

The Mayor was introduced and addressed the members, cordially welcoming them to the city.

A resolution of condolence with the family of the late W. C. Palmer, of Toronto, was passed.

Secretary Mortimer then read his report, briefly reviewing the work of the association since its organization and stating its financial condition, which was very satisfactory, there being nearly $400 on hand.

The following officers were elected for the ensuing year: President, J. J. Wright, Toronto; first vice-president, K. J. Dunstan, Toronto; second vice-president, John Carroll, Montreal; secretary-treasurer, C. H. Mortimer, Toronto; executive committee (new members), L. B. MacFarlane, D. A. Starr; (old members) H. O. Fisk, A. B. Smith, W. A. Johnson, D. Thomson, T. H. Wadland, John Yule, S. J. Parker.

Two committees were appointed; one on statistics and the other to revise the by-laws and constitution of the association.

The evening was spent profitably and pleasantly by the members in inspecting the new station of the Hamilton Electric Light and Power Company, whose officers entertained the visitors with a lunch.

At the morning session on Wednesday, the 15th, the first paper was presented by Mr. Hugh Neilson on "Long-Distance Telephony," in which he gave an account of what had been accomplished in this department, and described the equipment and line construction. Canada, he claimed, was the home of the telephone, having more instruments in proportion to its population than any other country.

Mr. D. Thomson next read a paper on "Central Stations," giving details as to the manner in which they should be constructed and arranged, and touching upon the best engines and dynamos to use.

The association was invited by Mr. Larke, representing the Dominion Government, to make an exhibit at the World's Fair, Chicago. The Government, he stated, would pay the cost of transportation and take care of exhibits in Chicago, and no duty would be charged by the United States Government.

Mr. H. O. Fisk then read a paper on "Carbons," treating the subject thoroughly and going into intricate details of manufacture, illustrated by photographs. The president remarked that this paper was one of special value, and a vote of thanks was given Mr. Fisk.

Mr. D. Thomson moved a resolution fixing the following standard of current in amperes: *Resolved*, "That it is the unanimous opinion of this association that when the carbons in an arc lamp are at the proper distance apart to give their maximum amount of light, without either flaming or frying, that the strength of current for a 2,000 (nominal) c. p. arc shall be not less than nine and a half amperes; for a 1,200 (nominal) c. p. arc it shall be not less than eight amperes; for a 1,000 (nominal) c. p. arc it shall be not less than six amperes; and for an 800 (nominal) c. p. arc it shall be not less than four amperes."

This resolution was seconded by Mr. D. A. Starr and considerable discussion followed, many members saying that it would be inadvisable to pass the resolution, in view of the threatened legislation of the Government fixing a standard. An amendment, postponing the discussion of the question till the next annual meeting, was carried.

Before assembling for the afternoon session the members visited the new exchange of the Bell Telephone Co., one of the handsomest and best equipped on the continent.

On resuming business in the afternoon, it was decided to hold the next meeting at Toronto in January.

The president read an interesting paper prepared by Mr. S. J. Parker on the "Financial Aspects of Electric Lighting in Canada," which led to considerable discussion amongst the members.

President Wright next read his own paper on "Steam and Electric Power," on which subject he gave much valuable information and many useful points upon the production and distribution of electricity.

A paper on "Multiple Switchboards" was presented by Mr. J. A. Baylis, of the Bell Telephone Co., Toronto.

After that Mr. W. A. Johnson read a paper on the "Possibilities of Electric Railroading," in which he described what would probably be the future development of electric railways. The trolley, he considered, would continue in general use, with the possible exception of short lines in large cities, where cost is sometimes a secondary matter.

In the evening there was an excursion to Burlington Beach and an informal banquet there at the Ocean House. A pleasant feature was the presentation of a handsome gold watch to President Wright, as an evidence of appreciation by the members of his services in the interests of the association.

At the closing session, Thursday morning, Mr. A. B. Smith, the inspector of the Canadian Board of Fire Underwriters, read a paper on "Safe Wiring." After this, votes of thanks were passed to the Bell Telephone Co., the Hamilton Electric Light and Power Co., the Great Northwestern Telegraph Co., and the Board of Trade, for invitations and facilities extended the association. Votes of thanks were also given to Mr. C. H. Mortimer, the popular secretary, and the press.

The association pledged itself to do everything in its power to secure a large and thoroughly satisfactory exhibit of Canadian manufactures of electrical apparatus at the World's Fair, Chicago.

The number of members in attendance was about seventy-five. After adjournment, the members were taken for a drive around the city and mountain.

ELECTRICITY AND ITS RELATION TO TRANSPORTATION.[1]

BY CHAS. SELDEN.

THE author began by giving a short résumé of the progress of electricity, beginning with the telegraph of Morse up to the most modern applications of electricity as a lighting and motive power.

Passing to the subject of the application of electricity as a substitute for the steam locomotive, the author remarked:

Eminent motive power people have told me that experience shows that, under the best conditions, the locomotive can only be utilized to the extent of 25 per cent. of its power, and 15 per cent. under unfavorable conditions which are met daily. There are several factors that bring this about; partial consumption of fuel under high speeds is one, loss of fuel through exhaust is another, lack of traction is another and so on.

The electric motor has practically dealt exclusively, up to this writing, with the carrying of passengers. There are a few isolated cases in which a freight car or two have been utilized, and records show that in one instance a single car in one year carried 10,460 tons, but unfortunately the records do not show the mileage made by the car, nor its earnings, and hence we cannot reduce the figures to tons carried per mile and earnings. Another difference in the method of accounting is that the figures are based upon the earning and expense per car mile, instead of the ordinary method employed by steam railroads. I have selected as a fair comparison, a steam road that pays a dividend and upon which the earnings from passenger service exceeded the expenses about 25 per cent., taxing the car mileage and reducing it to mile per car, likewise showing earnings per car mile and expenses per car mile. In arriving at my figures some of them were necessarily arbitrary, but in such cases, the percentages, I think, may be considered fair.

The charges to passenger service amount to 26 and a fraction per cent. of the entire operating expense. The cars in daily service were 618, and the mileage made during the year 36,672,550 miles, or for each car 59,340 miles. The earnings (including mail and express—a source of revenue the electric roads do not enjoy) were $7,078,147.64, or per car $11,453.31, or per car mile 19.30 cents.

The expenses, classified as above, were $4,552,992.84, or per car, $7,367.30, or per car mile 12.41 cents, a net earning per car mile of 6.89 cents. The mail and express included in the above earned over $1,100,000, or in the neighborhood of one-seventh of the whole.

From an average of a number of electric roads, good, bad and indifferent, I have found the earnings to be 30.31 cents per car mile, and expenses 11.10 cents per car mile, leaving a net of 19.21 cents per mile, or a net gain over the steam road of 12.32 cents per mile.

These figures seem to show that the average of electric roads earned much more per car mile than the steam roads, and at an expense of only 1.81 cents per car mile less than the steam road. This slight difference in expense looks somewhat discouraging, but it must be borne in mind that the electric road figures are an average of a number of roads compared against a dividend earner and a net passenger traffic. There are electric roads operating for 7.8 cents per car mile and earning 24 cents per car mile, a difference in their favor in both earnings and expenses that catches the eye at once. Again, the steam road enjoys cheap fuel as against the electric road's high priced fuel and water. A crew of five men to five-car steam trains, as against ten men to five electric cars, and a proportion of taxation is charged against electric and not against steam in the figures given, and there are other matters entering into the expenses of operation that do not enter into the maintenance of steam roads, such as street paving, per cent. of gross receipts, park tax, etc. Hence, when we analyze we have no reason to complain, and I think we can safely assert the economy of electric motive power over steam, at least in certain localities and under certain conditions, and I believe in nearly, if not all.

---

[1] Abstract of a paper read before the Association of Railway Telegraph Superintendents, Denver, Col., June 15, 1892.

Let me ask the general managers whether there is not some piece of road that is now operated at a loss that could be operated at a profit by electricity? You have track, you have coal, you have power houses. Is there not some such territory on your own road?

Take suburban roads, or suburban points upon a through line, do you not strive and spend money to build up the locations? Do you not sometimes for years maintain a non-paying territory clearly on hope and speculation as to the future? Do you ever satisfy the commuter? Does not a percentage want the 11 o'clock train made 12 o'clock, and *vice versa*, and perhaps both? You meet this by saying you are doing the best you can and losing money at that? Now, then, how much quicker could you build up such a territory by more frequent and less expensive trains, and carry freight cars too, one by one, or two or three, and thus supply your local traffic; or if needs be, steam must haul freight, let it be done on the same track; they will work right along together. But, say you, the question of "speed comes in." So it does, yet I think you will find that the suburban public would rather have 24 trains a day at 20 miles an hour than 12 trains at 40 miles an hour, and I do not intend here to beg the question of speed. When it comes to speed, *per se*, rotary motion is undeniably capable of it with less strain and wear and tear than the reciprocating.

The author then described the work now being undertaken by the Baltimore and Ohio R.R. in the substitution of electric locomotives for the steam in the hauling of cars through the Baltimore Belt Tunnel, an account of which has already appeared in our columns. He also described the electric street railway system of Mr. Elias E. Ries which operates by induction between a series of stationary converters below the surface of the street, and a converter feeding current to alternating motor on the car, thus avoiding all conduits, trolley wires, etc. A working model of this system was shown.

Letters to the Editor.

RELATIVE PROPORTIONS IN RAILWAY POWER PLANTS.

I AM glad to note the discussion provoked on the subject of relative proportions in railway power plants.[1] My object in writing on this topic is fully as much to learn as to teach, and I deem there is no better method of averaging up the best practice than through the interchange of experience in a journal of the character of THE ELECTRICAL ENGINEER. And yet the term "average of practice" is a bad one, inasmuch as there can be no general average, but each engineer must determine the best all-around results for himself to be obtained with the types of apparatus he works with, and the varying conditions to be met.

I see by the comments already made that I ought to have stated at the outset that my articles are directed mainly to the discussion of *small* power stations. If this fact is borne in mind it will help considerably to understand the drift of my statements. The big stations are backed by abundance of capital, and usually are carefully worked out on paper to start with. The little country stations are more apt to pursue an alleged economy in respect to their engineering, and suffer in consequence. To my mind the time has fully come when the little station should receive the special care and nursing to which the weak infant is always entitled. Hence my own personal interest has been almost wholly aroused in this direction, and my articles will please be interpreted in the light of this fact.

I note too, that both of your correspondents have anticipated the points which I had scheduled for future articles in the series. This of course cannot be helped, but from this fact I shall take the liberty to reply less fully at the present time, since the same ground will be gone over more sequentially in future papers.

Mr. Hewitt[2] is accurate in his statement that I am more familiar with the steam engine than with the dynamo, and I am almost disposed to accept this as a professional compliment. I was born to engines, achieved boilers, but had dynamos thrust upon me; and so I propose to fight shy of the dynamo side of the question so far as practicable, and turn the responsibility of that department over to the electrical engineer to whom it belongs. Nevertheless, it can hardly be supposed that I am ignorant of the fact that heat in a generator is a most serious difficulty, (in fact, I intended that my expression should convey precisely that idea,) or again, that the E. M. F. was impaired by overload. But these articles do not propose to consider the effect upon the car service, but will confine themselves strictly to the generating plant and the inter-relation of its three elements on the assumption that the right quantities are determined at the start. On that portion comprised within the steam plant proper, I feel that I may speak with some authority, even in its relation to the generators themselves.

Mr. Hewitt is, I think, quite right in his statement, that on plants of 25 cars and over, the average load is in the neighborhood of two-thirds of the maximum. I am not worrying myself much about roads even of this capacity, and Mr. Book[3] has hit the conditions exactly, when he states that the larger the station the simpler is the engineering problem. This I believe to be strikingly true, notwithstanding a hasty supposition to the contrary. I find it imposes a much greater tax upon my judgment to lay out the little 10-car plants, than it does stations of three or four times this capacity. Fluctuations of the widest and most unexpected nature are to be contended with, and how to get out of these conditions a reasonable performance as to fuel duty, and what proportion of units to adopt in the attempt, is a problem of no small complexity.

The fact that the doctors disagree on this subject is beautifully illustrated by your two correspondents. Mr. Hewitt would proportion a station about as follows:

Dynamo, 100 E. H. P. rated.
Engine, 92 E. H. P. rated.
Boiler, 86 E. H. P. rated.

Mr. Book on the other hand, would follow out a proportion, thus:

Dynamo, 100 E. H. P. rated,
Engine, 50 E. H. P. rated,
Boiler, 76 E. H. P. rated.

Evidently there is a lack of uniformity of experience here, and I may venture to disagree with both parties and tabulate my own practice about as follows, referring, be it observed always, to the small stations:

Dynamo, 100 E. H. P. rated,
Engine, 120 E. H. P. rated,
Boiler, 60 E. H. P. rated.

Moreover, I have chewed the string long enough to prove that this pudding is entirely wholesome.

I wish to say right here that some of my clients, who are practical operators of roads, have disagreed with me from the first on the policy of having an excess of power in the engine. They admit the desirability of being able to pull over the high spots without losing speed, but they also claim that it is a positive detriment to have an excess of power which will burn out everything in case of a short-circuit, and they would prefer to have the engine give warning of its excessive load by its inability to carry it at speed. It seems to me that I cannot altogether agree with this view, from the fact, that it is to a certain extent a damage to the engine to slow it down, and take off the compression which is the main dependence for easing its running qualities. I feel more disposed to depend on the fuses or circuit breakers, and let the engine stand right up to its work.

Since my first article was originally written some months ago, however, I confess to having become fairly convinced that a smaller horse power, that is, *rated* horse power, is admissible than I had originally ventured to adopt. This is not due to the line of reasoning alluded to above, but depends upon the ascertained fact that a compound engine, after all, has fully as large a margin of power over its rating as a non-compound. Mr. Book does not so regard the case and charges me with using excessive rated engine power on account of scant surplus in the engine itself. I beg to say that the excess of engine power is not for this reason at all, but rests purely upon the assumed comparatively rigid capacity of the engine as compared with the greater range of the generator. I find lately, however, no difficulty in getting engine performance, such as shown by the accompanying card without any diminution of speed, and Mr. Book will recognize that there is a margin here fully equal to the severe demands of the generator, and fully equal to the performance of any non-compound engine in this respect. If the card in question were from an engine

---

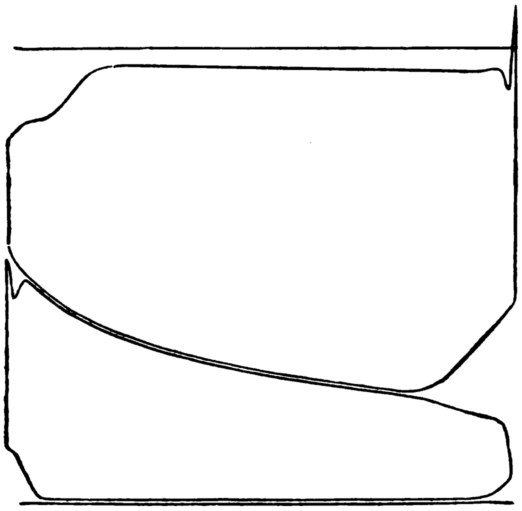
[3] THE ELECTRICAL ENGINEER, June 1, p. 552.

rating at 100 h. p., the load indicated would represent 135 h. p., and would give all the margin that the generator could be safely warranted to submit to. I would therefore repeat, that the tendency of my late experience is to come down on the size of the engine under certain circumstances, and let a common proportion be:

Dynamo, 100 E. H. P. rated
Engine, 100 E. H. P. rated,
Boiler, 60 E. H. P. rated.

This brings me directly up to the boiler question, on which I feel my position to be absolutely sound, at least within the lines of my own practice. Your correspondents evidently mistake the sources of my belief, and judge that I have arrived at the proportions of boiler power from some theoretical deduction based upon the average of the fluctuation of load. This is as far as possible from being the case, as any such deduction would be very dangerous, from the fact already pointed out in my second article, appearing in your last issue, that the average consumption of steam under fluctuating loads is a very different thing from the consumption of steam due to the average of the fluctuating loads. As a matter of fact, we arrived at this conclusion wholly unexpectedly to ourselves and along a very practical line of experience.

We had occasion to build a station in which the power was two compound non-condensing engines, rating at 100 h. p. each, and the boiler plant, not furnished by us, was four 60 h. p. horizontal return tubular boilers, one of which was intended as a relay. The operation of this plant speedily developed the fact that two of these boilers would furnish steam for the full capacity of the station under the heavy service, and, further, that the station could advantageously be run with a single boiler. In fact, this station is so run a considerable portion of the time. This was a striking instance and led to more careful investigation, which soon developed the proper explanation. It will be seen, therefore, that the fact was first observed, and the reasons subsequently worked out, rather than the contrary supposition.



It seems to me that it should not be difficult to understand that the boiler is taxed only to care for the average of the load, and has nothing to do with the maximum loads directly as such. The maximum load may be very far above the nominal capacity of the boiler, but this maximum will last only for brief intervals, and will be followed by comparatively extended periods of light load, or no load at all. During these periods the boiler is storing heat and pressure, and is prepared to let it loose in enormous quantities to meet the spasmodic demand. The case is precisely that of rolling-mills and saw-mills, and I confess that I am a little ashamed that we had not foreseen the whole thing before encountering it.

Mr. Book must not think that I am referring to any remarkably fine boiler at all. We have used almost every variety of boiler, and find the practice holds good. In fact, I do not see that the type of boiler has much to do with it anyway so long as its actual evaporative capacity is known. The boiler is only chargeable with making a certain number of pounds of steam in a given time; what that boiler can do in the way of developing horse power, then depends upon the intrinsic economy of the engine that takes steam from it. The real misunderstanding in Mr. Book's mind arises from the fact that his experience is doubtless based upon the usual performance of compound non-condensing engines, which will fluctuate all the way from 25 lbs. of water per horse power at full load, to 60 or 70 lbs. at quarter load. Now, since the railway engine is essentially an under-loaded engine—by which I mean that it runs for the greater portion of the *time* at a power far below its rating—it is, therefore, equivalent to saying that its average duty is way up in the air, probably in the neighborhood of 40 lbs. of water per horse power. Hence the "disgust of the stockholder," which a recent correspondent of the ENGINEER feelingly mentions, andhence, also, the obvious fact that the boiler has got to make all this extra steam—ergo, a larger boiler capacity is necessary. Now, to be of any value whatever, under fluctuating loads, a compound non-condensing engine should not exceed, at the outside, 30 lbs. of water per indicated horse power at, say, 20 per cent. of its rating. If the engine, therefore, fluctuates between limits of 24 and 30 lbs., under a railway load, instead of between 25 and 60 or 70 lbs., it does not take long to understand the effect on the boiler capacity.

I wish to give to the above statements all the strength that comes from saying that the foregoing is now our well-settled practice, regarding which there is with us no longer any room for doubt or experiment. We could cite any number of instances. I have already referred to one. In another station in Iowa, two 125 h. p. engines steam easily from two 80 h. p. horizontal boilers. In Michigan, two engines of the same size steam from a single 104 h. p. Babcock & Wilcox, burning wet slabs as fuel. In a station in Maine, two 100 h. p. Manning boilers were put in for two 125 h. p. engines, and as a matter of fact, one of them stands banked most of the time as a relay. In Detroit we are setting three 100 h. p. horizontal boilers to serve three 150 h. p. engines, and expect to keep one of these in reserve at that. In New Haven two 150 h. p. Manning boilers are to serve 480 h. p. of generators, with a third boiler as a reserve; and so on.

Now, I do not wish for a moment to lay down the foregoing statements as rules for anybody else to follow, nor do I even propose them to myself as rules to be invariably followed in every instance. I generally spend the first few days studying out the details of service of each road on its own merits, and I find the characteristics as varied and peculiar as those of human-kind. Each case calls for individual judgment, and my only claim is that this judgment and experience have taken certain well-defined shapes and have established a definite practice on our own part.

All this talk has been about the little ten-car roads. I hope it is clearly understood that the larger the road, the more the three units of generator, engine and boiler come up to the lines of ordinary mill practice in their relative proportions. I expect soon to have some definite results from a station of some 3,000 h. p. capacity, which is about being started, and I may have some experiences to submit in this direction later on.

I have trespassed inexcusably upon your space, and it only remains to say that I cannot see how any one should have inferred from my former article that I was against the idea of spare capacity in the boiler plant, or throughout the whole station, for that matter. It is undeniably true that every station, small or large, should have a complete spare unit in relay at all times. Unfortunately, most of the small stations do not have it, and cannot be persuaded into buying it. When such parties are encountered I am accustomed to insist that there must be spare boiler capacity any how, since when the boiler is laid off it is laid off for at least an entire day. If the road can afford to take its own risk and insure itself against accident, the best place to concentrate that risk is on the engine and dynamo, since there is a better chance for close inspection of this part of the plant, and a much stronger probability of being able to make necessary repairs between stopping and starting hours, Mr. Hewitt to the contrary notwithstanding.

WM. LEE CHURCH.

BOSTON, MASS.

WHOSE "NEW THREE-WIRE SYSTEM" IS IT?

IN your issue of June 15 I called attention to the fact that Mr. Rice's patent No. 463,364 covered the same subject-matter as Mr. Leonard claims under the title of "A New Three-Wire System." At that time I had not seen any patent issued to Mr. Leonard, and, in fact, cannot understand how the Patent Office could issue one consistently to Mr. Leonard, bearing in view the fact that Mr. Rice's patent issued before Mr. Leonard's was filed.

Mr. Leonard seems to think that Mr. Rice's invention is not operative. How he could arrive at that opinion after a careful reading of the patent it is difficult to understand. The patent is perfectly clear throughout, and Mr. Leonard might easily have discovered that the reversal of the field, which he lays so much stress upon, means the reversal of the *current* of the *series field*. In fact reversal of the field is impossible, since both the shunt and series field are co-operating under the conditions referred to, and the field strength is consequently at a maximum, and this condition is even expressed in the extract which Mr. Leonard has seen fit to make. Mr. Leonard after quoting this extract, says,—"The specification is very hazy in parts and seems to give rise to indications of serious doubt in the mind of the inventor of just what will occur," etc. This may be the condition of Mr. Leonard's mind in relation to the matter, but I submit that other inventors find the specification unusually clear. I am led to think that Mr. Leonard could not have read and pondered the following statement concerning the function of the compensating machine in Mr. Rice's patent.

"An initial excitation of the field of this machine is secured by a winding S^1 in shunt across the generator mains, but it may be replaced by other means of excitation, or, in fact, any arrangement securing a practically constant initial magnetism, which is *cut down* or *increased* by the current present in the winding D^1, according to the direction of the flow." D^1 is the small series winding which either cuts down, or, at other times, increases the field magnetism given by the shunt or constant excitation, according to the direction of flow in the series turns, which is reversed as the load shifts from one side to the other of the system, and this is the reversal which Mr. Leonard seems to think renders the system inoperative.

He says,—"But the reversal of the field is emphasized several times as an essential feature and is claimed distinctly," etc. This is decidedly not true. Such reversal is not emphasized, nor is it referred to "several times," but if Mr. Leonard will read the description in the specification carefully he will have no difficulty in understanding the nature of the invention. Fairness in criticism is demanded in order that such criticism should command respect.

Mr. Leonard quotes claim 3 of Mr. Rice's patent. He does not, however, quote claim 1, claim 2, or claim 4, which all relate to the same system, and which are thoroughly distinct and clear, as covering broadly Mr. Leonard's so-called new three-wire system.

It is hardly worth while to carry this discussion further. I would only call Mr. Leonard's attention to claim 2 of Mr. Rice's patent, and especially to claim 4. Mr. Leonard has called attention to claim 3, in which the words "so wound that its field is reversed," etc., occur. The claim is to be interpreted by the specification, and it will be seen that the field to be reversed is the series field alone, as I have already pointed out.

I am at a loss to see what my use of a motor generator, as contemplated in my patent No. 360,125, has to do with the subject under discussion, except that the system which Mr. Leonard describes would also be subject to the claims of that patent, though I will state, for Mr. Leonard's information, that notwithstanding the losses due to field excitation, friction, heating of the armature, etc., a motor-generator can be and has been so compounded, by the use of a small amount of series field, as to compensate for these losses and to maintain an exact balance between the two sides of a three-wire system.

I would call Mr. Leonard's attention to a patent to Mr. E. M. Bentley, No. 430,060, which, I believe, clearly covers certain features of his so-called new three-wire system, in addition to Mr. Rice's and my own patent referred to. I would also add in closing, without caring to refer to a number of minor matters, expressed in such statements as,—"the best relays for such purposes require two volts in pressure to actuate them, etc.," that the fact that a central station has been operating under the system which Mr. Leonard calls *his* system, for six months, does not in any way change the aspect of the case so far as the origination of the system is concerned. Mr. Rice's patent was filed February 13, 1891, and issued September 29, 1891. Mr. Leonard's patent was filed December 28, 1891, and issued June 7, 1892.

I have no wish to further prolong a discussion which any fair-minded person may settle by reference to the patents themselves, and in my former communication I merely called attention to the existence of these patents. ELIHU THOMSON.

LYNN, Mass., June 27, 1892.

DR. JACQUES' EXPERIMENT ON "WHAT ELECTRICITY IS."

IN THE ELECTRICAL ENGINEER for June 22, Mr. Townsend Wolcott in commenting on Dr. Jacques' experiment, sets himself up in opposition to Prof. Maxwell, to Dr. Jacques and to the writer. He thinks Maxwell's reasoning in leading up to this experiment was fallacious; that Dr. Jacques' conclusions from the experiment are incorrect, and that the writer is at fault in his interpretation of paragraphs 769 and 770 of Maxwell's celebrated treatise on electricity.

Prof. Maxwell is dead and cannot answer Mr. Wolcott's criticisms; Dr. Jacques seems rather inclined to let his experiment speak for itself than to enter into controversy, and it therefore remains for the writer to show that Mr. Wolcott is himself in error.

Prof. Maxwell in his "Electricity and Magnetism," paragraph 769, calculates out the mathematical expression for the mutual action between two parallel electrified surfaces moving together relative to some fixed point in space. Dr. Jacques takes up the problem here and shows by experiment that if the two parallel electrified surfaces be plates of brass and if the physical substance relative to which they move be the ether, the quantitative relations predicted by Maxwell will obtain.

Now, when we consider only the relative motion between the plates and the ether, it evidently makes no difference whether the plates move relative to the ether or the ether moves relative to the plates; it is wholly a question of relative motion. Since therefore Dr. Jacques' experiment shows that a current of ether flowing between the electrified brass plates exhibits both qualitatively and quantitatively the same properties as an electric current, it would seem to allow of no other logical conclusion than that a current of ether and a current of electricity are one and the same thing.

In paragraph 770 Prof. Maxwell calculates out the mathematical expression for the action of an electrified plate moving relative to a magnet, quite a different thing, though perhaps not less valuable, and experiments to test this relationship were made by Prof. Rowland in 1876 and were received with great interest throughout the scientific world when published. The mathematical predictions of Prof. Maxwell, the celebrated experiment of Prof. Rowland, and the recently published experiment of Dr. Jacques, are all links in a beautiful chain connecting the unknown with the known. Briefly Prof. Maxwell made certain mathematical predictions; Prof. Rowland showed that a moving electrified body was equivalent to an electric current; Dr. Jacques has shown that an ether current is equivalent to a current of electricity and thus demonstrates what a current of electricity is.

Mr. Wolcott attempts to point out certain "trifling defects in Dr. Jacques' reasoning," and says, "The deflections which Dr. Jacques expected to get, and which he thinks he did get, depend upon the repulsion of similarly electrified plates being diminished, and the attraction of similarly electrified plates being increased."

Now the words here quoted show very plainly that Mr. Wolcott has not correctly read Dr. Jacques' address and has missed the very gist of the experiment, and moreover they show an alarming ignorance of electric phenomena on the part of Mr. Wolcott, else he would not talk about "the attraction of similarly electrified plates," a phenomenon which any school-boy knows does not exist. Mr. Wolcott's article seems to the writer to savor rather of pugnacity than of purely scientific criticism.

VICTOR M. BERTHOLD.

BOSTON, June 24, 1892.

JUDGE ACHESON'S LAMP DECISION.

I NOTICE in your editorial of June 29, on the decision of Judge Acheson, what have impressed me, without any careful analysis of the situation, as misleading statements.

Regarding "a practical and public use." If I understand the matter, this was not a use of a practical or successful incandescent lamp, but only of a practical and successful method of building up carbons. Judge Acheson very clearly draws this line of distinction, as I read his opinion, and hence the fact that this process, which is the only thing covered by the Weston patent, was exhibited practically and publicly by Sawyer and Man, does not seem to me to bear out your conclusion that Judge Acheson's remarks have anything to do with Edison's subsequent success in the use of a filamentary carbon placed in an all-glass receiver exhausted of air.

Again, you say, "nearly all the incandescent lamps now made contain carbons which have been treated by the hydrocarbon process." Would it not be interesting in this connection to consider what proportion of the total number of the lamps manufactured to-day in the United States is produced at the factory of the Edison Company at Harrison, where no lamps are or have been commercially made by the treatment process? Of course the paragraph from which I make this quotation has no force unless it is limited to a consideration of the lamps made in this country alone.

Again you say, "the finding is directly contrary to that of the late Judge Bradley, in the McKeesport fibrous carbon case, who, on precisely the same evidences of fact, held that the work of Sawyer and Man," etc. The truth is that a considerable amount of new testimony as to questions of fact was taken in this Weston treatment case, and the record shows that in this branch of the case the evidence of the McKeesport case has been materially reinforced.

HYDRO-CARBON.

NEW YORK CITY, June 30, 1892.

ELECTRIC LOCOMOTIVES—A CORRECTION.

A PASSAGE in the newly published fourth edition of my "Dynamo-Electric Machinery" requires correction, being technically inaccurate. On page 616 the statement occurs that the electric locomotives of the South London Electric Railway are now being replaced by some of Messrs. Siemens' locomotives. In justice to Messrs. Mather & Platt it ought to be stated that the fourteen original locomotives supplied by them are still running, and that they have run in the aggregate not less than 450,000 miles. The two more recent locomotives supplied by Messrs. Siemens do not replace, but are supplementary to, the original engines.

SILVANUS P. THOMPSON.

LONDON, June 1, 1892.

THE NEW ELECTRICAL MONTHLY, *The Popular Electrician*, is to make its first appearance at Chicago June 15.

Literature.

DIGEST AND CLASSIFIED INDEX OF ELECTRICAL PATENTS.

WITH a view to affording attorneys, experts and others interested in electrical subjects a means of keeping abreast of the times and of prosecuting searches with ease and least expenditure of time, The Electrical Digest Publishing Company is about to issue a digest and classified index of all patents relating to electricity. The *Digest* will be issued monthly and will embrace a synopsis of each patent relating to electricity granted during the month.

A sample of the *Digest* before us shows great care in preparation and the illustrations accompanying the briefs lend it an additional value. The *Digest* will be published under the managership of Mr. R. W. Pope, No. 12 West 31st street, this city, and the first number will be issued August 9. The subscription price for the United States and Canada is $5 per annum; foreign countries, $7.50. There ought to be a large field for this publication and it deserves all the encouragement which can be given it.

Personal.

MR. A. L. ROHRER, of the Thomson-Houston Electric Company, of Lynn, well known to every electrical engineer, has just completed arrangements by which he will be transferred to Schenectady in the interests of the General Electric Company. His position there will be very similar to the one he leaves, and he will hereafter assist Mr. Kruesi in the same manner as he has assisted Mr. Rice for years past. For the next month or two Mr. Rohrer will divide his time between Schenectady and Lynn, but in the fall will settle down in Schenectady for good. Mr. Rohrer will be much missed in Lynn and Boston, as he has made hosts of friends and has occupied quite a prominent position in public affairs in the former city, being now a member of the board of management of the Lynn hospital and a member of the executive committee of the Lynn Board of Trade, having been its first president. A few notes regarding Mr. Rohrer's previous history, together with his portrait, will be found in our last issue in the article descriptive of the Lynn factories of the Thomson-Houston Electric Company.

PROF. F. B. CROCKER, vice-president of the Crocker-Wheeler Electric Company, New York, sailed June 18, in the steamer "Etruria" for Europe. While abroad he will meet all the prominent English and Continental engineers, to get, if possible, the results of their latest experiences in central station and power transmission work, and to compare notes on electrical matters in general, making a special study of improvements in electric motors with a view of introducing anything of value into his own practice.

MR. T. C. FRENYEAR, agent for the General Electric Company in New York State, with headquarters at Buffalo, has recently resigned his position to associate himself with the Cayadutta Electric Railroad Company, which is to connect Gloversville, Johnstown and Fonda, and is to do a general railway, as well as street railway business. Mr. Frenyear was secretary of the road at its inception, but has now become its general manager. Work will begin on the road in July. About $400,000 will be invested.

DR. CARL HERING, of Philadelphia, was married on June 30, in this city, to Miss Harriet B. Truesdell, also of Philadelphia. Dr. Hering expects to spend part of his honeymoon this summer in Switzerland, and will take with him the congratulations and best wishes of a host of friends.

Obituary.

JEREMIAH BORST.

A DISPATCH from Cobleskill, N. Y., under date of June 22, announces the death at that place, by suicide, of Jeremiah Borst, an old and well-known employee of the Western Union Telegraph Company in New York City. In the early part of 1867, Mr. Borst established *The Telegraphic Journal*, a weekly publication which was at the time supposed to have been issued under the auspices of the Western Union Telegraph Company, as it at once proceeded to wage vigorous contest against *The Telegrapher*, an independent journal which had been very outspoken in its criticisms upon the management and policy of that corporation in respect to its employees. Mr. Borst displayed considerable ability in the conduct of the *Journal*, but its career was brief. In November of the same year, it suspended publication, and its plant was taken possession of by the Western Union Company, which immediately thereafter commenced the publication as an official organ of the *Journal of The Telegraph*, under the editorship of J. D. Reid.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JUNE 21, 1892.

Alarms and Signals :—

Means for Preventing Collisions on Railways, H. G. Held, 477,212. Filed Nov. 19, 1888.

A system of automatic electric alarms for steam railways.

Electric Controlling Apparatus for Fire Alarms, G. Knowles, Jr., 477,214. Filed Dec. 3, 1889.

Has for its object to electrically control fire-alarm mechanism without the intervention of a local battery or generator.

Conductors, Conduits and Insulators :—

Cable Junction Box, J. D. McLeod, 477,218. Filed Dec. 15, 1891.

Distribution :—

Distribution of Rotary Electric Currents, A. E. du Bois-Reymond, 477,250. Filed April 30, 1891.

Relates to a multiphase system where the currents equaling or exceeding three may be used to energize a rotary current motor and conveyed by the separate conductors used individually through lamps or the like requiring but one alternating current.

Dynamos and Motors:—

Electric Motor, F. Yeiser, 477,433. Filed Sept. 22, 1891.

Has for its object to reverse the direction of rotation of the motor by the simple adjustment of the commutator brushes.

Heating:—

Electric Heater, C. E. Carpenter, 477,628. Filed Nov. 29, 1890.

Has for its object to utilize a portion of the secondary circuit of a transformer as the heated resistance for evolving heat upon the passage of a varying current through the primary circuit.

Lamps and Appurtenances :—

Carbon-Rod Contact for Arc Lamps, C. McNellis, 477,219. Filed Jan. 26, 1892.

Employs a tube detachably secured to the floor of the lamp, a contact brush and a ring pressing the flange of the contact brush against the end of the tube.

Electric Arc Lamp, L. Parker, 477,221. Filed July 13, 1891.

Has for its object to discharge the upper carbon when consumed and insert a fresh carbon automatically.

Electric Arc Lamp, N. F. Rutherford, 477,273. Filed Aug. 12, 1891.

Employs two pairs of solenoids one on the main circuit of the lamp and the other in shunt; carbons carried by levers pivoted at their point of intersection, one carrying the main magnets and the cores of the shunt magnets and the other carrying the shunt magnets and the cores of the main magnets.

Incandescent Electric Lamp Socket, J. S. Gibbs, 477,407. Filed Feb. 27, 1892.

Consists of a shell with a single division of insulating material supporting conductors to which the circuit wires are joined.

Electric Arc Lamp, F. V. Maquaire, 477,427. Filed Aug. 13, 1891.

Employs an electromotor automatically operating both carbon holders and an electro-metric balance regulating the motor.

Measurement :—

Means for Operating Ammeters and other Electrical Apparatus, H. M. Pilkington and R. S. White, 477,223. Filed Sept. 24, 1891.

Claim 6 follows:

The combination in an ammeter or indicator of several coils in separate line wires, a single pointer, a single scale, and means acted upon in conjunction by said coils for moving said hand or pointer.

Metallurgical :—

Process of Electroplating with Alloys, E. T. Burrows, 477,350. Filed Nov. 7, 1891.

Employs a solution of copper sulphate, caustic potash, zinc sulphate, chloride of tin, sal ammoniac and muriate of iron and an anode of copper, tin and zinc.

Miscellaneous :—

Electric Alarm Clock, B. Franklin, 477,206. Filed Sept. 12, 1891.

Rheostat, G. K. Cummings, 477,247. Filed Dec. 11, 1891.

Employs an electric conductor of high resistance embedded in a block of moulded insulating material.

Electric Jail, P. Hale and C. H. Sparks, 477,301. Filed Sept. 7, 1891.

Relates to electric alarm mechanisms for jails.

Thermotic Circuit Closer, W, H. Tapley, 477,315. Filed Aug. 14, 1889.

Has for its object to facilitate accurate adjustments of devices by which electric connection is made with a thermostat.

Electric Embossing Stamp, C. E. Carpenter, 477,627, Filed June 21, 1890.

Switches and Cut-Outs :—

Electrical Switch, C. J. Klein, 477,374. Filed May 28, 1891.

A quick-break jack-knife switch.

Electric Switch, J. L. Hinds, 477,595. Filed July 23, 1891.

Has for its object a simple and effective switch highly economical in manufacture.

Electric Switch, E. T. Greenfield, 477,409. Filed Dec. 16, 1891.

A snap switch provided with a spring-actuated arc interrupter of insulating material.

Electric Switch, E. A. Snow, 477,612. Filed July 23, 1891.

Employs a spring composed of a plate folded upon itself and a cam for engaging the central portion of said spring and forcing it into contact with the terminals.

Telegraphs:—

Printing Telegraph, C. J. Reed, 477,383. Filed May 27, 1891.

Employs a combination of a telegraph circuit with two or more type-writing machines.

Printing Telegraph, C. J. Reed, 477,384. Filed July 6, 1891.

Similar to 477,383.

Telephones and Apparatus :—

Test Circuit for Multiple Switchbords, C. E. Scribner, 477,579. Filed May 12, 1885

Employs a battery in the ground circuit at the central office and testing apparatus at the different boards to determine at any board whether a line is in use at any other board.

Electric Annunciator Drop, J. C. Warner, 477,616. Filed June 17, 1889.

Employs a soft iron shield about the coil to prevent inductive effects between the coils of the different magnets when placed near each other.

TRADE NOTES AND NOVELTIES

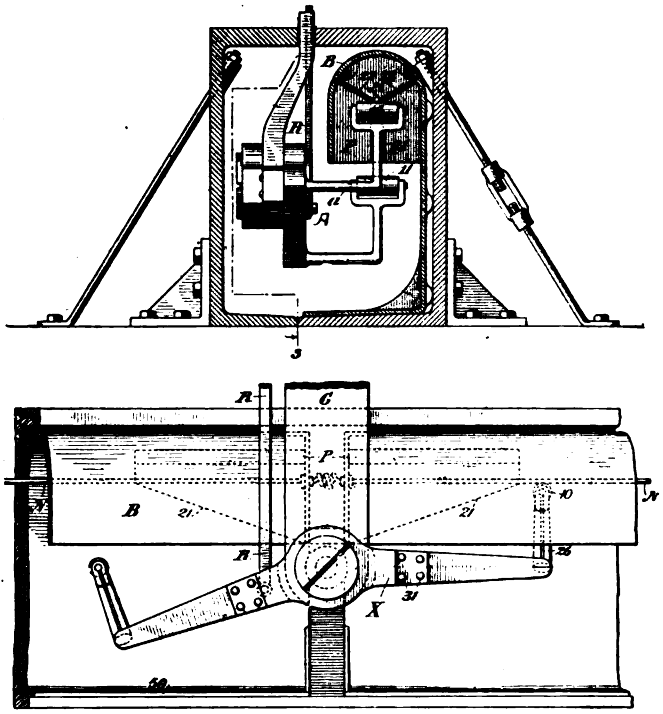
AND MECHANICAL DEPARTMENT.

When an eye first sees your advertisement it may appeal to the eye only; it is only in repeated efforts that advertising reaches its object—the customer.— D. T. Mallett.

THE "DIVING BELL" CONDUIT FOR ELECTRIC RAILWAYS.

THE accumulation of water and sediment in electric railway conduits has been a fruitful source of trouble that has gone far toward preventing their adoption. Almost all devices intended to remedy this defect have aimed at keeping the water out and have neglected the important point of the protection of the wire in case, through some unforeseen accident, it should effect an entrance. A very different plan however is that devised by Mr. R. W. Barkley, of this city, and shown in the accompanying illustrations.

As will be seen, the key to the system is the adoption of the diving bell principle, the conductor N being within a series of diving bells B, which open into the conduit C, such as that used on the cable railway. The diving bells effectively prevent water or mud from rising to the wire and causing grounds.

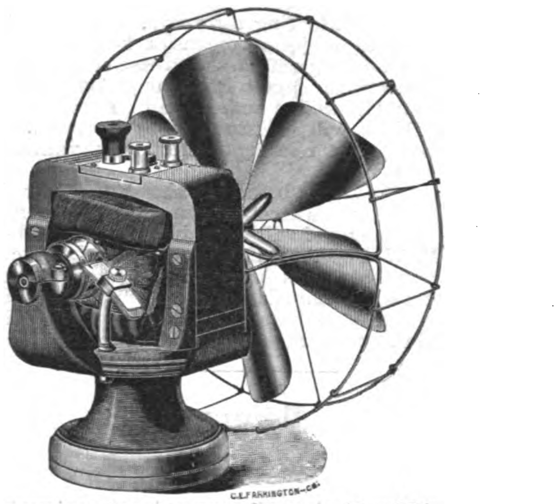


FIGS. 1 AND 2.—"DIVING BELL" CONDUIT FOR ELECTRIC RAILWAYS.

Between the diving bells, the wire is suitably insulated. The trolley A, having two trolley rollers 10 and 11, is pivoted to a support G from the car or truck. In the position of the parts shown, roller 10 is in connection with the motor, while roller 11 is dead; with roller 11 up and roller 10 down, matters are reversed in these respects. The inclines, 21, at each end of the diving bells, cause the working roller 10 in the case shown, to duck under the end walls P, of the diving bells while the rod R is used to raise and hold either of the rollers in contact with the conductor N.

THE BERNSTEIN ALTERNATING CURRENT FAN MOTOR.

WE illustrate on this page, a new motor of the alternating current type, for fan work, just brought out by the Bernstein Electric Company, of 620 Atlantic avenue, Boston. It will be remembered that the Bernstein continuous current motor was also noticed in our columns recently. This new little machine is known as the "T" type. It is ⅛ h. p., stands 9 inches high without the fan, runs at a speed of 1,600 revolutions, and consumes only 65 watts. It is wound for either 50 or 100-volt circuits, and for other special voltages if desired, It has but one brush, with bronze commutator, and self-oiling bearings. The fan is a 12-inch, and delivers a most refreshing breeze. The motor runs noiselessly and with a minimum of heat. It will also stand an overload without undue heating or danger of burning out. The company is desirous of securing agents for its fan motors in every town in the country.

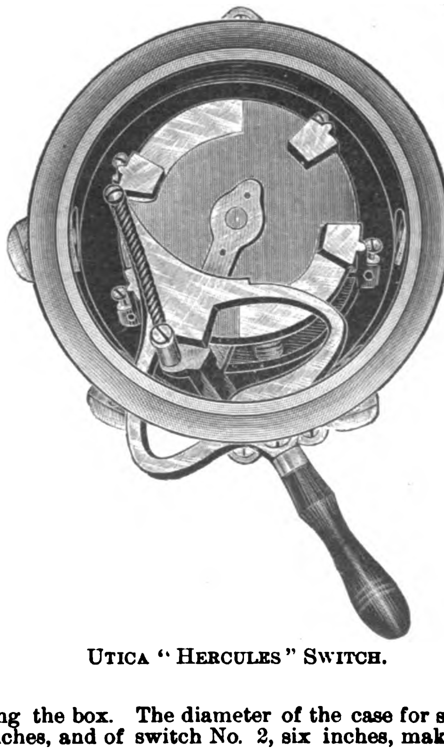


BERNSTEIN ALTERNATING CURRENT FAN MOTOR.

THE UTICA "HERCULES" SWITCH.

THIS cut shows the "Hercules" switch, made and sold by the Utica Electrical Mfg. & Supply Co., Utica, N. Y. It has double contacts—is quick acting and can be used either on arc or power circuits. It has heavy binding posts and contacts, is mounted on slate base and enclosed in a water-tight iron case, and currents from 25 to 100 amperes of high voltage can be safely handled, causing hardly a perceptible arc. The switch is of new and original design, and is automatic in its action when started in either direction.

"The "make or break" of contacts is not dependent on slow or fast movement of the operator's hand. The case is provided with porcelain bushings for the protection of wires in entering and leaving the box. The diameter of the case for switch No. 1, being 8 inches, and of switch No. 2, six inches, makes it a most compact article.



UTICA "HERCULES" SWITCH.

THE SECHRIST AUTOMATIC CONTROLLER FOR INCANDESCENT LIGHTS.

A valuable patent was granted to Albert Sechrist of Denver, Col., on the 7th day of June, which covers a new system of controlling electric lights. The system is similar to that used in electric gas lighting and, in fact, answers the same purpose for controlling electric lighting as the automatic gas burner. The system is a combination of an automatic switch, push buttons and an ordinary battery, or shunt circuit. The automatic switch answers the same purpose as an ordinary switch, but instead of being operated by hand it is controlled by push buttons the same as gas keys located at any number of different points. The switch is simple in construction as is seen by reference to Fig. 1, while Fig. 2 shows the whole circuit. The white buttons operate a magnet which turns on the light, and the black buttons operate a similar magnet which releases a spring and turns off the switch. The system is especially adapted for residence lighting and in that capacity gives a great range of possibilities. The switches are located in some out-of-the-way place and only the neat and ornamental push buttons are to be seen, located conveniently on the door casing at the entrance to the various rooms. Besides presenting a much neater appearance, the same light may be controlled from any number of different points. This is often a great convenience; take for example the second-story hall light, which may be operated from the first, second and third story halls and also from each of the chambers on the second floor. In this way a person may pass through the house in any direction without the necessity of ever being in the dark, as by simply touching a button, here or there, it will turn on the light ahead or extinguish the light no longer needed.

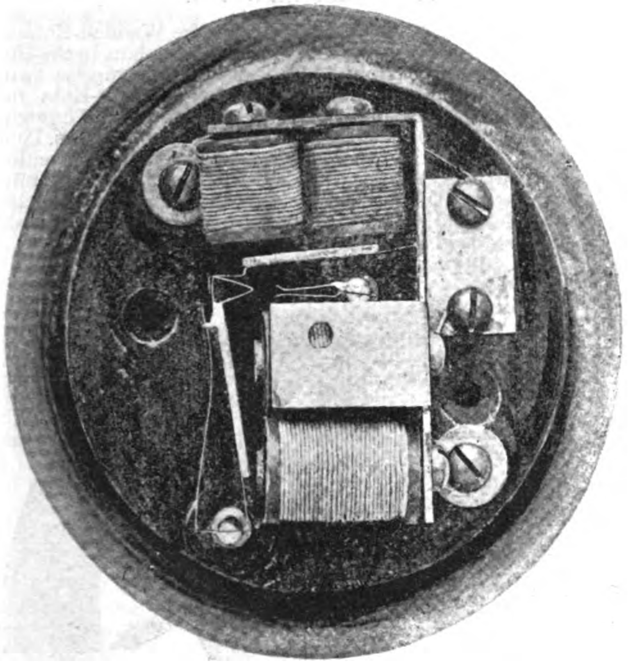


FIG. 3.—SECHRIST AUTOMATIC CONTROLLER.

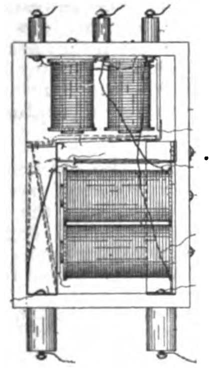

FIG. 1.—SECHRIST AUTOMATIC CONTROLLER.

A set of buttons may be located in the chamber to control the entire house. The porch, hall, parlor and library lights may be controlled from the front and side entrances. The system is also useful as a burglar alarm; the wires may be attached to the ordinary burglar alarm system of the house and whenever a door or window is open the light is automatically turned on, to the utter rout and confusion of the burglar; or the wires may be attached to an ordinary clock; the light will be turned on or off at any desired time.

Although the system has only been in use six months in Denver, over 50 residences are being lighted with the Sechrist automatic switch, and the prominent architects are specifying the same for new residences that are being built.

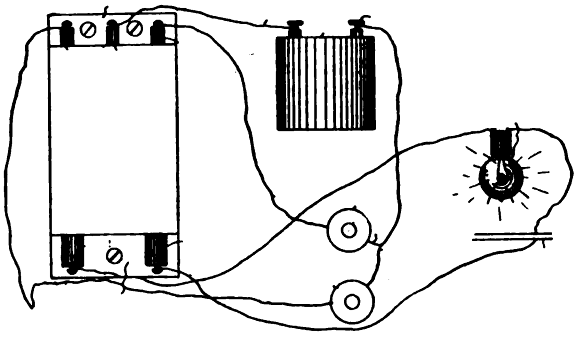

FIG. 2.—SECHRIST AUTOMATIC CONTROLLER.

Fig. 3 shows a new and very convenient form of the switch, with regular metal cap screwed on; and the whole mounted on a fine porcelain base. In the engraving, the cap has been removed. The screw holding the cap engages in the small hole shown in the flat leaf covering one of the magnet spools.

THE JOHN L. GISH IDEAL RHEOSTAT.

THE accompanying illustrations show a rheostat designed by Dr. John L. Gish, of Jackson, Mich., to meet the needs of surgeons and dentists. The form shown in Fig. 1 is intended for use in connection with electric mallets, mouth lamps, etc., and will furnish a sufficiently strong current to treat all diseases of the teeth and mouth.

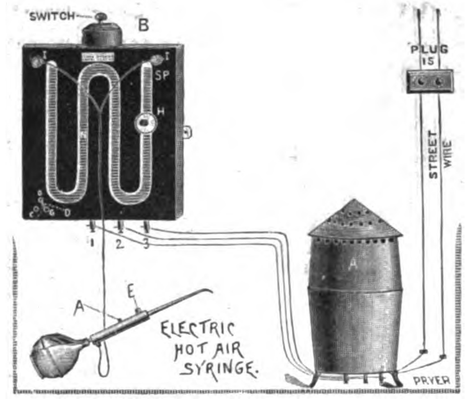

FIG. 1.—THE JOHN L. GISH IDEAL RHEOSTAT.

Fig. 2 represents a larger rheostat for faradic work, both therapeutic and diagnostic, and is also claimed to operate the electromagnet to a remarkable degree of nicety. A gradual change of voltage from zero to 80, and of ampereage from zero to 2¼ can be obtained. In another form of this device, designed for cautery work, the arrangement is such that the voltage may be diminished and the current increased to meet all requirements.

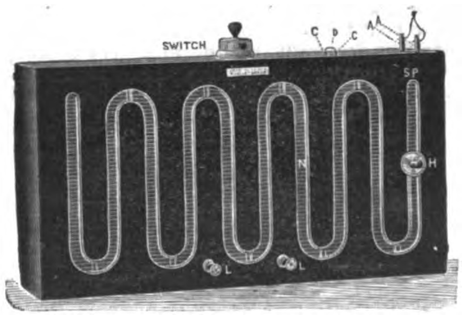

FIG. 2.—THE JOHN L. GISH IDEAL RHEOSTAT.

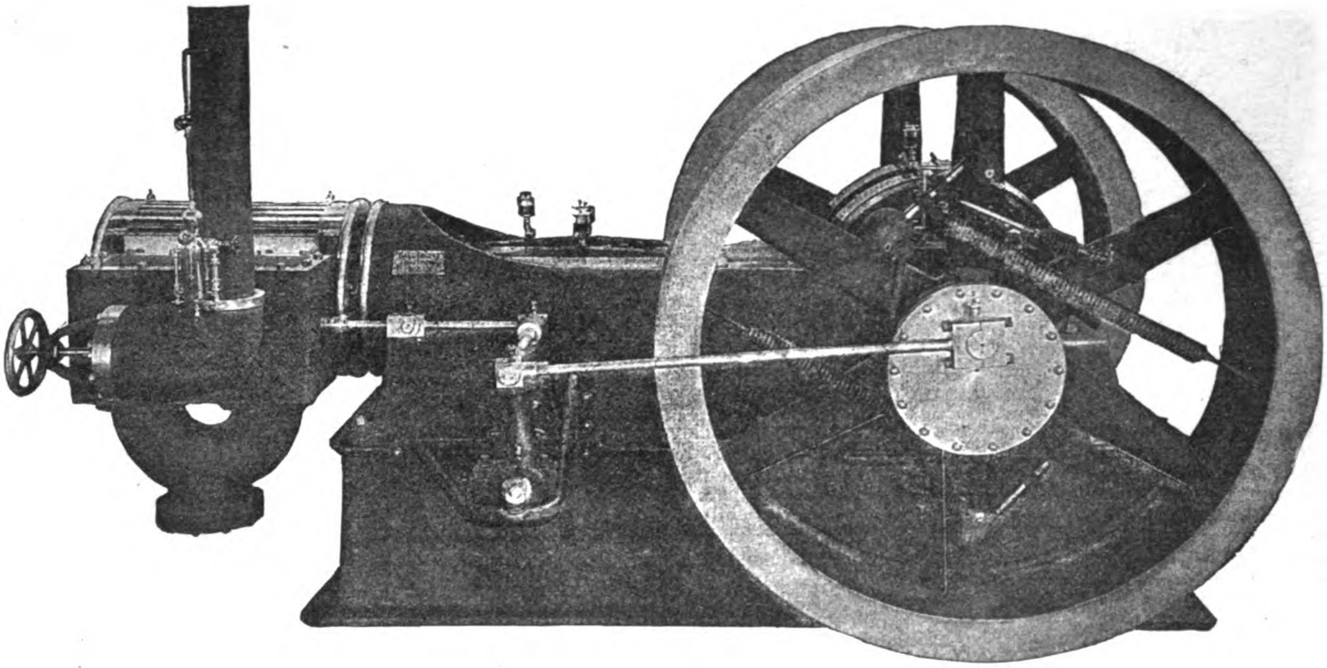
The rheostat is placed in the street circuit, while the operator takes from a shunt a current of the character best suited to his particular work. The instrument is attractive in appearance and is mounted in a handsomely finished black enamel case.

HEAVY DUTY BALL ENGINE FOR ELECTRIC RAILWAY SERVICE.

The extremely varying load which a steam engine in an electric railway power station is so often called upon to carry calls for the fulfillment of special conditions, prominent among which are great strength and prompt acting of the governing mechanism. It is through lack of one or both of these essential points that some of the engines in the early installed stations have shown themselves unfit for the task assigned them.

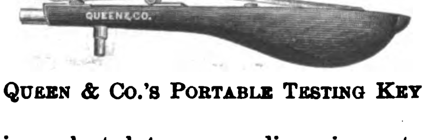
In the accompanying illustration is shown an engine recently brought out by the Ball Engine Co., of Erie, Pa., especially for electric railway service. It will be seen that this engine is, for its cylinder capacity, of great strength and weight, the makers claiming that the engines they build are, for the horse power, the heaviest engines made. The connecting rod and crank shaft are of forged steel. The crank shaft is 8 inches diameter in the crank pin and in the journals. The crank pin boxes are lined with strictly genuine babbitt; the cross-head boxes are of pure copper and tin. The cross-head pin is of tool steel. The system of oiling the running parts is very simple and thorough. The valve which has been used by this company with such great success in the past in their electric light engines, is continued in the "Heavy Duty" engine. This engine has shown in practice perfect regulation under conditions where the variation in load on the generator from zero to the full capacity has occurred during less than five seconds of time. The makers of this engine, working on the theory that the electric railway interests demand a strictly first-class engine, are using the very best possible material and workmanship throughout, and claim to give perfect satisfaction.



Heavy Duty Ball Engine for Electric Railway Service.

QUEEN & CO.'S PORTABLE TESTING KEYS.

While practically all galvanometer and other electrical keys are portable in that they can be carried about, yet the type illustrated herewith is decidedly unique and very useful. Every one who has occasion to make insulation tests away from a laboratory knows how essential it is to have apparatus that is reliable, and at the same time adapted to surrounding circumstances; that is, accuracy must be combined with portability.



Queen & Co.'s Portable Testing Key.

A short-circuit key or a contact key that can be thrust into one's pocket will commend itself for convenience to those engaged in outside work, and we are informed by Queen & Co., of Philadelphia, that they can "fill the bill" with their new products. The keys are made of hard rubber, polished, with brass connections, and platinum contacts, and the desired effect is produced by simple pressure of the hand.

As to "weights and measures," none are longer than 5½ inches, and they weigh not over five oz. each. Three forms are now made, viz., single contact, double contact and short-circuit. A full description with price-list will be found in circular No. 340 just issued by Queen & Co., which will be forwarded upon request.

PHILADELPHIA NOTES.

Messrs. Wright & Starr, agents for the Waddell-Entz Co., have the contract for installing an electric light plant in the Union League Club of Philadelphia. The plant will comprise two 80 kilowatt direct-coupled generators of the Waddell-Entz make driven by two Straight Line engines of 120 h. p. each. The switchboard, which will be a model one, is being built by Messrs. Pepper & Register. The limited space for machinery and the condition of things about the building renders this plant a most difficult one to engineer. Dr. W. A. Drysdale, the consulting electrical engineer, is doing himself credit in this undertaking after its having been abandoned by several other engineers.

The Heisler Electric Co.—In response to a letter sent out by the Heisler Electric Co. to numerous plants installed by them throughout the country wherein they ask to be informed as to the dividends declared to stockholders, they have received many very gratifying letters stating the appreciation of the working of the Heisler long-distance lighting apparatus and quoting dividends ranging from 7 to 22 per cent.

Dr. W. A. Drysdale.—The electrical equipment for "The Stentor," the new hotel in process of erection at Broad and Spruce streets, has been completed under the direction of Dr. W. A. Drysdale, the consulting electrical engineer. The building is wired for 550 lights, Vulca tubing being used throughout. The Novelty Electric Co., have the contract for the work.

A baseball nine, composed entirely of employees of the factory of the Partrick & Carter Co., will challenge to play a nine from any other electrical company in the city.

WASHINGTON NOTES.

The Washington Electric Conduit Co. find that a great many companies are in the market for a good and cheap conduit system that shall enable them to put their wires underground, and hence the summer with them is busy. Mr. Wilmot Lake, their engineer, has left Washington on a trip through Cincinnati, St. Louis, Chicago, Minneapolis, Detroit, Buffalo, Rochester, Albany and other points, to look after the company's interests in those places.

A GREAT ENGINEERING ENTERPRISE IN JAPAN.

THE last mail from the Orient brings a very interesting account of the completion and successful operation of a great government work in Japan. Lake Biwa, having an area of 500 square miles, is located seven miles from the city of Kioto and at an elevation of 143 feet.

A navigable canal has been cut from this lake to Kioto, involving two miles of tunneling and an aqueduct of considerable length. At the eastern extremity of the city, to which point the canal has been brought, there is a sharp decline of 118 feet, from the base of which the canal is continued to the sea. This difference in level is overcome by inclined planeways 2,100 feet in length, on which boats are raised and lowered from one canal to the other. These ways are operated by electric power furnished from a Pelton water-wheel connected with a Sprague motor.

The fall above named affords also a very valuable water-power, a part of which has already been utilized for various mechanical purposes by means of electric transmission. The power station is located at the foot of the incline, and consists of three 8-foot and two 6-foot Pelton wheels, aggregating about 600 h. p., which are supplied with water from the high-level canal by three lines of 36-inch pipe, 1,300 feet in length, delivering water to the wheels under a head of about 100 feet.

These wheels are at present operating three Edison dynamos of 80 kilowatts each, the power from which is distributed about the city within a radius of two miles, running rice mills, spinning mills, a watch factory and various other machinery. One Thomson-Houston alternating current dynamo of 2,000 volts supplies the city with 1,300 incandescent lights, as well as many arc lights.

The above works, involving an expenditure of $1,500,000, were planned by and executed under the direct supervision of Mr. S. Tenabe, an eminent Japanese engineer, and their operation is said to be a great success, both from a mechanical and a financial point of view.

PURITY OIL FILTER MFG. CO.

THE PURITY OIL FILTER MFG. CO., of Pittsburgh, Pa., recently shipped the Schmulbach Brewing Co., Wheeling, W. Va., one No. 2; the Pearson Cordage Co., Boston, Mass., one No. 4; Crook, Horner & Co., Baltimore, Md., one No. 2, Ideal oil refiners. They have a letter from San Francisco, Cal., saying their Ideal oil refiner at the Pacific Rolling-Mill is doing splendid work; that the oil contains 3 per cent. of sand, cinders and ashes before being purified, and that a powerful magnifying glass fails to reveal any of it after refining. The following from Pittsburgh is also of interest:

PITTSBURGH, PA., June 1, 1891.

PURITY OIL FILTER MFG. CO.

Gentlemen.—The Ideal steam oil refiner you placed in the power house at Oakland for this company last March, is giving good satisfaction, and is saving us a large amount of oil. The oil is a better lubricant after being used on the engine, and purified under your process, than when first taken from the barrel. We use it on the pins of our large Wetherell-Corliss engines with splendid success. I think you have the best waste-oil reclaimer I ever saw. I have used a number of different devices in my capacity as erecting engineer. I will recommend the Ideal refiner to my friends, and wish you the success that this invention merits.

Yours truly,

JAMES GORMAN,
Chief Engineer Pittsburgh Traction Co.,
Late Erecting Engineer for Robert Wetherell & Co.,
Chester, Pa.

R. THOMAS & SONS.

THE firm existing during the past nine years under the name of R. Thomas & Sons, and manufacturing porcelain at East Liverpool, Ohio, has merged into an incorporation which will be known hereafter as the R. Thomas & Sons Co.

This company have recently purchased from the Westinghouse Electric Co. their entire porcelain plant which, with their already large factory, employing over 200 operatives, gives them, it is claimed, the most extensive works in this country making porcelains for electrical purposes a specialty. They have just issued an elaborate catalogue of 45 pages illustrating over 200 designs of porcelain used in the electrical trade, but which does not include one-third the variety they are making. It is very essential that all porcelain for electrical purposes should be very hard and vitreous. The Thomas Co. pride themselves upon making throughly non-absorbent goods.

F. P. LITTLE & CO.

F. P. LITTLE & CO., of 141 East Seneca street, Buffalo, N. Y., have closed a contract for lighting the new Columbia Theatre at Binghamton, N. Y. The plant will consist of an "H. I." Thomson-Houston dynamo, with wiring complete for 600 lights, and all the regulators necessary for stage lighting and special effects. Mr. Little has also sold a 90,000-watt Thomson-Houston dynamo for the new Capitol Building at Albany. Business is quite brisk with the company, and looks as though it would continue so indefinitely.

A NEW ELECTRICAL DICTIONARY.

MESSRS. NORMAN W. HENLEY & CO., the publishers of scientific books, 150 Nassau street, New York, have nearly ready for publication "*The Standard Electrical Dictionary*" by Prof. T. O'Conor Sloane, author of "*Arithmetic of Electricity*," "*Electricity Simplified*," *etc., etc.* The author's previous works have been endorsed very highly by the press. He is very well known, and will, no doubt, produce a work of merit. Further information in regard to same may be had by addressing the publishers.

NEW YORK NOTES.

NEW STOCK COMPANIES are formed daily in every State, and they all must have a book of stock certificates. The most effective certificates can be procured, at the smallest cost, by using ready lithographed forms, which are adapted to the need of any corporation by the addition of a few printed lines. A. B. King, of 89 William street, N. Y., is headquarters for these certificates; he carries seventeen patterns in stock. He will furnish a book, at about one-third the cost of a specially lithographed one of inferior design, and can deliver it complete within three days. He has, also, forms for bonds, with ten to sixty coupons, which afford like advantage for providing handsome-looking bonds, quickly and at low cost.

WM. C. MCINTYRE & CO., agents for the Eddy Motor, report the following recent sales in Philadelphia: Singer Sewing Machine Co., 7½ h. p.; Penn. Mutual Ins. Co., 10 h. p.; E. K. Tryon & Co., 5 h. p.; J. E. Ditson & Co., 5 h. p.; Buchler, Bonbright & Co., 4 h. p. At Wilmington, Del., *Evening Journal*, 10 h. p.; Heyson & Co., 5 h. p. At Allentown, Pa., Breinig & Bachman, 10 h. p.; Bitner & Hunsinker, 7½ h. p.; Allentown Shirt Co., 3 h. p. Mr. McIntyre says they have been compelled to refuse several orders during the last three weeks on account of not being able to procure machines from the factory, where they are reported to be over one hundred machines behind on their orders.

THE OKONITE COMPANY are to be congratulated upon the continuous success of their high grade wire, the sales for the past week amounting to upwards of one million feet, through the hands of the Central Electric Company, their general Western agents. One single order amounted to 225,000 feet, besides a constantly increasing demand among the regular customers. The large stock held by the Central of all sizes of wires, coupled with the quality of the product is perhaps some reason for the favor with which the wire is regarded.

MR. A. C. WHITNEY will hereafter represent the Crocker-Wheeler Electric Co., and will find his large experience among central stations of great service to him. He was for some time connected with the Crosby Electric Co., and then joined the Consolidated Electric Storage Co. in the capacity of manager of agents. After this he became associated with the Union Electric Co. and succeeded in introducing their battery very widely.

MR. F. S. TERRY, the manager of the Electrical Supply Co., of Chicago, has been East on a visit during the sessions of the Democratic Convention in the big Wigwam, which stood right in front of his office windows. Had the building been of higher class construction, Mr. Terry thinks it might have answered fairly well for a convention of the customers of his company. No place smaller would suffice.

MR. A. L. TINKER has severed his connection with the Engineering Equipment Co. of this city, it being understood that he has sold out his interest in the concern. He has held the positions of secretary and treasurer.

MR. E. T. BIRDSALL, the well-known electrical engineer of this city, was married on June 22d to Miss Louise Banker, daughter of Mrs. Amanda Stevens Goetchius. The wedding took place at St. George's Church.

NEW ENGLAND NOTES.

DR. A. F. MASON, whose name is known to every one in the electrical trade, returned about two months ago from a winter sojourn in Florida, and related to a number of his friends a few interesting "fish stories." We were pleased, however, a few days ago, to accept an invitation to view one of the specimens of the doctor's prowess in the piscatorial art, and congratulated him upon a very fine tarpon which he had just received, handsomely mounted on a polished board. This fish weighed when caught 101 pounds, measures just 5 feet 10¼ inches long, and took the doctor just 55 minutes to land. It is a beautiful specimen of this noble fish, now getting somewhat scarce, and will, doubtless, be kept by Dr. Mason for many a long year as a memento of his fishing excursion in 1892.

The Westinghouse Electric Company through their New England agency are in receipt of the following orders: 100-light isolated plant for the Norman Paper Company, Holyoke, Mass.; an increase of a 60-light alternating current arc light dynamo with lamps for the Uxbridge and Northbridge Electric Company; an 800-light alternating incandescent dynamo for the new plant of the Stamford Electric Light Company, of Stamford, N. Y.; and four car equipments, single-reduction motors, for the Keokuk Street Railway Company, Keokuk, Iowa. The order for the alternating arc light dynamo is particularly interesting, as it is an increase and has been ordered by the Uxbridge Company on account of the satisfaction of the first apparatus installed for them.

Mr. **George R. Lean**, who has been for some years connected with the Bernstein Electric Company, of Boston, and who has had a long experience in the manufacture of incandescent lamps, has resigned from his position with that company, and has accepted a somewhat similar position with the Heisler Electric Light Company, of Philadelphia, who as is well known, make a specialty of long-distance series incandescent lighting. Mr. Lean's long experience in this particular line, will doubtless make him a valuable acquisition to the Heisler Company, and he enters his new field with the best wishes of all his friends in the East.

Mr. A. H. Trott, who has been for some time connected with the Thomson-Houston International Company, has just returned from Demerara, where he has had charge of the arc and incandescent station in the city of Georgetown. Mr. Trott has gone to his home in England for a short vacation, but expects to return in the fall. Mr. Trott is the son of Captain Trott, of the cable ship "Minia," well known to all electricians in Boston, New York and many other cities in this country.

The Redding Electric Company, of Boston have sent out a circular letter to the trade, notifying them that on account of the large increase in their trade for electric light specialties, they have decided to give up their household goods department. They have a large stock of these goods on hand, and desire to close them out at once at very low prices.

The Waterbury Brass Co., of Waterbury, Conn., are putting up their new wire mill, which will be of iron designed and furnished by the Berlin Iron Bridge Co., of East Berlin, Conn. The rolling mill will be 100 feet wide by 160 feet long, with a wing (to be used for drawing wire) 40 feet wide by 230 feet long.

The Davidson Fan Ventilating Company, of Boston have been offered the contract for furnishing all the fans to be used in the ventilating of the buildings of the World's Fair in Chicago. About 100 fans will be required, varying in size from 12 inches to 60 inches in diameter.

Mr. T. McCoubray, of "Okonite" fame, was in Boston during the past week, and tried to enliven things generally. Mr. McCoubray once lived in this section and is warmly remembered and welcomed by a large number of friends.

Mr. E. R. Weeks, of Kansas City, was in Boston during the past week, and met a large number of his friends while here, who were all glad to see him, as he does not frequently get so far East.

WESTERN NOTES.

The Electric Appliance Company are just at present rejoicing over the completion of their catalogue, and are very busy now distributing several thousand copies among the trade. They certainly have reason to be proud of their efforts as they have issued a very complete and attractive volume. It has been their aim from the start to produce a catalogue that would contain the greatest amount of information in the smallest possible space. How well they have succeeded is shown by the fact that in a catalogue 5 x 8 with 200 pages, they have included practically everything in the electrical supply line, giving a complete list of supplies in the following departments of the business: Electric light and power supplies, electric railway supplies, electrical house goods, fire-alarm supplies, telephone supplies, telegraph supplies, physicians' electrical supplies, electrical toys and novelties. That the catalogue will be appreciated by the trade goes without saying, as there has undoubtedly been a demand for a catalogue that would in a single volume cover all of the departments of the business.

The M. C. Bullock Manufacturing Co. have secured the order for a 250 h. p. Bullock-Corliss engine, three 100 h. p. steel boilers, and jack shaft and friction clutch pulleys, for the power plant of the Belle City Street Railway Co., Racine, Wis. They will also do the erecting and turn the plant over to the street railway company under steam. In addition the past week has brought the company orders for a 250 h. p. Corliss to go to Logansport, Ind., and a 350 h. p. Corliss for the works of Wm. Deering & Co. Besides these they have booked orders from New York City for seven large friction clutch pulleys fitted with their own friction device, which is being favorably received for use in electric light and street railway work.

The Central Electric Company report having sold during the past week 150,000 feet of assorted sizes of Interior conduit, with elbows, junction boxes and couplings. The Central Electric Company are the general Western agents for the Interior Conduit & Insulation Company, manufacturers of the tube, and carry a large stock of it on hand at all times, which enables them to fill orders promptly, and to meet the growing demand of the business. The Central Electric Company are selling large quantities of incandescent switches, and key and keyless sockets of approved manufacture at low prices. They keep a very large stock of these on hand, and do not delay their customers in filling orders, while the prices are at the lowest market rates.

The Buckeye Electric Co., of Cleveland, Ohio, makers of the Buckeye incandescent lamps for all classes of work, have received orders during the last two weeks from points as widely separated as California, Nova Scotia, Louisiana and New York. The area of use of Buckeye lamps widens daily and the orders grow in size, with corresponding rapidity. The company have offices in Chicago at 437 "The Rookery," and have now opened comfortable quarters in the new Mail and Express Building, New York City.

George Cutter reports some large sales of the Germania shade holders for which he is the Western agent.

PITTSBURGH NOTES.

Twenty-one electrical construction companies of Pittsburgh and vicinity have formed what is called The Master Electricians' Association of Allegheny County and have united on a uniform schedule of prices for all manner of construction work, which each and every one is compelled to adhere to under a heavy penalty.

The Supply Manufacturing Co., the enterprising builders of commutators, have, during the past week, received orders for commutators alone which will amount to several thousands of dollars. They have excellent manufacturing facilities, and are undoubtedly the most extensive builders of commutators in this country.

The R. D. Nuttall Co. have recently added several new gear cutting machines to their large factory in Allegheny and continue to run 22 hours per day. They report a large demand for their rawhide pinion gears and trolley poles.

The Miller Electric Construction Co. have taken the agency for Pittsburgh and vicinity for dynamos, motors and instruments manufactured by the La Roche Electric Works of Philadelphia.

Mr. William N. Famous of the Pennsylvania Electric Engineering Co., Philadelphia, is in the city and reports having taken several large orders for the Pennsylvania lamp.

The Washington Carbon Co. are receiving orders for carbons fully as fast as their factory can produce them, which is something unusual at this time of the year.

The Purity Oil Filter Manufacturing Co. are shipping large numbers of their oil refiners to central stations throughout the country.

SOUTHERN NOTES.

Newport News, Va.—The new power house for the Newport News Shipbuilding & Dry Dock Co., at Newport News, Va., will be designed and built by the Berlin Iron Bridge Co., of East Berlin, Conn., U. S. A. In order to have the building absolutely fireproof, no woodwork will be used about the construction, as the side walls will be of brick, the floors of iron and concrete, and the roof will be made with an iron frame covered with the Berlin Iron Bridge Company's patent anti-condensation corrugated iron covering. The steam, compressed air, hot air and electric light plant for the entire shipyard is concentrated in this one building, and it is therefore absolutely necessary that it be fireproof in every particular.

BALTIMORE NOTES.

Crook, Horner & Co., Baltimore representatives of the Ball Engine Co., Erie, Pa., have recently furnished two 150 h. p. engines of this manufacture to the North Avenue Street Railway Co., Baltimore, and two 150 h. p. tandem compound condensing engines and complete steam plant to the Chesapeake Light and Power Co., Hampton, Va.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

THE
Electrical Engineer.

VOL. XIV. JULY 13, 1892. No. 219.

A CENTRAL STATION METHOD OF LOCATING GROUNDS ON ARC CIRCUITS.

BY

Edgar E. Stark

ALL electrical circuits are subject to occasional grounds, and it is desirable to have these removed as soon as possible. A number of articles have appeared from time to time on the use of high resistance voltmeters, such as the Weston, in measuring the insulation resistance of incandescent circuits and dynamos while the current is on, but little has been said about locating grounds on arc circuits, while in operation; and the writer is therefore of the opinion that a description of the methods in use in a number of large lighting stations will prove interesting to station managers.

An apparatus is used consisting of a bank of thirty or more 100 to 120 volt lamps in series. These are arranged generally with contacts and a switch so that their number can be increased or decreased, after the manner described by Mr. M. D. Law in remarks made before the National Electric Light Association.

In this method one end of the series is connected to earth; the other has a flexible cable attached which is to be connected to either pole of the circuit under test. If the lamps glow when so connected, there is a ground or leak on the circuit. If the leak be through a high resistance then only a few lamps can be made to glow; if the leak be through a good earth connection it may make all the lamps glow from one or both terminals. Thus a rough estimate can generally be made of the location of the ground. In each test by the above method the resistance of the ground or leak is included as part of the bank of lamps circuit, and on a high voltage circuit of, say, 3,000 to 4,000 volts, this leak resistance is by no means constant even for a short time.

About two years ago the writer made an apparatus, utilizing the Wheatstone bridge principle with the object not only to detect a leak on an arc circuit but to locate it between lamps, irrespective of its resistance. It consists of two banks of 45 to 120 volt lamps, A and B, Fig. 1, connected in series, each bank with a metallic lever sliding over a series of segments connected to the junctions of the lamps in turn, as shown in dotted lines. An auxiliary switch *y* is arranged with two contact blades to touch two adjacent segments of the series, thereby straddling one lamp; the two blades are attached to a Weston voltmeter, which can thus read the voltage of each lamp in the series. I use 120 volt lamps on account of the small current they

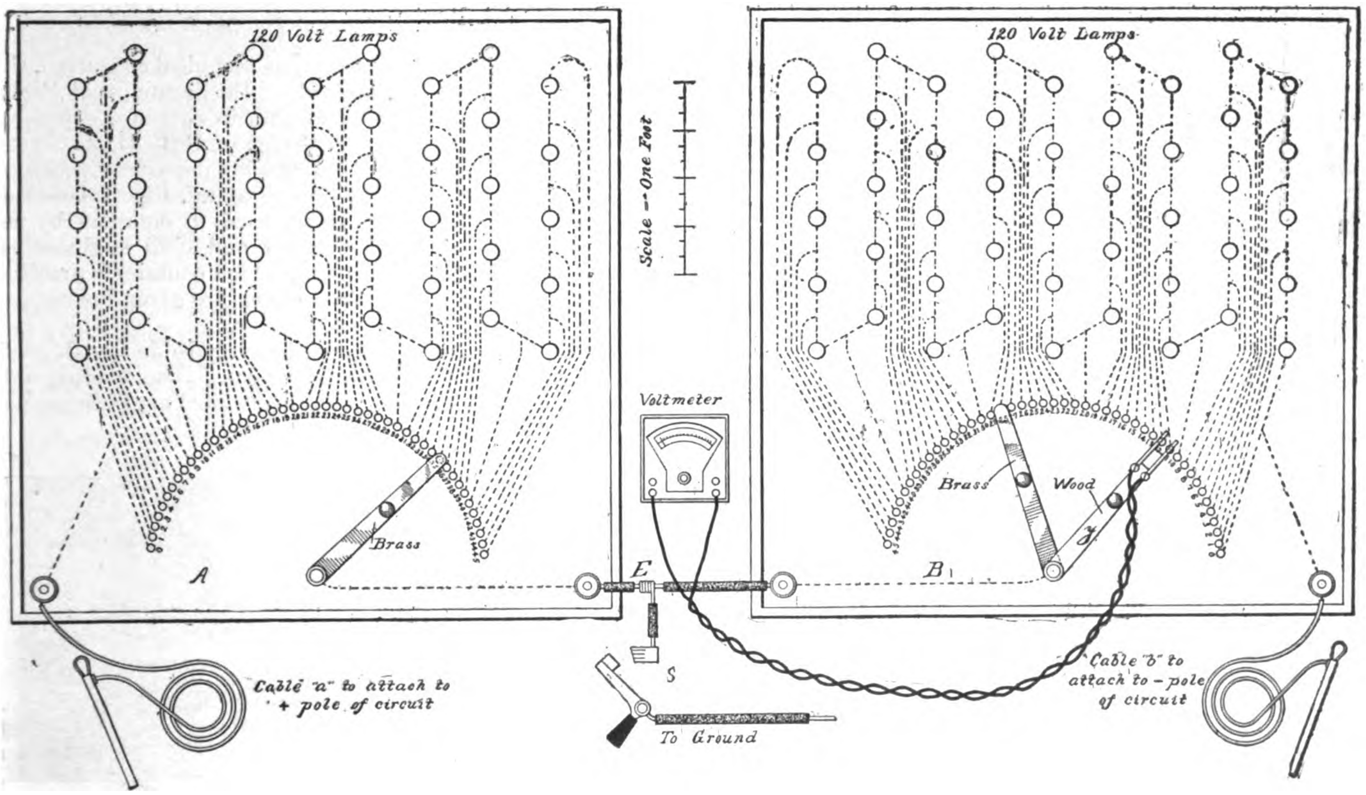


FIG. 1.—STARK'S CENTRAL STATION METHOD OF LOCATING GROUNDS ON ARC CIRCUITS.

take when run at 50 volts, the current being too small to be noticed when diverted from the arc lamp circuit. These banks or arms, A and B, are connected by a wire E which is attached to the switch S with its ground connection; to the other ends of the arms A and B are attached flexible cables *a* and *b* to connect to the circuit terminals under test.

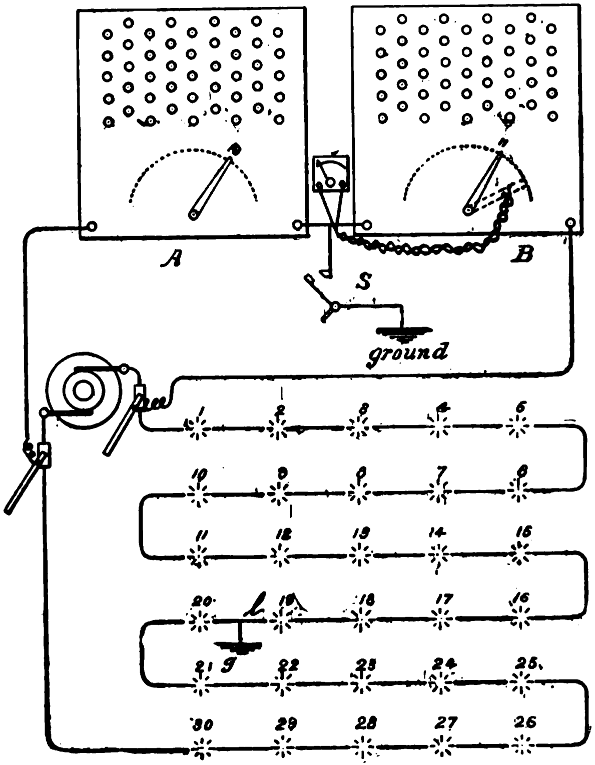

Fig. 2.—Locating Grounds on Arc Circuits.

On installing a set of lamps, each arm is to be calibrated. This is done by connecting cables *a* and *b* to the + and — ends of a circuit of, say, 80 arc lights; then with all the incandescent lamps in and the levers on lamp No. 45, the voltage of each lamp is measured by the use of the auxiliary switch *y* (which is arranged to be unbolted and attached to either board) and the voltmeter. Any lamp that is more than two volts from the average is discarded and a better one is put in its place. The average voltage is taken and a lamp selected that equals this average voltage and this lamp is used hereafter as the standard in computing voltages, etc.

Having the boards thus arranged, after the circuit has been started the cables *a* and *b* are attached to the circuit + and — terminals. All the incandescent lamps are cut in; that is, the levers are on segment No. 45 making 45 lamps of A and 45 lamps of B, or 90 lamps in all, in parallel with the outside arc lamp circuit. The ground switch is now opened and closed and the operator observes if there is any change in the brilliancy of the lamps in the arms A and B. If there is any change when the levers of A and B are in equal and then in largely unequal positions, on the opening and closing, respectively, of the ground switch S, it is indicative of a ground on the arc circuit.

Now comes the "bridge" part of the arrangement. A balance is obtained by altering the number of lamps in arm A or B, as required, so that upon opening and closing switch S there is no change in the voltage of the standard lamp, as indicated by the voltmeter. We have then this proportion: The number of lamps on of A is to the number of lamps on of B, as the number of arc lamps on the positive leg of the circuit to the unknown ground is to the number of lamps on the negative leg to the ground. Or A : B :: number of + lamps: number of — lamps. But if we alter A and B so that the voltage of the standard lamp is 50 (or equal to the voltage of the arc lamp on the circuit, if other than 50), then A equals the number of lamps on the positive leg, and B equals the number of lamps on the negative leg to the unknown ground; and A + B equals the lamp equivalent of the running circuit; A + B times 50 equals the voltage of the circuit.

Fig. 2 illustrates a case of an arc light circuit with a ground leak at *g* of *l* ohms resistance. The ground test bridge is applied as shown; cable *a* is on the positive pole and cable *b* is on the negative pole of the switchboard. The levers are placed each on No. 45 and the switch S is opened and closed; and the operator observes if any change in brilliancy is effected with the levers in this position of equality, or after moving one of them to, say, lamp No. 10.

In this case there would have been a change in brilliancy of the lamps during the first test. Then by altering A and B so that there is no change in the voltage of the standard lamp a balance is obtained and, as stated above, A : B :: the number of + lamps : the number of — lamps. Or, should we adjust A and B so that the voltage of the standard lamp is equal to the voltage of an arc lamp, then A = number of + lamps, and B = number of — lamps to the ground.

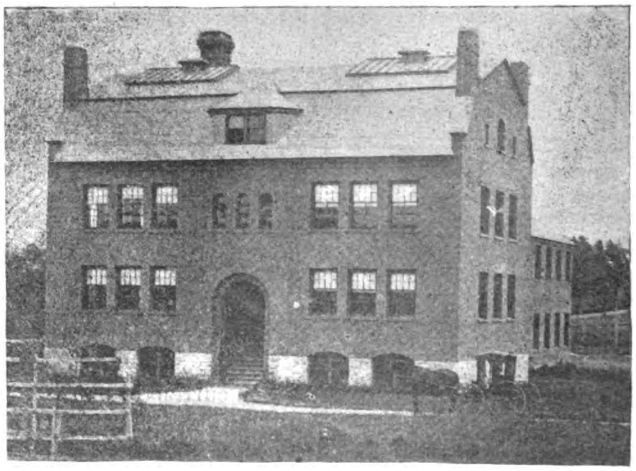
The voltmeter will detect a variation of less than ½ volt per lamp. The apparatus will locate between lamps a leak of over 40,000 ohms resistance on an 80-light circuit.

ELECTRICAL ENGINEERING AT THE UNIVERSITY OF VERMONT.

In keeping with the progress of technical education, the University of Vermont, located at Burlington, that State, has recently organized a department in electrical engineering which has been placed in charge of Prof. H. A. Storrs.

The main building of the engineering departments, which is shown in the accompanying engraving, Fig. 1, contains the recitation and drafting rooms used in common by the students of electrical, mechanical and civil engineering. At the rear will be seen a wing, which contains a machine shop and foundry where the students are given instruction in shop practice.

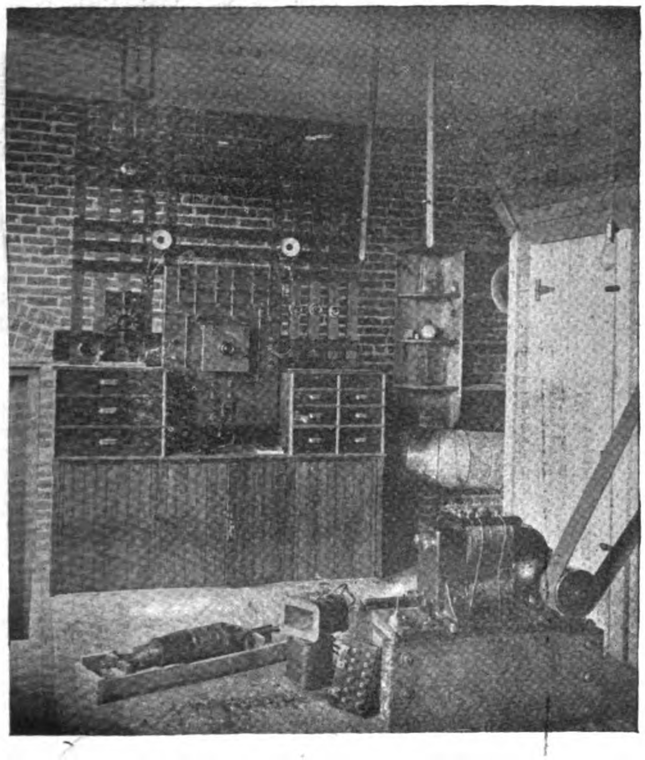
The work in electrical engineering is designed to fit students for practical electrical work. The leading subjects of study are mathematics, mechanical engineering and electricity; but some work in literature, history and modern languages is also required.



Engineering Building, University of Vermont.

In general, a student follows nearly the same line of study in electrical as in mechanical engineering, except that a part of the shop work and mechanical laboratory work is omitted to give place to special subjects in electrical engineering. These subjects, which begin with the Junior year, include the theory of potential, electrical measuring instruments, dynamo-electric machinery, etc., with laboratory work, such as comparative tests of batteries, efficiency tests of dynamos, etc.

Original investigations are permitted when deemed beneficial to the student, chiefly as an aid in the preparation of the graduating thesis. Technical essays, involving a study of different authorities and of the latest published articles, are frequently prepared by each student and presented for discussion in the class-room. The library is well supplied with electrical and other scientific papers, and with standard works in electricity.



Dynamo Room, University of Vermont.

The electrical equipment includes galvanometers of recent design for accurate work, sets of standard resistance coils, a Wheatstone bridge, Thomson's electrical balance of wide range, also his graded voltmeter and electrometer, besides much apparatus suitable for the use of the less experienced students. A dynamo, specially designed, and provided with extra armature and field coils, enables the student to learn by actual tests the relative merits of different types of direct current, arc and incandescent dynamos ; it generates electricity for the lamps which light the engineering building and shops, and for charging the secondary battery, as well as for tests of lamps, motors, etc. Sixty accumulators, mostly of the Julien type, and many varieties of primary batteries are available for experiments. An alternating current dynamo, with accessories, will shortly be added to the equipment, and among the more important accessions to the instruments are a Thomson large electrometer, graded voltmeter and composite balance.

The engraving Fig. 2 shows a corner of the engine-room where are placed a small dynamo designed more especially for experimental use, and the switchboard for controlling the lamps by which the building is lighted and for manipulating the storage batteries.

Up to the present time nine students have been enrolled in the electrical engineering course, which was opened at the beginning of the present year.

NEW DYNAMO OF THE DETROIT ELECTRICAL WORKS.

The accompanying engravings are two views of the new type of dynamo now being manufactured by the Detroit Electrical Works, and which on account of its many novel and valuable features deserves a detailed description. The type illustrated is that which has been adopted by the Detroit Electrical Works for all sizes up to, and including, the 30 kilowatt. As will be seen, the machine is of the two-pole ironclad type, in which the frame and bed-plate consist of one solid casting. Above 30 kilowatts the type will be similar to that illustrated, except that the machines will be multipolar.

The journal boxes are provided with self-centering and self-oiling sleeves, which insure perfect alignment and lubrication. Each bearing is provided with a gauge glass which shows the height of oil in the oil chamber, and with a cock by means of which the oil can be drawn off whenever desired. The lubrication of each of these bearings is accomplished by the use of two rings which revolve and carry oil to the top of the shaft, from which it is distributed by means of oil grooves in the self-centering sleeve. Directly over each of these rings, in the outer shell of the bearing, is a brass plug, which can be lifted out when it is desired to ascertain if the rings are working properly, or to put in new oil.

The rocker arm which supports the brush holders is mounted directly on the self-centering sleeve, thus insuring the brush-holders being kept central with regard to the commutator. Carbon brushes are used on all these machines, both for motors and generators. The brush holders are of a new type which provide just the tension requisite to make good contact of the brushes with the commutator without more tension than is required, consequently avoiding heating of the commutator by unnecessary friction. This tension is obtained by the use of a spring coiled in the form of an involute the outer end of which is continued straight from the side of the coil—which is below the brush holder—up to and a little above the outer ends of the carbon brushes. The idea is to have the tension due to the coil, when the straight end is in a perpendicular position, just sufficient to insure the proper contact; then, the coil of the spring, being mounted upon an adjustable axis which can be moved in or out at will, the commutator brushes near the spring can be moved inward, yet always maintaining its straight end in a perpendicular position. This insures at all times the same tension of the brush upon the commutator without changing the adjustment of the spring itself in any way whatever. This adjustment can be made at any time very easily by a single movement. As the carbon brushes feed radially they consequently wear squarely across their entire thickness and never require trimming.

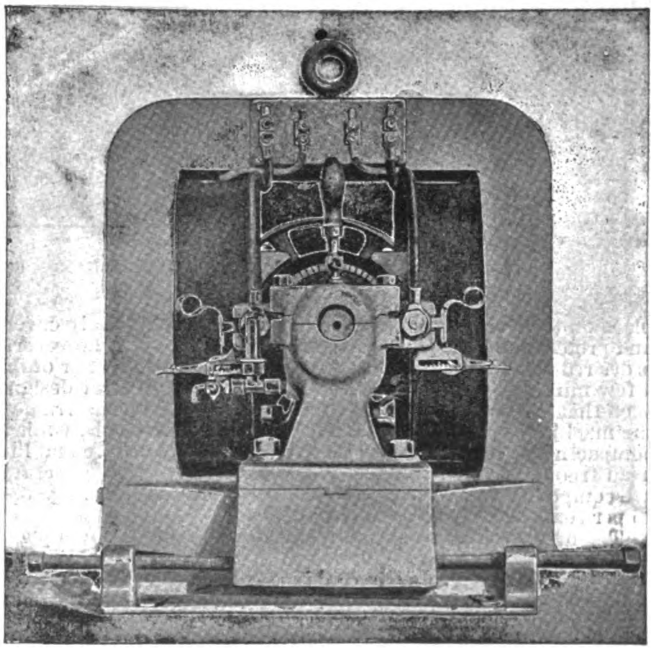


Fig. 1.—New Dynamo of the Detroit Electrical Works.

The two features of the lightest possible tension of the commutator brush on the commutator, and the use of the carbon brush, serve to lengthen greatly the life of the commutator, not only by reducing the wear but also by reducing the possibility of damage to either brush or commutator by sparking if the machine is overloaded, such as would naturally result from the use of copper brushes. This means a great saving in the matter of repairs, as the commutator is the most expensive part of a dynamo. The expense for brushes is also much reduced as carbon brushes not only cost much less than copper, but wear many times longer.

A case in point is the record made by a generator furnished by the Detroit Electrical Works to the Posselius Bros. Furniture Co., of Detroit, which machine, although one of the old type, was fitted with their improved brush holders and carbon commutator brushes. After sixteen months' use, every working day of which time the machine was running for a number of hours each evening, the original set of brushes furnished with the machine was still in use and not one-third worn out, while the commutator itself, although glazed by long use, showed no actual signs of wear when a straight edge was applied to it.

The armatures of all the new machines up to, and including, 30 kilowatt are of the drum type, but a special winding is used, which not only economizes space at the ends of the armature core and holds the wires at the ends in position firmly so they cannot chafe, but also has as its most important feature the advantage of having no two wires adjacent to each other that have between them any great difference of potential, thus doing away almost entirely with the probability of burn-outs. This winding also gives the largest opportunity for ventilation, and makes the danger of crosses at the end of armature as small as possible. The commutators of these dynamos are of a new design; mica is the sole insulating material used throughout in their construction.

The field coils are wound on metal spools and then slipped into place on the pole-pieces, where they are almost entirely covered and protected by the iron frame of the machine. If, however, it is desired to replace any coil with a new one it is a matter of only a few minutes' work to accomplish this. The general design is such that the armature is protected on all sides by the frame of the machine and the metal flanges of the field spools, while its compactness necessarily requires very small floor space and little head room for machines of their capacity. All generators are compound wound to give any desired increase in voltage up to 15 per cent. at full load.

The under side of the bed of each machine has grooves planed in it so that the machine can be mounted on slides for taking up slack in belt; or if it is desired to hold the dynamo in a fixed position, the lugs cast on the side of the bed-plate near the grooves can be used for bolting the machine down to its foundation. The dynamo shown has a motor headboard, which simply provides the necessary terminals for connections. On the headboards of the generators there is also provided in addition to these connections a double-pole quick-breaking head board switch, so that, when desired, the machine can be entirely disconnected from the mains, entirely independent of the switchboard appliances. These dynamos have a fixed point of commutation which renders possible the reversing of the machine and changing from no load to full load without any sparking whatever at the commutator. In designing this machine the advantages of slow speed have been kept in view, as well as the matter of efficiency.

The standard sizes of these dynamos now being made ar as follows, the ratings being in kilowatts: ⅛, ¾, 1½, 3, 5. 7½, 9 15, 20, 30, 40, 60, and 100. Larger machines of the multipolar type will soon be brought out.

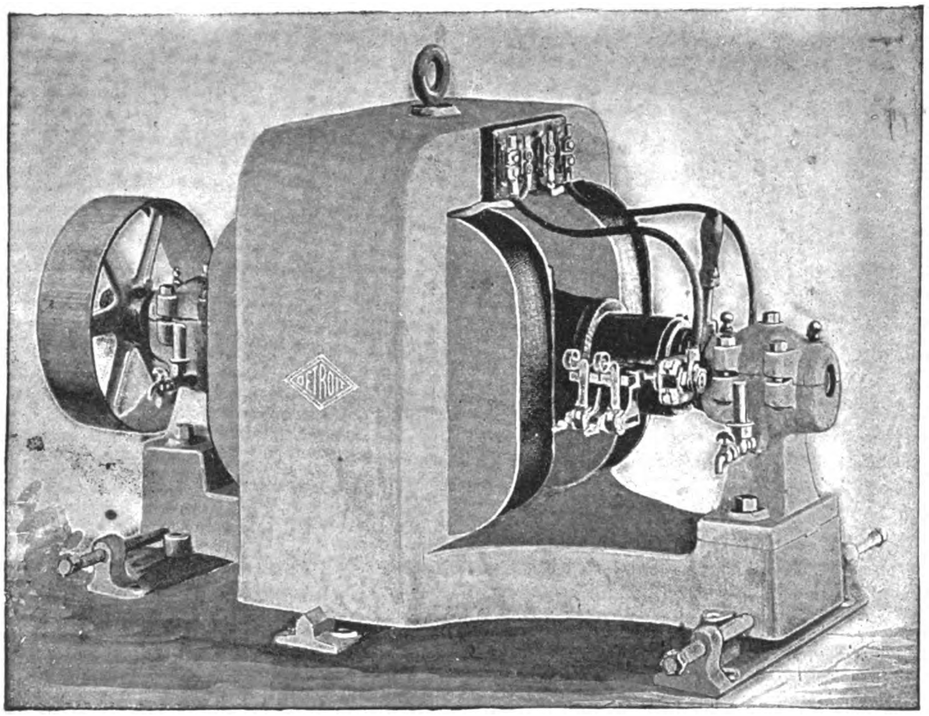

FIG. 2.—NEW DYNAMO OF THE DETROIT ELECTRICAL WORKS.

CENTRAL STATIONS.[1]

BY D. THOMSON.

IN time past when fabulous prices were obtained the profits were so great that a few extra pounds of coal consumed was not noticed, but now that competition has brought the prices of lighting to just barely living profits, it becomes imperative that the operations should be carried on in as economical a manner as possible if the shareholders are to receive any return for their money invested. The securing of such return is undoubtedly their right, and one that must be of foremost consideration in central station management, for without the capitalists, where would the electrical interests, both in manufacturing of apparatus and the supplying of current in its various forms, be to-day? To sum up then, just what a central station should consist of: The building should be one story high, built directly on the ground, with good and substantial walls of either brick or stone, set on well-footed foundations, with peaked roof and fan-lighted ventilators or windows running its entire length, the windows of which can be operated from the ground by means of levers. The material for the roof should be corrugated galvanized iron fastened to the beams and purlins, which are preferably made of angle iron, care being taken to see that the corrugated iron has some good fire-proof non-conducting lagging laid under it to prevent the condensation of the moisture contained in the warm air inside the building from coming in contact with the cold roof. A proper tower should be provided at one end, or the centre of the building, for the entrance of the necessary wires; markedly in contrast to the old plan of utilizing the woodwork on top of any window or door that might be the handiest to honey-comb with holes for that purpose. Proper stone and cement foundations should be provided for engines, shafting and dynamos, which must not have any connection with either the walls or the foundations of the building; the floor to be preferably of concrete with a rock asphalt top of at least ¾ of an inch in thickness, except where there are pipes and pits that cannot be well covered with other material than wood, on account of the necessity of being able to get at them at any time; such wood floor should be at least two inches in thickness, of good red pine, well seasoned, laid on good strong joists and beams, the beams being supported on brick or stone and cement piers suitably placed.

In the matter of engines, there can be no doubt that in stations of any considerable size (say, from 100 h. p. up) the most suitable for the purpose are what are known as cross connected twin engines of slow speed, and where water is available for condensing purposes, they are preferably built with high pressure cylinder on one side, and low pressure condensing on the other, though where the boilers are such that very high pressure can be carried (150 lbs. or more) it is a question whether results just as beneficial cannot be obtained by using a third cylinder, and a consequent triple expansion of the steam admitted at the first cylinder at such high pressure. There cannot be any doubt whatever that such engines can be operated at considerable saving over the best of high speed engines that are manufactured, and these high speed can only be recommended for isolated or small plants where slow running single engines would be apt to cause a fluctuation in the lights when passing their centres, which in high speed is entirely eradicated owing to their velocity. In the matter of boilers, there can be but one opinion where tests have been made, and that is in favor of water tube boilers, such as the Babcock & Wilcox, Crandell, Zell, or some other modification of them, for aside from the fact that they possess an element of safety that the ordinary return tubular boilers do not possess, they are quick and economical steamers and cost very little for maintenance.

---

[1] Abstract of a paper read before the Canadian Electrical Association, Hamilton, June 15.

After the steam plant comes the belting, line shafting and pulleys, which for satisfactory working should all be of the best. The shafting should be fitted with self-oiling bearings, with oil reservoirs and ring feeders; said shafting and the necessary hangers or standards, should be constructed in such a way and of such material that they will be capable of standing a strain equal to at least 100 per cent. more than that which they will be ordinarily required to carry. The pulleys should be of the grip or clutch type, built so as to be able to carry at least double their ordinary load; such pulleys to be of such a design that if it should be necessary to stop one of the dynamos, both the pulley and the grip will stop together, and only the driving mechanism continue to revolve, thereby enabling the setting up of the grips or clutches on any one if required. This is the point that designers of central stations would do well to bear in mind. It has occurred in the writer's experience that where grip or clutch pulleys whose grips revolve with the shafting were used, it became necessary to stop an entire line of shafting together with engine to adjust one slipping clutch out of some four or five on the same line shaft, the pulley in that case being an elegant one in every particular but in this one point, that the clutch could not be stopped with the pulley.

To conclude, have your station fitted out with the best of dynamos and generators, and don't buy such apparatus simply because the price is low; in fact, cheap machinery is generally the dearest in the end. Let your switchboards be models of completeness and have them kept so continually. Bear in mind that they are your distribution points, and that if they fail you, your entire plant will be jeopardized. Have your lines and circuits equipped with good and efficient lightning arresters so that danger from this source will be a nullity. Make this part of your plant such that it can easily be got at, and if an arc should be caused through any means, have the necessary appliances at hand to break it as quickly as possible; one of the best things for such purpose is a bucket full of dry sand. Last, but not least, let your station be a model of cleanliness and neatness; have a place for everything and see that everything is kept in its place.

MAGNETIC PROPERTIES OF ALUMINUM-IRON.[1]

BY C. EICKEMEYER.

A PRELIMINARY test showed that the magnetic properties of aluminum-iron differ so little from those of ordinary cast iron that it was necessary, in order to determine any difference whatever, to reduce the castings to standard size. The test was made by balancing the aluminum-iron with a test piece of Norway iron, the magnetic characteristic of which is known.

The Al-iron was not compared directly with the standard Norway iron, but to reach a greater exactness in determining the difference between ordinary cast iron and the samples of Al-iron, first, a sample of ordinarily good cast iron was tested by comparing it with the standard Norway iron, thereby determining its magnetic characteristics. The Al-iron was then compared with this sample of ordinary cast iron and the difference between both determined.

This method eliminates the influence of remanent magnetism, to a greater part in the comparative tests, thereby increasing the accuracy and also serving as a check upon the work, since the piece of ordinary cast iron had been tested before. In the comparisons made, the piece containing the smaller percentage of aluminum proved to be superior to the one containing the larger percentage of aluminum in the cast iron. From which we can state that the addition of aluminum has no very marked influence upon the magnetic conductivity of cast iron, but slightly decreases its permeability.

[1] Abstract from the Cornell *Crank*.

ELECTRIC RAILWAY MOTOR TESTS AT MINNEAPOLIS.[1]

BY PROF. GEO. D. SHEPARDSON AND EDWARD P. BURCH.

THE experiments here discussed were undertaken for the purpose of obtaining definite information about the performance of electric railway motors under various conditions. There is a diversity of opinion about the relative merits of regulation by rheostat and by commutated fields, the use of one or two motors on a car, value of wetting rails, causes of "bucking" and other points. It is commonly understood that electric roads using rheostat regulation require larger capacity at the generating station than those using the commutated fields. It is also known that one large road has substituted rheostat regulation for commutated fields on all its motors. One large road has effected marked reduction in the motor repair account by reducing the pressure on the lines considerably below 500 volts, this however being also accompanied by better instruction of the drivers.

Much has been said and written, but the data published are meagre and in some cases misleading. It was therefore thought desirable to obtain data from careful tests under working conditions in the hope of substantiating some of the claims made, and of bringing out some new facts. The tests were conducted for the most part by Mr. Edward P. Burch, a senior in electrical engineering in the University of Minnesota, in connection with his graduating thesis, and by courtesy of the Minneapolis Street Railway Company, especially the master mechanic, Mr. William Cooper. Most of the tests were made upon a No. 6 Sprague double-reduction motor of the type described by Mr. H. F. Parshall before the Institute May 21, 1890, and April 19, 1892. Some experiments were also made upon a single-reduction motor. Each machine is used at the repair shop for testing armatures, being anchored to a heavy crib sunk eight feet into the ground. Each car axle is replaced by a short shaft carrying a heavy cast-iron wheel with solid web, upon which two oaken blocks are bolted for use as a brake. This was made into a Prony brake by removing the angle irons that held it to the floor and bolting on a plank to which an iron plate was fastened, so as to give a knife-edge bearing at a distance of 63.1 inches from the centre of the shaft. This plate rested upon a knife-edge supported upon platform scales by which the turning moment could be measured. The mechanical horse power delivered at the car wheel is

$$\text{H. P.} = \frac{2\,\pi\,R\,P\,N}{33,000} = \frac{P\,N}{1,000},$$

in which P is the pressure on the scales, N the revolutions of the car axle per minute. The speed was measured by a common speed indicator with soft-rubber tip to prevent slipping. For slow speeds a stop-watch was used, the time for five revolutions of the car wheel being noted. Current and potential were measured by new Weston instruments, about 12 feet distant from the motor.

The Sprague motor armature has 56 sections of eight turns each of No. 12 B. and S. G. wires. The speed is reduced 11.765. The field coil as used at first was in three sections, coil A of 700 turns, coil B of 820 turns, and coil C of 620 turns, all being No. 12 B and S. G. wire. By means of the well-known barrel switch these coils are thrown into the following combinations:

Clip 2, Coils A, B and C in series.
Clip 3, Coils A and B in series.
Clip 4, Coils A and B in parallel, C in series.
Clip 5, Coils A and B in parallel.
Clip 7, Coils A, B and C in parallel.

Several sets of efficiency tests were made with each combination. The three pairs of coils were then replaced by a single pair of coils connected in series and having several terminals so that the number of turns used might be altered. This was used in connection with a Thomson-Houston rheostat. Efficiency tests were made with and without the rheostat. Only a few of the tests and curves obtained can be given in this paper. In comparing these curves among themselves and with the result of other experimenters, it should be noticed that the voltage was considerably below that for which the motors were designed, and that the power delivered was measured at the car axle. Different armatures were used on different days, and the curves in different plates are not strictly comparable; but the curves given in any one plate were taken with the same armature and with approximately the same voltage. Each of these armatures had been recently repaired and although they had been well baked there may have been some leakage through the green shellac. The Foucault currents in the cores were probably greater than in new armatures. With the same armature and fields the efficiency is a few per cent. higher cold than when hot. It has been the aim to run as nearly as possible at the temperature of ordinary running, so that the fields were comfortably warm but not hot. It is confidently believed that the efficiency of these machines would be considerably above 90 per cent. if taken at armature shaft and with full voltage.

---

[1] A paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 6, 7 and 8.

Fig. 1 shows efficiency curves for the motor with different combinations of the field coils.

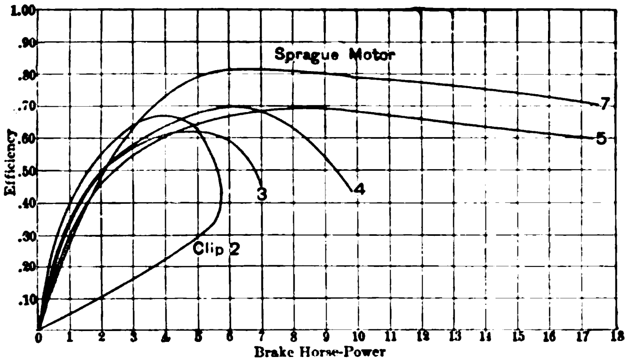

FIG. 1.

In Fig. 3, curves A and B show efficiency of the machine with 857 and 611 turns of No. 7 wire in the field coils. It will be noted in Figs. 1 and 3, that the motor has highest efficiency with the larger number of turns on field coils until the iron is saturated, when the better efficiency is given with smaller number of turns and consequent lower resistance in field. This shows the advantage of working on the fifth and seventh clips with barrel regulator, or of cutting out part of the turns on field when the load is heavy. On starting the car, the current is very heavy and the field is saturated with a small number of turns; hence the torque with a given current is nearly the same whatever the windings of the field. The speed and counter E. M. F. are small at starting; hence the potential difference at the armature brushes should be reduced until it passes only enough current to start the car without jerking. The easiest way of reducing the potential difference at the brushes is by interposing resistance; and the heat developed by the C² R can be cared for more easily and cheaply in an open rheostat than in the field coils. Rheostats of iron and mica are cheaper and more heat-proof than cotton-covered wires. This forces the conclusion that for the heavy load due to accelerating the car at starting, the field should have the smaller number of turns, and as the car reaches normal speed, and the H. P. and C become less, the efficiency of the motor would be raised by increasing the number of turns in the field. This conclusion is exactly the reverse of the common practice of manufacturers who sacrifice some efficiency for speed at small horse powers. It is also in line with the experience of the road mentioned, that replaced the commutated fields with a single series coil of No. 7 wire, and later with No. 5 wire. This heat-loss could be saved and the average efficiency raised, by using the two motors in series at the start, and afterwards cutting out one or putting the two motors in parallel, if necessary, as the speed increases and H. P. decreases. An average of 12 tests on the road shows that with two motors on a car, it requires 27 per cent. less current if only one is working.

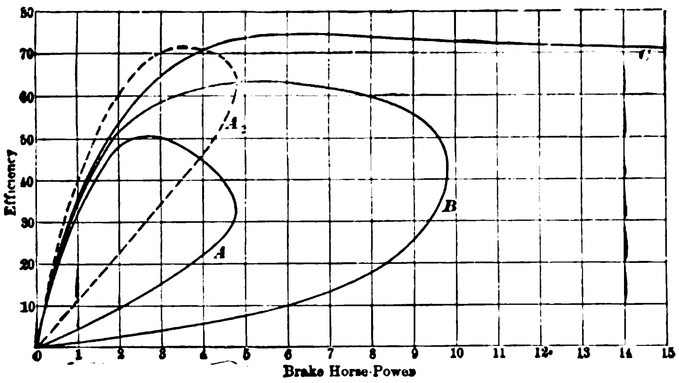

FIG. 2.

In Fig. 2, curve A shows the efficiency of Sprague motor with single pair of coils, when the whole of a Thomson-Houston rheostat is in circuit. B shows about ½ of the rheostat in use; and in C it is all out. The dotted line A_2 gives the efficiency as calculated from the difference of potential about the motor alone. Curve A_2 is not strictly comparable with the others on account of the necessary variations in the voltage at the motor; but it does show the increased efficiency to be obtained by utilizing the superfluous voltage in a second motor in series. In this connection it is interesting to note that the resistance of a rheostat as calculated from current and potential difference, decreases with increase of current. This is as expected, since the larger part of the resistance is due to surface contact between the plates of iron in the rheostat, these being pressed together more closely as the iron heats. A similar effect but much more marked has been noticed in earlier experiments by one of us, with alternate plates of carbon and iron.

Figs. 4, 5 and 6 show curves of torque, speed and horse power, referring to the No. 6 Sprague motor. In Fig. 5, A shows horse power and horizontal effort on a 30-inch wheel; B, C, D, E and F, clips 2, 3, 4, 5 and 7, respectively. In Fig. 6, A shows speed and horse power, with all of the rheostat in; E with ½ of rheostat in; B, C, D, F and G, clips 2, 3, 4, 5 and 7, respectively. These may be compared with results presented by Prof. S. H. Short before the Chicago Electric Club, March 28, 1892. Fig. 7 gives curves of current, torque, speed and efficiency from a 15 h. p. Thomson-Houston single-reduction motor. The reduction ratio is 4.7857.

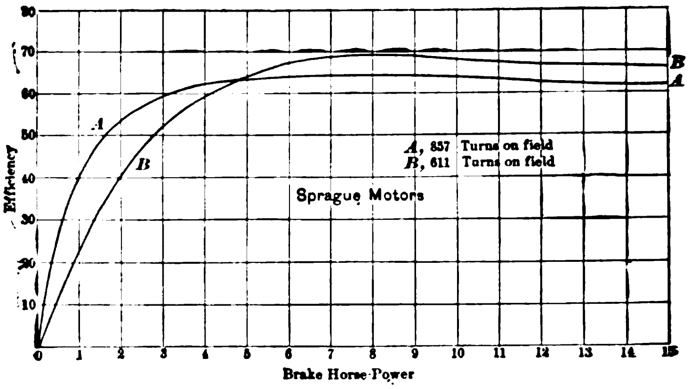

FIG. 3.

A large number of running tests were made on cars in regular service. Fig. 8 shows a run on the Interurban line between Minneapolis and St. Paul. The distance is about ten miles, the schedule time 55 minutes, cars equipped with two 25 h. p. single-reduction motors. Special trains sometimes make this trip in 30 minutes or less. Fig. 9 shows three runs on the University line of Minneapolis on successive days, with the same car and same driver. The lower curve was taken when the rails were dry and dusty, middle curve with wet rails, and upper curve when the ground was covered with snow, eight inches deep on the level. The snow-plow had been over a part of the track about an hour before. The curves show variation of time, number of passengers being noted.

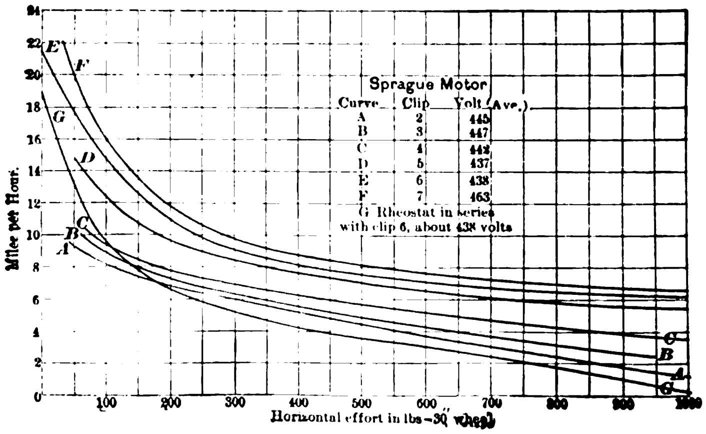

FIG. 4.

It will be noted that the current was less with wet rails although there were more passengers. The load at the station is about the same for a rainy day as for dry, the difference being probably made up by the increased leakage on the lines, and by the larger number of passengers on some cars.

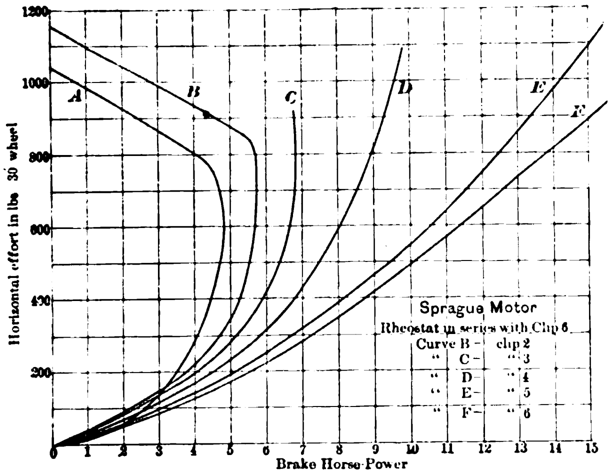

Fig. 5.

	Feb. 5.	Feb. 6	Feb 7.
Condition of track...............	Dry.	Wet.	Snowy.
Number of stops......	38	50	36
Average voltage......	445	450	440
Average amperes.....	15.15	14.9	17.5
Average amperes while working.....	23.4	20.9	28.1

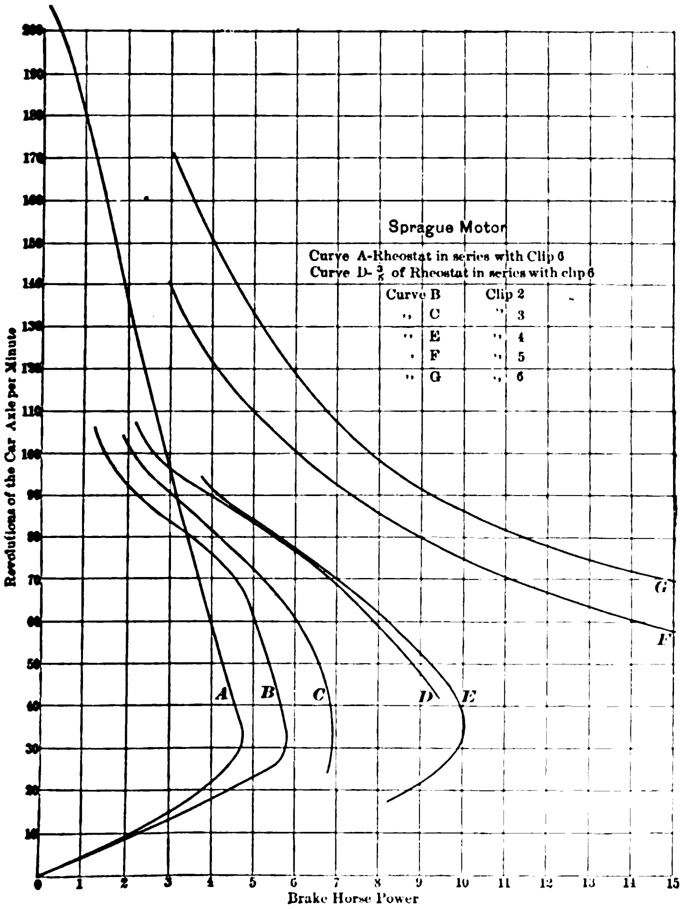

Fig. 6.

Fig. 9 shows variation of current on a single car. Fig. 10 shows variation of current on a feeder to line with five cars, the average current being about 60 amperes. Fig. 10 is plotted from readings taken at intervals of two seconds. The ammeter stops some little time at the high and low points, showing that these are actual values of the current and not due to the inertia of the ammeter.

Fig. 11 gives the results of readings one second apart taken on the main ammeters in Minneapolis and St. Paul and on one feeder in Minneapolis. There were about 190 cars on the Minneapolis line, 100 on St. Paul lines, and 32 on the one feeder.

The wide fluctuation of current from 1,400 to 2,600 amperes within a half minute is remarkable, since it is generally supposed that the load is more uniform on a road with so many cars. Continued observation of the main ammeter (but without record) indicates that fluctuations nearly if not quite as great as that shown in the curve, occur several times an hour. It emphasizes the desirability of heavy fly-wheels in railroad power houses and also explains why in some cases the electrical output was largely in excess of the mechanical horse power as calculated from the indicator cards taken at the same instant.

Fig. 12 gives the daily load of the Minneapolis power house, the curves being plotted from readings of the ammeters taken at ten-minute intervals throughout the day. In this case the power units are unusually large, there being two triple-expansion condensing Corliss engines, the constant loss from friction in engines, shafting and dynamos averaging 218 h. p. Indicator cards were taken simultaneously by means of electromagnetic attachments on each of the twelve indicators, the same current also giving signals to the observers at the ammeters.

A series of thirteen tests were made for ascertaining the effect of wetting or greasing the rails on a curve. Two cars were coupled by a spring dynamometer and the pull noted while rounding the curve at ordinary speed which was kept nearly uniform by means of a brake on the motor car. The average pull on dynamometer is as follows:

	Dry.	Wet.	Greased.
Outer track.....	500–800 lbs.	400 lbs.	800 lbs.
Inner track.....	650 "		400 "

The inner rail was wet or greased in each case; but on the inner track the greasing was not so thorough on account of the lateness of the hour. It is noticed that wetting the rail reduces the power required about one-third, and greasing reduces it one-half. Readings of the ammeters on the car correspond in general with the dynamometer readings.

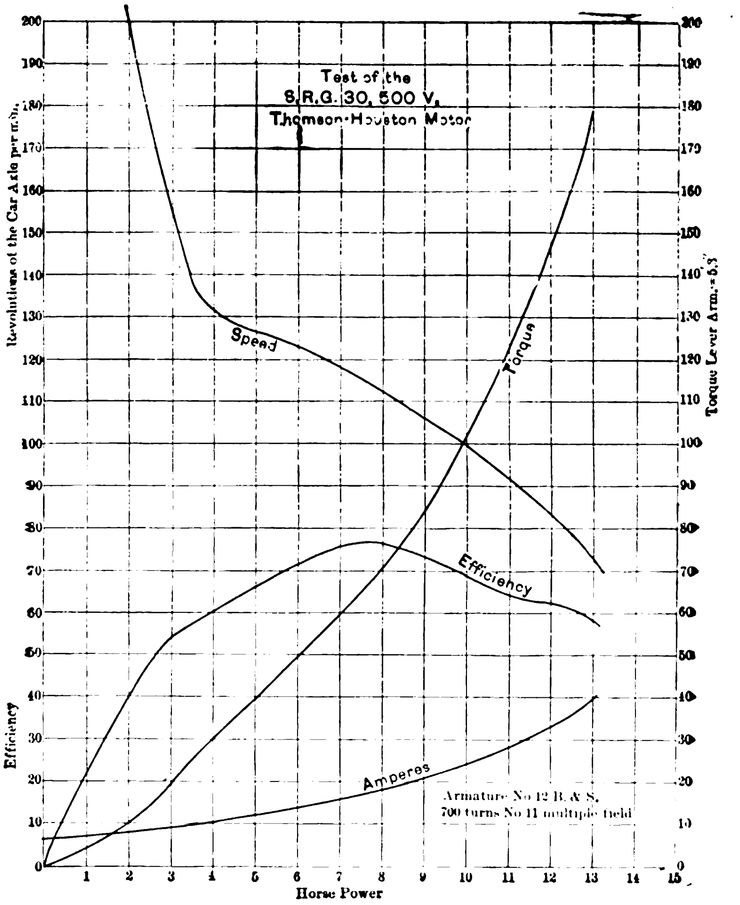

Fig. 7.

The "bucking" of street car motors is a subject of considerable interest to street railroad men although it seems never to have been discussed in public. From the silence of the books and papers, and from the ideas current among railroad employees, the conclusion is reached that little is known about its conditions, causes or remedy. It is therefore thought wise to present the results of observation and tests, with a theory for the cause and remedy. It sometimes happens that an electric car suddenly stops as if by collision. In some cases the car refuses to go further, but usually it goes ahead immediately as if nothing had happened. This is known among railroad men as "bucking." To explain the action it is noted that in common practice the motor fields are connected between the armature and trolley, the armature being grounded at the negative brush. If a second ground occurs on any part of the machine except between the fields and trolley, a heavy current passes to ground giving an intensely strong field while the armature is short-circuited by reason of the two ground connections. It therefore acts as a dynamo on short circuit, and becomes a powerful electric brake that stops the car very suddenly. This agrees with the facts, since a second ground either from loose connecting wires or broken insulation always causes bucking. Evidently if the ground occurs entirely outside of the machine no bucking follows, since the series motor cannot excite its own fields, and act as a dynamo unless the armature connections are reversed. It is common practice to connect the two motors together between the fields and armature to equalize the work of the two machines. When a ground occurs in such a case, both armatures act as brakes and the bucking is more violent than when the "equalizer" connection is not used. A loose reversing switch has been known to reverse the motors accidentally and spasmodically. There are many cases of bucking where no evidence of a second ground can be found. Doubtless some of these may be accounted for by temporary ground which burns itself out—a common method of

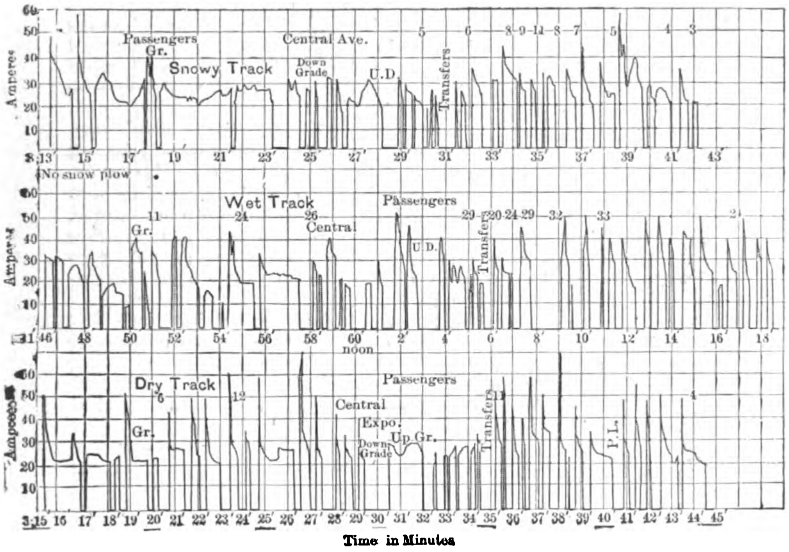

FIG. 9.

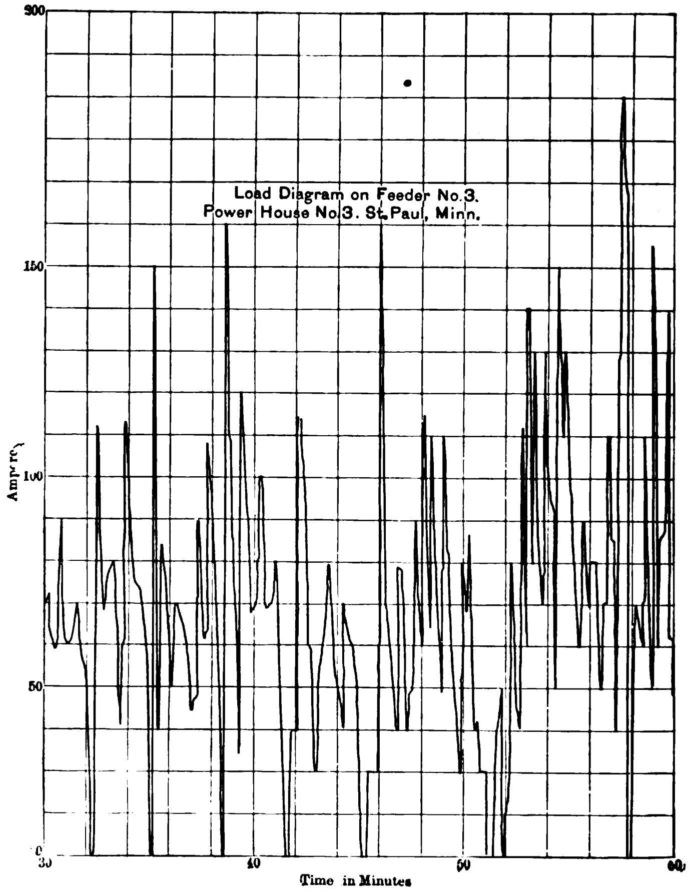

FIG. 10.

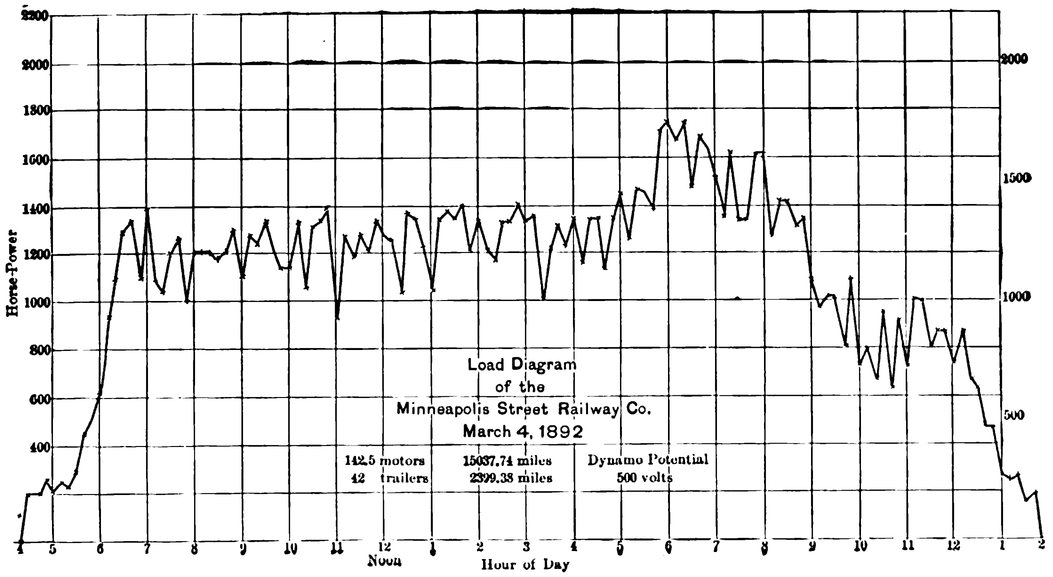

FIG. 11.

removing grounds and crosses. This explanation will not hold in many cases. Extended inquiry was therefore made among railroad men in order to gather as many facts as possible. Some of these reports were incredible at first, but seem to be honest testimony and were afterward corroborated by others.

It may be well to state that the term "bucking" is used with some looseness, being sometimes applied to cases where a motor acts badly for a variety of reasons, but as used in this article it is to be taken in the sense above noted. There is a tradition among the car drivers that a motor is very liable to buck if the current is full on while running down hill, but no case of this sort could be substantiated. Cases are reported of a motor bucking when the circuit is opened for an instant, as may be caused by the trolley jumping off and on, or by the car passing over a dead rail or over a very dirty track. It is not plain that this is a true case of bucking, but rather of a sudden cessation and re-application of the propelling force.

Sometimes a car will buck at regular intervals. Examination of the motor shows a small bright spot on one brush which rolls to and fro at the contact between brush and commutator. This is intensely bright like a ball of melted metal and grows larger until nearly three-fourths of an inch in diameter, when it suddenly explodes with considerable noise and a blinding flash, and at the same instant the motor "bucks." The car goes on again at once, and the cycle is repeated again in the time required to run from one-half to four city blocks at ordinary speed. In such a case the bucking is stopped by shifting the brushes.

One case is reported where a motor bucked hard although the brushes were removed so that the armature was entirely disconnected. Here the field was charged by being in parallel with the field of the other motor, and a cross in the armature coils short-circuited it. The foreman of the repair shop where our efficiency tests were made, states that on six or eight occasions he has seen a motor buck because the carbons were not properly placed in the holders. In testing armatures rapidly, the carbons are sometimes placed carelessly so that the presser-foot rests partly on the carbon and partly on the holder. This presses the carbons against the commutator so as to give good contact until the carbon wears off a little, when the presser-foot no longer feeds it in. Vigorous flashing occurs, culminating in a buck, the shock of which may jar the presser-foot into its proper position, when the motor runs on as if nothing had happened, leaving behind no trace to indicate cause of trouble.

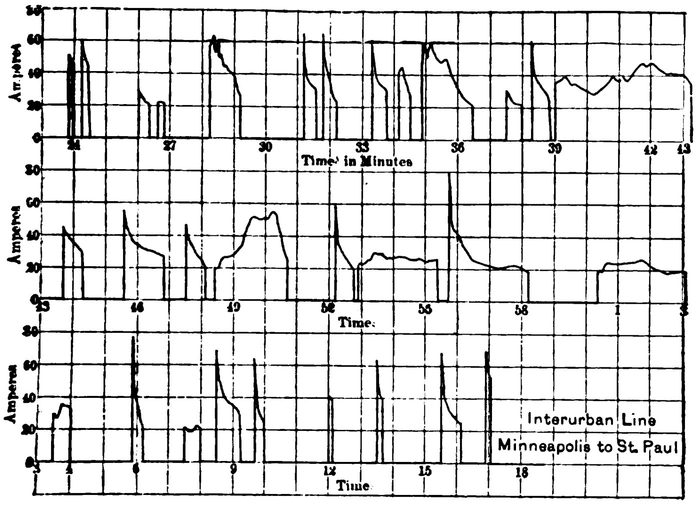

FIG. 8.

Cases have been reported where a wire on the track touched the motor as it passed, thereby grounding it and causing it to buck. Similar grounding may be caused by water or mud being thrown upon certain parts of the motor.

The motors with Gramme ring armatures are known to buck more frequently than those with drum armatures. These buck worse when run on the "loop," *i. e.*, with part of the field coils cut out, some of them bucking regularly every time the loop is cut out. This is one reason why the use of the loop has been abandoned on this road except in a few cases. The machines with commutated fields would buck when the field coils became old, although they showed no signs of being grounded. Bucking became much less frequent when the commutated fields were replaced by a single pair of series coils.

It was noticed that bucking was very commonly preceded by flashing at the brushes, although flashing was not always followed by bucking.

The explanations offered are various. One is that the iron in the fields varies in magnetic quality so that one motor works harder and by some means acts upon the other as a dynamo. Another is that one motor becomes reversed while the other does not. Another is that bucking is caused by poor brushes or brush holders.

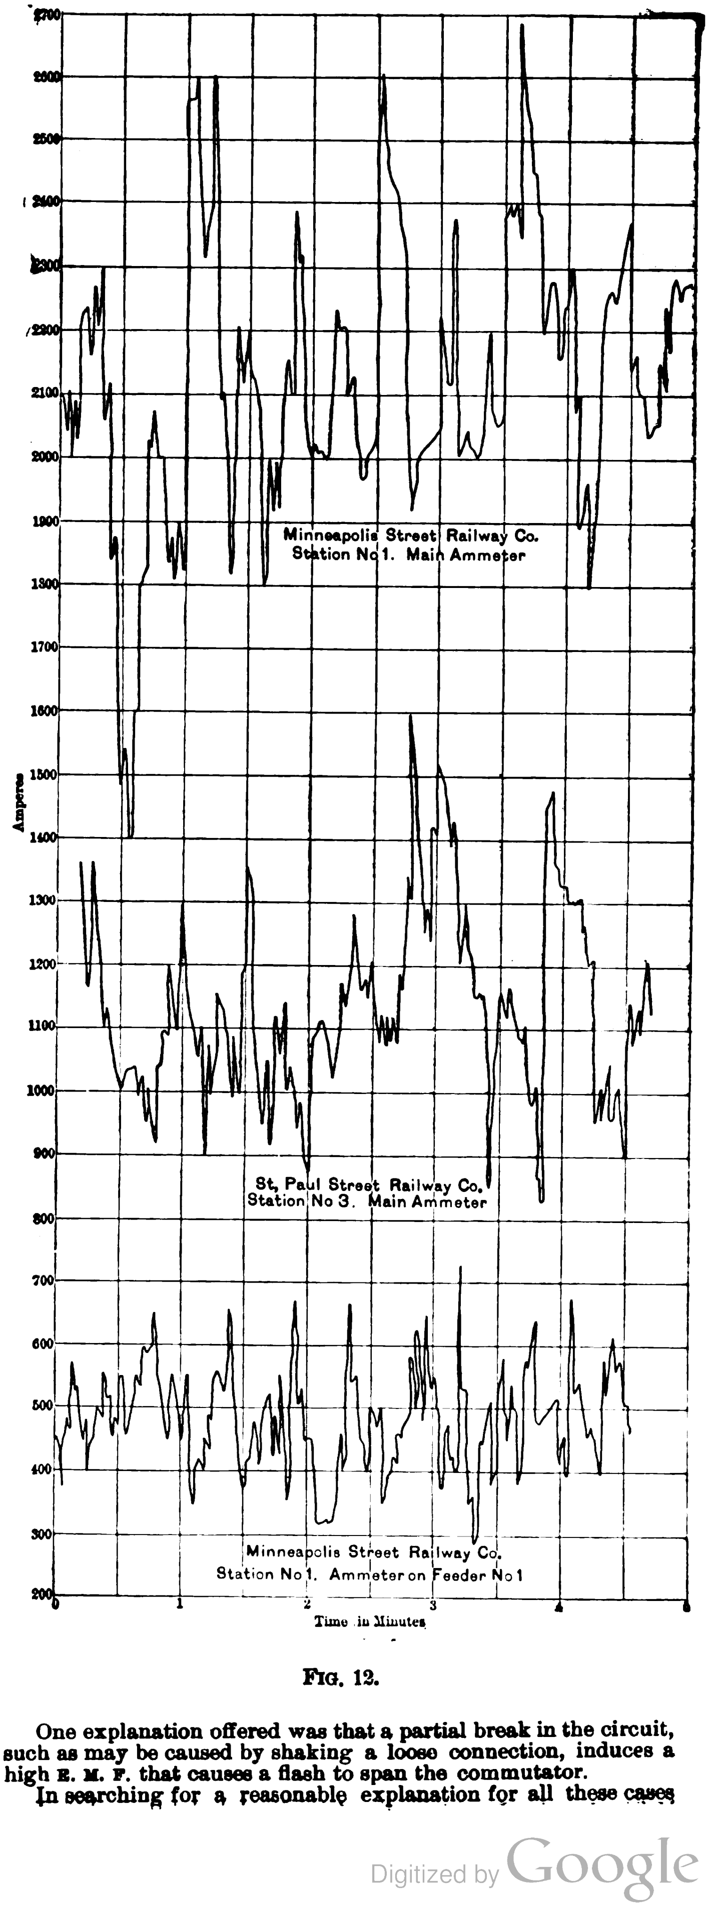

FIG. 12.

One explanation offered was that a partial break in the circuit, such as may be caused by shaking a loose connection, induces a high E. M. F. that causes a flash to span the commutator.

In searching for a reasonable explanation for all these cases in which no second ground connection existed, it was noticed in each case that bucking was more liable to occur when the field was comparatively weak; also where the armature reaction was greater. In each case the neutral line is shifted and the coils under the brushes are in an active field. The large current in short-circuited coils further distorts the field, and the sparking at brush becomes excessive, causing a vigorous flashing. As soon as the counter E. M. F. in the sections leaving the brushes rises above 20 volts, the arc is carried around from one brush to the other, thus grounding the positive brush and short-circuiting the armature, which then acts as a dynamo and causes the motor to buck. Such bucking is usually less vigorous than when caused by a dead ground, on account of the resistance of the arc. This explanation covers all the cases noted.

Such being the causes of bucking the remedies are plain. Armature reaction must be reduced. This militates against the conclusion drawn by Mr. Parshall, in his recent Institute paper, that the strength of field is of little importance, and that the windings of the armature should be a maximum. The liability to bucking would be reduced even when there is a large armature reaction, if the armature is divided into a large number of sections.

An obvious remedy for bucking caused by direct grounding would be to connect the fields between armature and ground instead of between armature and trolley. With such an arrangement, a ground on the fields would simply cut out a part of the coils and cause that machine to work harder. A ground at brush between armature and field would cause a sudden forward impulse on account of the field requiring some time to lose its magnetism, and would blow the fuse. A ground on armature would likewise cause a sudden forward impulse and blow the fuse. With such an arrangement there would be no true bucking except in case of the flashing as noted. An incidental advantage of this arrangement is that the difference of potential between the field and the frame of the machine is reduced to a few volts caused by the drop through the field; hence there is less danger of grounding the field. The increased difference of potential between armature and core is only a few volts and would not affect the insulation very much.

INSULATION.[1]

BY THOMAS A. EDISON.

TO telegraphy the insulation of the circuits is so vital a matter that at the risk of making history repeat itself, and of recounting an oft-told tale, a short paper on the subject may be tolerated.

As a class, gases are the best insulators; next liquids, and solids last of all. The insulation of gases is so good that no determination appears yet to have been made of any leakage through them. If it were possible to make an experiment at or near the centre of the earth, so as to be beyond the reach of gravitational force, an electrified body might be left for hours in a gas without any visible means of support, and observations then made to determine whether any loss of charge took place through surrounding gases. Under existing circumstances, the loss of charge which always does take place on electrified bodies, cannot readily be traced beyond that through the suspension or support that holds them. Even in moist air the loss of charge has not yet been brought home to the aqueous vapor. Professor Boys exhibited before the Physical Society of London in April, 1889, a pair of electrified gold leaves, suspended in moist air by a short hook of quartz. The loss of charge appeared to be about 25 per cent. in five hours. A glass hook, under the same conditions, would have allowed the charge to disappear, it was said, within one minute.

If any perfectly insulating solid could be found, telegraphists would soon discover any surface leakage from their wires through the air, for the surface of a No. 8 B. & S. wire is 224 square feet, or 20.8 square metres per mile.

The loss of charge which takes place convectively into the air over any sharp point in an electrified body, is a phenomenon of a different nature. There the layer of atmosphere over the point is continually being torn by the magnitude of the forces brought locally to bear upon it, and the particles of moving air carry away the charge.

Some liquids have also a very high insulation, notably most mineral oils. Animal and vegetable oils are by no means so good, or, at least, there is greater diffculty in obtaining them in a highly insulating condition. Water, contrary to prevailing notions, is quite an insulator. In the purest distilled water, resistance as high as seven megohms per cubic centimetre have been recorded; that is to say, a block one centimetre cube of water pressed between two opposite conducting plates as electrodes, would offer a resistance of seven megohms; but the least trace of impurity brings the resistance down.

Ice at —12° C. has been measured at 2,240 megohms per cubic centimetre. There are two conditions of surface upon which bare wires miles in length, laid on the ground, have been worked telegraphically—one over the dry desert sands of Africa, the other over dry ice in the far north. Sea water has a resistance of about 30 ohms per cubic centimetre at 5° C. It would appear probable that liquids cannot conduct without electrolytic decomposition. A microscope will show that one microampere decomposes the drop of water it traverses.

One of the most important and promising modern theories of chemistry is based upon the assumption, in accordance with a considerable array of facts, that solutions only conduct by the transfer of atoms or ions to the electrodes, each carrying an electric charge, and the conductivity of a liquid measures on this hypothesis the number of uncombined or dissociated ions permeating its mass. These free ions are the porters carrying the charge, and the conductivity of the liquid depends upon the number available and the speed with which they can migrate.

Liquids, too, have, as a class, the quality of elastic insulation to high tensions, which is an important feature to the electrical engineer. Air for the first few centimetres will break and allow a spark discharge to occur when the pressure reaches from 10,000 to 50,000 volts per centimetre (25,400 to 127,000 volts per inch) according to the shape and condition of the electrodes, but rosin oil is said to stand about 75 times the pressure of air per centimetre without disrupting.

The following is a list of actually observed resistance in commercial samples of well-known insulating substances. The results are given in megohms per cubic centimetre at or near 18° C.:

Paraffine wax	110,000,000	megohms.
Heavy paraffine oil	8,000,000	"
Olive oil	1,000,000	"
Lard oil	350,000	"
Creosote	5.4	"
Stearic acid	350,000,000	"
Sperm oil	0.077	"
Benzine	14,400,000	"
Balsam copaiba	211,000	"
Benzole	1,320	"
Oil of wood tar	1,670,000,000	"
Crude ozokerite	450,000,000	"

All transparent solids are insulators, but of course the opposite statement is not true that all opaque solids are good conductors. There is now good evidence for believing that the process by which light is propagated, the mechanism by which it is transmitted through space, is purely electromagnetic, and the magnetic vibrations passing through a conductor would generate electrical currents and be absorbed in the substance as heat, that is to say, it would be opaque to the light, failing to transmit the energy.

The difficulty with solids is not so much to find insulators, for the great majority of solid substances freed from moisture are poor conductors, but to find an insulation of suitable mechanical qualities. Glass, porcelain and mica seem to be almost the only practically available insulators that will support considerable stresses and these for many structural purposes are far weaker than is desired. In American telegraphy, glass is almost the universal insulator, but in Europe, particularly in the south and west, the atmosphere is so much more humid, and glass so hygroscopic, that no circuit of any length could be operated with glass insulators except in dry weather. Porcelain or vitrified stoneware insulators are used instead, and in quite a variety of forms. Practically speaking, the insulation of a line is never that of the material forming the insulators, but always that of their surfaces, and the films of dust and moisture that may have become encrusted thereon. The most perfect insulators are those which have underneath the hood a cup filled with oil, in such a manner that the current leaking from the wire to the ground has to pass over the oil, or else through the substance of the insulator itself. These insulators are certainly more expensive, and require to be refilled with oil at intervals, but they will defy weather and keep the insulation nearly as high in fog as in sunshine.

When a long, leaky wire is opened at the distant end, and tested for insulation, the insulation per mile always appears to be somewhat more than it is for any actual mile, since the more distant portions of the line are tested with a reduced pressure owing to the leakage over the nearer portion. When the wire is grounded at the far end, and its conductor resistance measured, the leakage will on the other hand make the apparent resistance per mile too low. But if the conductor resistance is reduced in a given ratio, say as 100 to 95, the insulation will be overindicated in the exact inverse ratio of 95 to 100, provided that the insulation of the line is uniform. So that if a wire's conductor resistance at its temperature of observation is known to be 10 ohms per mile, but appears by leakage over the whole length to be 9 ohms, then if the insulation per mile apparently measures 400,000 ohms, it will be really 360,000, and each mile taken separately might be expected to measure 360,000. As is well known, telegraph lines work better up to a certain point if the insulation is rather low. A wire has to be emptied of its charge between the impulses of the key sufficiently far to keep the relays from sticking. If the insulation is perfect, this quantity has to be cleared through the ends to the ground, but if the line leaks it can escape more readily at all points.

The longer the line, the more essential good insulation necessarily becomes. The insulators are perhaps never more carefully tested than those intended for the long circuits on the Asiatic plains. It was at one time customary to test each insulator before it went out, by taste. The insulator was immersed nearly to the rim, head downwards in the water, and a battery of 100 cells was connected with one pole to the water and the other to the insulator stalk through a particular kind of key. The operator first rested his moistened finger on this key and then applied his tongue to it. If he tasted no current, the insulator was passed out as satisfactory. The test was sensitive and expeditious, and saved the care and handling of a galvanometer.

---

[1] A paper read before the Railway Telegraph Superintendents' Association, Denver, Col., June 15 and 16.

The insulation of a wire is a definite term and stands for a definite property so long as it is not necessary to measure it very accurately. There is usually no difficulty in finding the insulation of any overhead wire within 5 per cent. at any one time, and two observers measuring the line from the same end with different instruments would generally agree in their results to that limit; but as higher degrees of accuracy are attempted (a condition that fortunately does not practically occur) the difficulty of obtaining concordant results may increase rapidly. A resistance coil of wire at a uniform temperature can have its resistance measured to within one-fiftieth of one per cent. if necessary, but a leakage resistance is essentially liable to variation. The atmospheric conditions may be altering, or there may be polarization, or inductive disturbances from neighboring wires, or a combination of conditions that may set close measurement at defiance. It is generally advisable to employ galvanometers for this purpose, that even if sensitive, are slow of movement and dead beat. The only instances in which accurate measurements of installation are possible and necessary, are in connection with subterranean or sub-aqueous wires. Jute and paper, dry or saturated with compound, are rapidly coming into use for subterranean wires sheathed in lead, while for long cables under water, india-rubber and gutta-percha are invariably employed. With conductors highly insulated by these methods, the insulation can be measured much more closely, and is definite for a given temperature of the core, but even in this case the current that will flow from a battery into the wire freed at the distant end is not all leakage. A considerable portion may be stored up in the insulating substance, and be returned from the wire to ground after the battery has been removed. This "polarization" is particularly noticeable with gutta-percha and india-rubber covered wires, and their insulation may be apparently 50 per cent. greater after three minutes of charging than at the end of the first minute. In specifications it is usual to call for a certain insulation per mile at 75° C., and after a definite interval of charge.

The insulation obtained from a given thickness of covering depends on the diameter of the wire as well as on the quality of the cover, for a large wire supplies a larger leaking surface. Also if an insulating coating of a certain thickness produces an insulation of 100 megohms per mile, doubling that thickness will not double the insulation because the leakage will take place with greater relative facility through the greater surface of the second coat. The exact increase of insulation will depend upon the diameters of first coating and wire.

When a wire is well and homogeneously insulated, its insulation resistance at a given duration of charge or period of electrification will appear to be the same with different battery powers or voltages applied, but if, on the contrary, it contains any small faults or defects, it will generally show less insulation with increasing testing pressures. This often forms a criterion as to the reliable insulation of a long cable. The insulation in an ocean cable under the pressure of great depth and near the temperature of melting ice that deep oceans approach, might be 15,000 megohms per nautical mile at the fifth minute. With a small incipient fault the insulation might still reach 3,000 megohms per mile and seem excellent, but it is probable that when tested with 5 cells and with 50 cells, the insulation resistance in the latter case would not appear so high. It would also probably be different with the zinc or copper pole to line.

The only value that can attach to a high measured insulation is the assurance it conveys that no flaws exist in its covering or supports, and will therefore remain in good signaling order unless disturbed. In fact a very high insulation as we have seen actually tends to retard signaling. Mechanical security from the loss of insulation is the great desideratum rather than a very high degree of insulation itself.

NOTES ON WIPING CONTACT METHODS FOR CURRENT AND POTENTIAL MEASUREMENT.[1]

BY PROF. BENJ. F. THOMAS.

In the discussion on Mr. Milton E. Thompson's paper on "A Study of an Open Coil Arc Dynamo," read before the Institute on the 21st of May, 1891, Dr. Geyer referred to some work done at Stevens Institute by the writer, in which work the wiping contact method seems to have been used for the first time. The following brief account of the work is presented at the request of several members of the Institute.

In the latter part of July, 1880, President Morton requested the writer to determine the power required to maintain the arc of a Brush arc light, supplied with current by a Brush dynamo machine.

Ammeters and voltmeters were then unknown, and in among the electrical instruments in the Stevens laboratory the most convenient for the purpose seemed to be a tangent galvanometer for the current measurement, and a condenser and Thomson galvanometer for potential. The condenser was a one-third microfarad standard, and the galvanometer a 7,000 ohm, four-coil astatic, both made by Elliott Bros. As every one knows would be the case, trouble was encountered the moment the potential readings began. Wishing to know the character and magnitude of the variation of potential, the writer devised what is now known as the wiping contact method, the natural and only expedient for the purpose.

The condenser was joined, through the usual discharge key, to the terminals (or other points) of the dynamo, by two well-insulated wires. At the dynamo one of these wires was cut, and the cut ends attached to a pair of well-insulated springs of flat metal, mounted on the outer end of a radial arm, the latter fastened to a horizontal rod, coaxial with the armature. A well insulated piece of metal was fastened radially on the face of a disc attached to the armature shaft, and the two brushes set so that they were lightly touched by the radial strip at each revolution of the armature. A pointer attached to the horizontal shaft carrying the radial arm and contact springs, moved over a divided circle on the support of the arm, so that angular positions could be read. The contact device thus acted as an open circuit key, the closing of which, and the consequent charging of the condenser, could only take place when the armature was in a definite position. The process of obtaining the curve of potentials through a revolution of the armature is now so familiar that further description is unnecessary.

In carrying out the examination of the machine, a non-inductive resistance of German silver wires was prepared to avoid complications from the action of the arc lamp. When this was used as a load for the machine, the throws of the galvanometer changed at once from the erratic behavior observed at first, to the beautifully regular and uniform character now so familiar to all who have used the method under proper conditions.

The most interesting curves and results were presented as a joint paper by Prof. Morton and the writer, and read by Prof. Morton before the American Association for the Advancement of Science, at its Boston meeting, Aug. 25–30, 1880.

Our experience with the method leads us to prefer the Thomson portable electrometer and Leyden jars, to all other instruments, for high potential curves. The electrometer is dead beat, is a zero instrument, and is easily and quickly set. As usually made, its constant is from two to three volts per division, and one can easily set to within that amount. The error resulting from an improper reading, say one division wrong, would be of course serious in reading low potentials, but these readings only occur on nearly straight parts of high potential curves, and might be entirely omitted without serious error.

Next to the portable electrometer, we prefer the Thomson electrostatic voltmeters. For low potential curves nothing has yet proven superior to the potientiometer method as used here, and described by the writer at the American Association meeting at Washington, last August. The potential difference to be measured is balanced against that produced by a battery in a resistance as in the accompanying illustration.

In Mr. Thompson's paper referred to above, reference is made to Joubert's use of the method in 1881, and in the recent edition of Thompson's Dynamo-Electric Machinery, it is described as Joubert's method. In view of the work here described, and its presentation before the American Association in 1880, it seems proper to claim the method, which in the hands of Prof. Ryan, Dr. Duncan and others has led to such valuable results, as an American method.

"A POSITIVE PLEASURE TO READ YOUR PAPER."

In a communication dated July 2, the Standard Paint Co., of 2 Liberty street, this city, write us as follows: "We certainly think that the article descriptive of the plant and processes of the Thomson-Houston Co. is one of the most complete papers of the kind we have ever seen published. It has become a positive pleasure to read the recent issues of your paper, and its growth, which has been marvelous, has kept pace with the rapid developments in the electrical field. We congratulate you on your last issue and on the valuable journal you publish. We shall be pleased at all times to give your paper such support as it is possible for us to do, and with good wishes for its future welfare, in which Mr. Shainwald, our president, asks to join, we remain, yours very truly, The Standard Paint Co., per Frank S. De Rond."

---

THE
ELECTRICAL ENGINEER.
[INCORPORATED]
PUBLISHED EVERY WEDNESDAY AT
203 Broadway, New York City.
Telephone: 3860 Cortlandt. Cable Address: LENGINEER.

GEO. M. PHELPS, President. F. R. COLVIN, Treas. and Business Manager.

Edited by
T. COMMERFORD MARTIN AND JOSEPH WETZLER.
Asso. Editor: GEORGE B. MULDAUR.

New England Editor and Manager, A. C. SHAW, Room 70—620 Atlantic Avenue, Boston, Mass.
Western Editor and Manager, W. FORMAN COLLINS, 347 The Rookery, Chicago, Ill.
New York Representative, L. W. COLLINS, 203 Broadway.
Philadelphia Representative, W. F. HANKS, 501 Girard Building.

TERMS OF SUBSCRIPTION, POSTAGE PREPAID.

United States and Canada, - - - - - - - - per annum,	$3.00

[*Entered as second-class matter at the New York, N. Y., Post Office, April* 9, 1888.]

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can 'entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, JULY 18, 1892. NO. 219.

There can be no reality in science if at this late day it cannot predict that certain proposed inventions are impossible, as well as declare that others are in accordance with established principles.—Joseph Henry.

TEN YEARS OF THE TELEPHONE IN AMERICA.

AS a matter of fact the development of the telephone in this country has taken place within the period between 1880 and 1890, so far as it constituted a large business based on the central exchange. Before 1880, as the Tenth Census report said, "the business amounted to little or nothing," yet at the end of 1880 it had already established itself as one of the great fields of electrical invention and investment. With 1890, began another active period of great importance, that of long-distance telephony, and now it is evident that the decade dating from that year will also witness an enormous development of the telephone as a means of intercommunication in residences, hotels, offices and factories. Even to-day the office of THE ELECTRICAL ENGINEER is practically the only place in New York City, outside the telephone headquarters, where a number of telephones have been installed by means of which, without a switchboard and a switching operator, several persons or departments can converse freely with each other. There is no end to the opportunity for such work, yet as we all know, and as the fact just mentioned indicates, this special development has but barely begun.

The figures compiled by Mr. A. R. Foote for the Census Office, in regard to the telephone industry, have just been issued in Census Bulletin, No. 196, and are Mr. Foote's first publication as special agent in charge of electrical statistics. The work appears to have been done with intelligence and accuracy, as might have been expected. The grand totals are embodied in the subjoined table of the Eleventh Census:

Items.	1880.	1890.	Increase. (Amount and number.)
Number of companies, firms, and persons reporting	148	53	
Total investment	$14,605,787	$72,341,736	$57,735,949
Gross earnings	3,098,081	16,404,583	13,306,502
Gross expenses	2,373,703	11,143,871	8,870,168
Net earnings	724,378	5,260,712	4,536,334
Number of exchanges	439	1,241	804
Number of telephones and transmitters	108,638	467,356	358,718
Miles of wire	34,305	240,412	206,107
Number of employees	3,338	8,645	5,307
Number of subscribers	48,414	227,357	178,943
Number of conversations	....	453,200,000	

It will be observed that the number of operating companies is little more than a third of what it was in 1880, and it is not unsafe to predict that consolidation will be carried still further. As to the profitableness of the industry, about which so much is heard, it would appear from an analysis of the figures that the per cent. of net earnings on total investment in 1890 was 7.27, and that the per cent. of aggregate dividends on share investment was 4.70. Such figures certainly do not bear out the extraordinary statements that have been made from time to time in the daily newspapers as to the profits of the telephone business, nor does the fact of an undue return on the investment appear in any of the other figures of the report. It is true that there is no definite information given as to the cash investment, so as to show how great or little has been the amount of "water" injected; but such figures would not be at all a fair test of values, as the capitalization to-day should properly cover many valuable elements such as rights of way, city franchises, improved real estate, good will, etc. It might also, perhaps, be held to cover a fund of experience bought very dearly during ten years of trial, experiment, failure and success, with a variety of methods and apparatus that long since went into the junk heap and were written off.

The report is but fair in saying that the service is more valuable and satisfactory to the subscriber to-day than it was in 1880, due to the introduction of better instruments, the resort to metallic circuits and probably to numberless little fine touches in supervision and management that have been added so gradually that it would be hard to tell just when the change was made. Some idea of the trouble and expense to which the operating companies have gone is furnished in the brief statement that they now have 54,690 miles of wire underground.

Surprise is often expressed at the statement that the service in the larger exchanges costs more than in the smaller, and hence must be more highly paid for. One of the tables included by Mr. Foote shows that the average of calls daily per subscriber runs from 4.80 per day in exchanges with 100 subscribers and less up to 8.86 per day in exchanges of 1,500 subscribers and over. Here are the extremes within those limits, but in the largest exchanges the number of calls is often even greater. Yet the average price paid per subscriber per call only rises from 3.25 cents to 3.50 cents, the lowest price being paid, naturally, in the handy little exchanges of about 1,000 to 1,500 subscribers.

STORAGE BATTERIES IN CENTRAL STATIONS.

We may be pardoned for again recurring to a subject to which we have alluded a number of times recently, but the importance of the matter justifies us in again calling attention to results which bear out our previous estimate of the value of storage batteries in central station work. Another set of independent figures on the subject have been given in *L' Industrie Electrique*, made by M. Vitte, at the electric light works of the gas company at Lyons, France. The cells there employed are of the Tudor type, and from the 5th to the 31st of March, that is 26 days, they were given a charge of 2,828 kilowatt hours. They gave a discharge of 2,477 kilowatt hours, thus showing an efficiency of 87½ per cent. The battery has a practical capacity of 150 kilowatt hours, but is only worked up to two-thirds of its capacity at the present time. The above figures lead M. Vitte to the conclusion that, contrary to the general opinion, the storage battery is an apparatus possessing the highest mean monthly efficiency. These figures bear out very strongly the statements made in one of our recent issues by Mr. Currie, regarding the work of storage batteries in the central stations of Paris and ought to lead to some active consideration of the subject in this country.

INCANDESCENT LAMP LIFE AND EFFICIENCY.

The life and efficiency of incandescent lamps has long been a favorite topic of investigation, and has from the very birth of the lamp given rise to discussions, some of which, indeed, have not been of the most pleasant nature. That the subject is still considered a live one, and perhaps justly so, is evident upon the perusal of the paper read by Prof. Thomas and Messrs. Martin and Hassler, before the American Institute of Electrical Engineers at Chicago. It is not to be wondered at, of course, that we should find some differences in the life and efficiency of the various makes of lamps tested, but viewing the tests broadly, they show, with the exception of one or two makes, tolerably uniform performance within the limit of six hundred hours, and even beyond that point. Collectively, the tests show that a decided improvement has been achieved in the incandescent lamp manufacture during the last five years, but it is to be regretted that obvious considerations make it impossible to reveal the identity of the lamps and thus prevent a discussion of the subject from the standpoint of the method of manufacture. It would be of the greatest interest to know which among the lamps have their filaments treated by the flashing process, and which have not; while a disclosure as to the nature of the fibre employed would also be of great value. But the paper has served to bring out a fact which may prove of the greatest importance in the future manufacture of incandescent lamps. The blackening of the lamp to-day constitutes its most serious defect, and if it should be demonstrated after further tests, that by the employment of mechanical vacuum pumps exclusively, blackening can be avoided, as the tests of Prof. Thomas and his associates seem to show, it would prove one of the most imprortant advances made since the manufacture of incandescent lamps was begun. The paper also draws attention to a matter which must sooner or later call for action from some authoritative body, that is, the determination of the life of an incandescent lamp. The authors of the paper incline to the opinion that when a sixteen-candle lamp has dropped to fourteen candle power at the end of two hundred and forty hours its life is ended; but we are scarcely inclined to concur in this estimate, and need only to refer to the millions of feet of alleged twenty-candle gas, which the gas companies are selling, and which in many cases hardly reaches fifteen candles, without evoking any complaint from the consumer. Something between the limits suggested by the authors, and that proposed by others, namely, when the lamp has fallen to one-half its ordinary candle power, would seem to be more equitable to all concerned.

TESTING ARC-LIGHT CIRCUITS.

The difficulties attending the testing of a "live" circuit of any kind are greatly enhanced when the potential is very high, and hence it has come to be a general practice to delay hunting up trouble on arc circuits until after the circuits were shut down. Some approximate methods of testing have been in vogue, but the value of a method which will enable the station manager to locate accurately the cause of trouble will be at once recognized. A testing arrangement by which this is accomplished is described elsewhere in this issue by Mr. Edgar E. Stark, who has employed it with marked success for some time past. The value of accurate measuring instruments, such as the Weston voltmeter, is here again demonstrated. With this method available, there ought now to be little excuse for the long existence of dangerous grounds on arc circuits, which, besides the constant menace they offer to the safety of the station employees, may be the cause of no little waste of current.

MT. WASHINGTON'S SEARCH LIGHT.

Some little time ago note was made of the proposal to place a very powerful search light on top of Mt. Washington. It is now stated by General Manager Tucker, of the Maine Central Railroad, that sufficient money has been raised to carry out the plan. The light will be the highest and strongest in the world, and will be visible from Maine, Vermont, Massachusetts, New Hampshire, Canada and New York. It is proposed to signal from the mountain to Boston and other cities; even to Montreal. Although no special reference has been made to the value of such a prominent search light for army signaling, it must be evident that the proposed installation offers exceptional opportunities for testing the value of the projector as a military signaling device.

ONE OF OUR UNAPPRECIATED MERCIES.

Mr. W. Crookes is credited with saying at the recent conversazione of the Royal Society that the only reason the earth has not long ago been deluged in a sea of nitric acid is that the igniting point of nitrogen is higher than the temperature produced by its combustion, and therefore the flame is not hot enough to set fire to the adjoining gas. Were it not for this, the first lightning flash would probably have fired the air, seriously interfered with the development of the world and made things generally uncomfortable.

A LIFE AND EFFICIENCY TEST OF INCANDESCENT LAMPS.[1]

BY PROFESSOR B. F. THOMAS AND MESSRS. P. MARTIN AND R. H. HASSLER.

MUCH has been written and said concerning the efficiency of the incandescent lamp and of the relation between its efficiency and the length of life to be expected from it. High efficiency lamps have their advocates and low efficiency lamps have theirs. It is pretty well understood by those whose work has put them in a position to appreciate the facts, that the question as to the choice of the lamps which will have best influence on the profit and loss account of the consumer depends on other things than first cost, efficiency and life. It is understood by such persons that the cost of producing the current supplying the lamps and the steadiness of voltage maintained on the lines are important factors in the choice, the high efficiency, short life lamp being best under condition of steady voltage and expensive current, and the low efficiency, long life lamp where current is cheap or regulation poor.

There is as great divergence between the published claims of lamp makers and the statements of the experience of station managers. Makers generally say that they will guarantee 600 hours' life for their lamps, and from 10 to 14 or more lamps per horse power, but some station managers insist that they do not get an average of 400 hours' life.

Considering it of prime importance for our object that the lamps tested should be of the same character as those usually sold to consumers, we bought some lamps of regular dealers, as in the usual course of business, and obtained others from lots supplied for central station use. Lamps of the following makes were obtained, no attempt being made to get lamps of any given efficiency of any make: A. B. C., Beacon, Columbia, Economic, Packard, Pennsylvania, Standard, Thomson-Houston, Edison, Perkins, Sawyer-Man and Steuben. In ordering (through persons purchasing for us in Chicago and New York) we called for ten 110-volt lamps of 16 c. p. in each case, but on receiving the lamps we found three lamps out of ten of one make labeled 111 volts. The three were excluded and seven put in, but another lot of ten of the same make, correctly labeled, was obtained. Ten of another make were received with the original marking, 111 volts in ink, changed by pencil to 110 volts. They were also excluded, and a new lot of ten of that make, correctly labeled, obtained. Ten Sunbeam lamps were divided into two lots of five each, evidently supplied as a sample lot, and were excluded. We could not get others of that make in time to enter the test. There were, therefore, in all 127 lamps, labeled 110 volts and 16 c. p., of 12 well-known makes, 17 lamps in two separate lots of one make, and ten each of 11 different makes.

A Thomson centiampere balance provided also with a resistance for obtaining standard potential readings was used as a standard for current and potentials. Two Weston milliampere meters and two Weston voltmeters were used in the current and potential readings on the lamps.

Current was supplied to the lamps by a 200-light Thomson-Houston dynamo, of the spherical armature type, which proved to be an excellent machine for the purpose. Owing to the variable speed of the engine, due to varying load and steam pressure, a special automatic regulator was devised and applied to the dynamo, to keep the potential at the centre of distribution constant. This was effected by causing a small motor to slide a contact-piece along two vertical German silver wires joined to an extension of the field coil of the dynamo, a current being sent through the motor in one direction or the other as needed, by relay points, the relays being controlled by an indicator attached to wires leading to the centre of distribution. As used, the combination proved very satisfactory, keeping the potential difference at the centre at 110 volts, within a limit of ¾ of a volt either way. It could readily have been set to a smaller margin, but that was not considered necessary.

For the candle power measurements a two candle power Methven screen was used, the gas being passed through a Methven carbureter containing pentane. Its constant was checked by standard candles. Three 32 c. p. Edison lamps were used as working standards.

Before the duration test began the mean horizontal candle power of each lamp was determined in the usual way, and the ratio of this mean to the candle power found when the plane of the ends of the filament was perpendicular to the photometer bar was found, and used as the distribution factor. All results are expressed in terms of mean horizontal candle power. The unavoidable delays encountered in starting the test made it impossible to determine the spherical distribution without cutting short the time of run which we had set as desirable, viz., 1,200 hours. The duration test was begun on March 17, and it was necessary to run night and day, Sundays excepted, until the night of May 14, to complete the 1,200 hours. The run began with 77 lamps on the rack. The remaining 50 lamps were received later, and placed on the rack with the others 187 hours after the start.

As the methods used involve nothing particularly new, and have been fully described in print many times, we have considered it unnecessary to do more than state the general outlines, as above.

The object we had in view in undertaking the test was to determine the character of the incandescent lamp as a commercial product, not as a scientific instrument. The number of lamps of each make taken was, of course, too small to base a fair judgment on as to the absolute or relative merit of the lamps generally sold by the makers. For that purpose some hundreds of lamps of each make, taken from different lots, would have to be tested, which it was of course impossible for us to do. For this reason we have considered it unfair to the several makers concerned to give their names in connection with the results on their lamps, but have instead designated each make by a letter, and each lamp by a number. We believe, however, that the average of the results of all makes may be taken to represent fairly well the character of the average commercial lamp.

The results of the test are given in the following tables, the values given being in each case the average for a given make of lamp. Table I gives in the second column the average value of the distribution factors found for the 10 lamps of make "A," and the average value of the mean horizontal candle powers for those lamps at intervals after the beginning of the duration test, expressed in hours by numbers in the first column. The third column gives corresponding values for the lamps of make "B," and so on. Table I includes the lamps started March 17. Table II contains similar data for the lamps started 187 hours later.

1,200	7.1	7.2	......	7.4	7.6	6.7	6.7	6.5	....	....	....	....	....	7.0

Thirty-one lamps in all were broken, distributed as follows: All of the C's (10), 2 D's, 8 E's, 2 K's, 4 L's, 1 M and 2 N's. All the lamps of A, B, F, G and O makes survived, the O's for 1,018 hours, the others for 1,200. The average life of the C's was 836 hours.

Plate XIV gives two sets of curves. One set gives the curve of general average of percentage of initial candle power with respect to time, derived from the averages of the several makes, and beside it the curve of the make which showed highest percentage throughout, marked min. drop, Make M, and also the curve showing lowest percentage, marked max. drop, Make L. The other set shows the general average of watts per candle power, and also the curves of the two makes showing the maximum (make N) and minimum (make M).

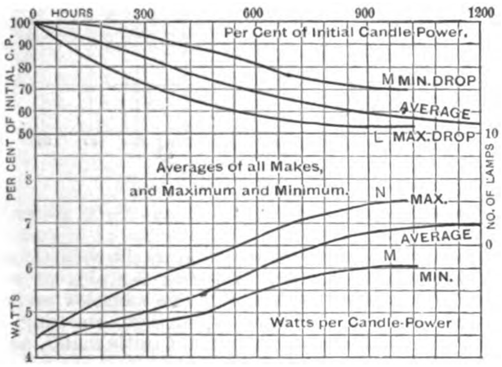

Plate XIV

Examining the results first for candle-power, we find the value 14.5 as the average of all the lamps tested at the time the current was first turned on them. Of the 13 separate lots, six only show an initial candle power of 16 candles (neglecting tenths), though one make which started at below 15 rises above 16 within the first 100 hours. The lowest initial candle power is found for make M. Makes G, K and O start at 17 candles, the highest figure reached at the start.

Looking at the curve which gives the average percentage of initial candle power, Plate XIV, we find that the lamps on the average grow dim at a steady rate, falling off to 90 per cent. in about 200 hours, to 68 per cent. in 600 hours, and end at 1,200 hours with a little less than 55 per cent. Deferring the consideration of the C lamps, the M lamps sustain their power best, losing only about 6 per cent. in the first 3 0 hours, and ending a little under 70 per cent. of their initial candle power. The L lamps drop rapidly on the start, losing 30 per cent. in the first 300 hours and ending at 54 per cent. The E's and the O's drop to 47 per cent. at the close, but sustain themselves better than the L's in the earlier part of the run.

With respect to efficiency, using the term in its ordinary signification, as measured by watts per candle power (though in this sense the reciprocal is the proper measure), Plate XIV shows an average initial value of 4.2, rising to 5.0 at 300 hours, 5.9 at 600 hours, 6.8 at 900 hours, and 7.0 at the end. The M lamps again have the best place, starting high but ending low, at six watts per candle power.

But what shall we say of the results as bearing on the question of the life of the lamp? The answer depends on what we shall define the life of a lamp to be.

Is a lamp alive as long as current will go through it? Adopting this view, our test shows 96 out of 127 lamps decidedly alive at the end of an average of 1,120 hours, and the leveling of the average curves of Plate XIV promises a considerable extension of their existence; 31 only have proven their mortality, and several of them lived to a good old age. The C's, poor things, all died young.

If we set the time of decease at the time when the lamp gives 50 per cent. of its initial candle power, as some claim, the lamps tested have passed 1,000 hours on the average, and certain makes have passed 1,200. If life be defined still with reference to percentage of initial candle power, but the limit be placed at 75 per cent., some individuals are still alive, but on the average, all died at 450 hours; 80 per cent. as limit cuts them off at 330 hours, and 90 per cent. at 180.

But there is yet another way of defining the life of a lamp. The one who ultimately pays for the lamp is the one whose premises are lighted by it, and the thing he is supposed to pay for is light. For him, the lamp is dead when it ceases to give a certain candle power, without reference to what its candle power was when it was new. His premises, let us suppose, are properly lighted by a certain number of new lamps which actually give 16 c. p. But when their light drops to 14 (12½ per cent.), he is no longer satisfied (and he ought not to be). For him the average lamp lasts about 240 hours. But if he is at liberty to choose the make of lamp, without reference to its efficiency, he will probably call for lamps of the G make, and get 400 hours' service from them. If, however, he can induce the maker of the M lamp to make a lamp giving 16 c. p. when new, and having the same characteristics as those we tested, he will chose M's, and get 500 hours' life. And that is the best that can be done for him, so far as this test shows. He would not have B's, L's or M's, as at present made at all, because they do not give 14 c. p. when new, and if the station manager put in F's or N's he would order them out in less than a week. The state of things revealed by this test, as to the actual candle power of new lamps, is certainly not what it ought to be.

At the conclusion of the life test we dismounted all the lamps and placed them on a large table covered with clean drawing paper and uniformly lighted. The several lots were carefully examined with reference to blackening, the lot which was blackened the most being graded 100, and the other lots graded as closely as we could judge by comparison with the blackest lot and with one another. The grades are as follows: 10, 12½, 25, 28, 30, 32, 35, 42, 45, 50, 75 and 100 per cent. of the blackening of the blackest lot. When the sorting and grading were satisfactorily completed, and the letters on the lamp bases examined, it was remarked that *the two lots which were least blackened were of the makes which are advertised as exhausted by mechanical pumps.* That they should both be so much alike in blackening, and both only one-half as much blackened as the least blackened of the mercurially exhausted lamps, is, to say the least, worthy of notice. It is, of course, not established that the observed freedom from blackening is due to the absence of mercury vapor in the lamps, as the makers claim, but if investigation should establish the claim the mercury pump will probably become once more a laboratory instrument. [The lot of lamps graded 10 per cent. and the lot graded 100 per cent. were mounted together on cardboard and exhibited.]

So far as the lamps tested may be considered to fairly represent it, we draw from the test the following conclusions concerning the average 16 c. p., 110 volt, incandescent lamp:

First. The mean horizontal candle power of the lamp as defined is only 14.5 when, new instead of 16 as labeled.

Second. The candle power of the lamp diminishes at a fairly uniform rate as it is burned, the rate of decrease being roughly 10 per cent. of the initial candle power for each 200 hours burned.

Third. The lamp makers' claim that the lamp will burn for 600 hours before breaking, is more than established, 96 out of 127 lamps being unbroken at the end of over 1,100 hours.

Fourth. Defining the life of a lamp to be the number of hours it will burn before it will fall from 16 c. p. to 14, we find the life of lamps in all respects like those tested, but so made as to give an initial candle power of 16, is 240 hours

Fifth. The initial efficiency of the lamp is 4.2 watts per candle power. At 600 hours it is 5.9 watts and 1,200 hours 7 watts. The average efficiency during the first 600 hours is 5.04 watts.

Sixth. There is considerable difference in the rating of lamps by different makers, who nominally furnish the same article, the average initial candle powers of the several lots ranging from 12.5 to 17.0. There is also considerable difference in the uniformity of the product of different makers.

The above conclusions properly complete this paper, so far as the purpose for which the test was undertaken is concerned. Some interesting points in the relative performances of different lamps may perhaps be alluded to in addition, since they cannot affect the makers.

The most interesting result arises from a comparison of the lamps L and M. The L's have the highest initial efficiency (3.8), and the M's the lowest (4.8), excluding, of course, the C's, which cannot be classed with good lamps, but after 250 hours' burning the efficiencies are the same (4.75). At the start the L's are furnishing light at the least cost, but after 250 hours the M's have the advantage in this respect. If we suppose both makes to be used for 700 hours, the average efficiency is the same for both. But at this time the M's are giving 75 per cent. of their initial candle power, while the L's are giving only 55 per cent. For the consumer the M lamp then is the better of the two, since the lighting of premises will be more uniform throughout the 700 hours of use supposed, and the cost of current for a given aggregate of candle power hours is no greater than with the L's. If the time of use of the lamps be, say, 400 hours, the choice is not so evident, and will depend on whether the slight difference in cost (watt hours) is of greater or less importance than constancy of candle power of the lamps.

The paper was accompanied by a series of curves showing the behavior of each individual set of lamps.

THE MAGNETIC PERMEABILITY OF SPECIAL IRONS FOR ELECTRICAL PURPOSES.[1]

BY MILTON E. THOMPSON; PERCY H. KNIGHT; AND GEO. W. BACON.

THE writers have recently made, in the laboratory of Cornell University, quite a number of tests of samples of various special irons from different manufacturers throughout the country; it was believed that some of the results obtained would prove of interest to the general electrical fraternity. The method used for these tests was a modification of that used by Rowland, the samples being prepared in the form of rings, and wound with two sets of windings, a primary and a secondary. The magnetizing current was passed through the primary circuit and measured by means of a Weston ammeter. A ballistic galvanometer placed in the secondary circuit measured by its throw the magnetic induction due to any given change in the magnetizing current.

Two different plans were tried in taking the curve and found to give slightly different results. The first was the reversal method, in which the current was commenced at its maximum value, and its direction reversed several times by means of a reversing switch, in order to bring the magnetism up to its full value, the secondary circuit being open during this operation. The secondary was then closed through the galvanometer, the current reversed, and the induction measured by the throw. The current was then slightly reduced, reversed several times as before, and the induction again measured on reversing the current. In this way the magnetizing current was gradually reduced to zero, and from the data thus obtained, curves were plotted with magnetic lines per square centimetre for ordinates and magnetizing force for abscissæ. In the other method, which was used for taking most of the curves, and which gives results more nearly like those obtained by Hopkinson and which are generally accepted as standards for wrought and for cast iron, the sample was first completely demagnetized. In some cases this was done by simply reversing the current through the primary and at the same time gradually reducing it to zero. By this method however, no samples except those composed of wrought iron sheets were successfully demagnetized, which might suggest that the Foucault currents set up by the reversal of the magnetizing current tended to keep up the magnetization. An alternating current of both high and low periodicity was also tried without success, and it was only by finally heating the samples to a cherry-red heat and allowing them to cool in air, so as not to change materially their softness, that total demagnetization was obtained. The sample being demagnetized, a small current was passed through the primary and the induced magnetism measured by the throw of the galvanometer. The current was then slightly increased and the deflection of the galvanometer again noted, and so on up to the maximum magnetizing force, the current being gradually increased step by step. The current was then reduced step by step to zero, reversed, and increased step by step to a maximum equal to that of the other direction. This descending and reversal curve was taken simply to serve as a check upon the demagnetization and upon the accuracy of the observations of the ascending curve and only the latter was plotted. Curves obtained from the same sample by the reversal method and by the step-by-step method were found to differ from each other by eight or ten per cent. at maximum values, the curves by the reversal process reaching the higher values. The magnetization of field magnets of dynamo machinery would probably reach values higher than that given by either of these methods of testing, for the iron being subject to vibrations from the rotating parts of the machine, and being at the same time under a continuous magnetizing force, would no doubt reach as high magnetic values as could be obtained by any method of testing.

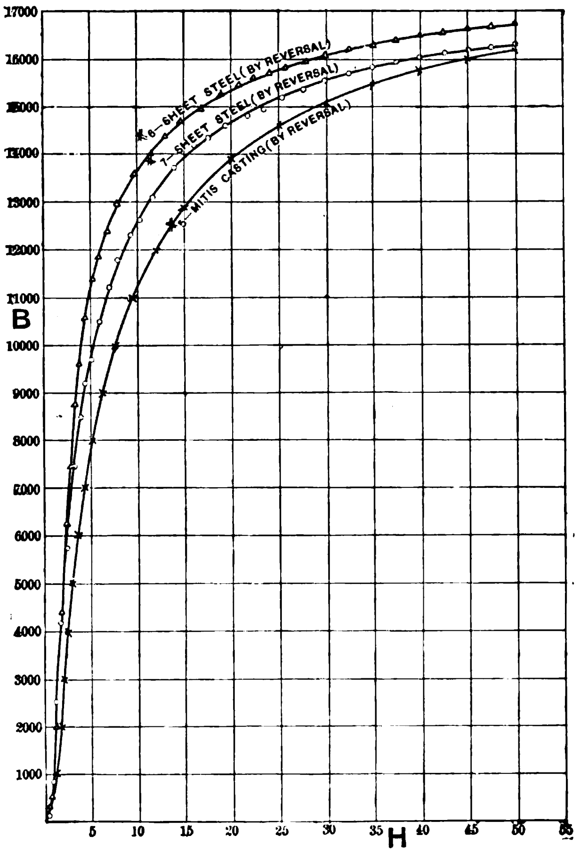

FIG. 1.

Some of the results obtained are embodied in the accompanying curves. Those in Fig. 1 were all taken by the reversal method. Curve No. 5 is the average of two different samples of wrought iron castings from the same maker, the two samples prepared at different times and from different pourings, showing almost identical qualities. The magnetic value of mitis metal, as shown by curve No. 5, differs very little from that of steel of good quality, as shown by curve No. 4. Curves No. 6 and No. 7 are from two samples of sheet steel of somewhat peculiar manufacture, inasmuch as they are said to contain no manganese, that element being perhaps the most objectionable impurity in mild steel, so far as its magnetic properties are concerned. The two samples from which the curves were taken were made as an experiment, and by slightly different processes. They show excellent magnetic values, especially No. 6, and seem to indicate that sheet steel may some day come into extensive use for armature cores, etc. Curves No. 14 and No. 15, Fig. 2, represent two different samples of wrought iron, used by two electric companies for field magnets. These curves were taken by the reversal method, and indicate for the metals a value considerably below that of the best wrought iron. Curves No. 16 and No. 17 are both from the same steel casting, and show the difference between the step-by-step method and the reversal method. Curve No. 16 is by reversal, and No. 17 by step by step. Curves No. 18 and No. 19 are both from one sample of sheet iron, No. 18 being taken by the reversal method, and No. 19 by the step by step. A similar difference in the methods is indicated by these two curves. A comparison of these and other curves plotted seemed to show that there is still a chance for the standard of cast iron to be raised, that the magnetic value of the average steel casting is only about eight per cent. below that of the best wrought iron, that there is practically very little difference in the magnetic values of steel castings of the best quality and mitis castings, and there seems to be no good reason for believing that the former cannot be made of quite as good quality as the latter.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 6, 7 and 8, 1892.

The magnetic values of both of those metals are found to be so far superior to that of cast iron that it seems quite certain that only the cost of production can stand in the way of their rapid and almost universal introduction for field magnets of dynamos and motors. When we consider that the cost of steel rails is but little different from that of cast iron, it seems reasonable to suppose that when the art of making steel castings comes to be better known and more fully understood, and better facilities are provided for their manufacture, such castings can be produced at a cost but little in excess of that of cast iron. Considering then the great superiority of cast steel over cast iron for electrical purposes, it seems safe to predict that the day is not far distant when steel castings will almost entirely replace cast iron in the construction of dynamo machinery, and the improvement in such machinery resulting from this change will be perhaps one of the greatest steps that has ever marked the progress of the electrical industry.

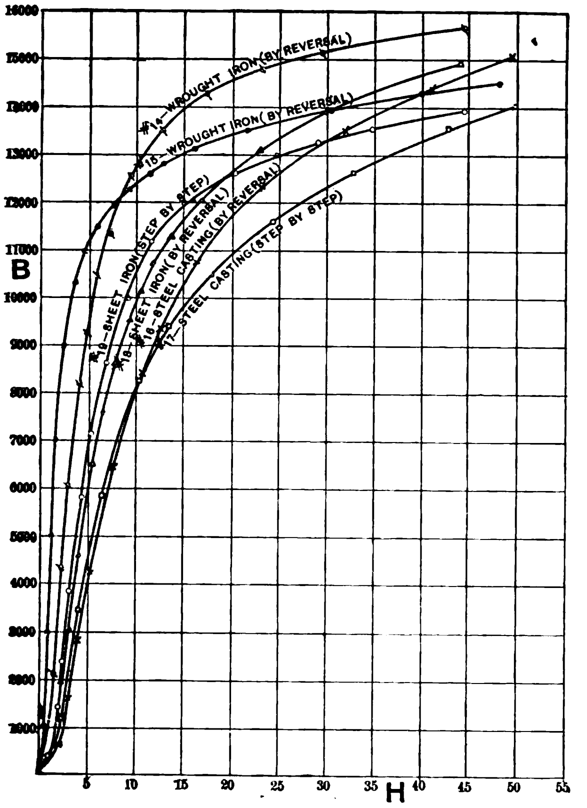

FIG 2.

SPORTS IN CANADA BY THE ELECTRIC LIGHT.

A SUCCESSFUL application of the arc light to the illumination of out-door grounds, in order to permit athletic sports and races to be held at night, has just been made by the Citizens' Electric Light and Power Co., of Montreal, at the grounds of the Montreal Amateur Athletic Association, on the occasion of their annual spring games. The programme included putting-the-shot, jumping, foot races and bicycle races, which events were seen by the spectators, with the aid of the electric light, nearly as well as by daylight and without the discomfort of the heat of the sun.

Heretofore these games took place on Saturday afternoons, but the experiment just made has shown that it is more advantageous to hold them at night, owing to the larger attendance of spectators; more people having time to attend in the evening, and there being, besides, no counter attractions then, such as la crosse or baseball matches. So successful was this experiment that the association will repeat these performances each month during the summer. In the fall it is their intention, instead of holding football matches in the day time, to hold them at night by the electric light. As proof that the public are pleased and attracted by this innovation, it may be stated that the recent games were held on two evenings, a week apart, and that the attendance on the last evening was considerably larger than on the first night.

The grounds in question are 650 feet by 560 feet and have a third of a mile track. The grand stand is 780 feet in length. After trials of different arrangements, it was found that the best illumination was given by 17 arc lamps of 2,000 c. p. each, located around and directly above the outside edge of the track. Eight of the lamps are placed along the front of the grand stand, in order to secure a more brilliant illumination of this portion of the track, where the field and sprint events take place and the long-distance races finish. The remaining lamps are distributed at equal distances apart around the rest of the track supported on projecting arms. At first the lamps were provided with clear glass globes, which, it was found, cast on the track troublesome shawdows of the globe holders; this objection was entirely overcome by the use of ground-glass globes.

Legal Notes.

EDISON LAMP PATENT SUSTAINED IN AUSTRALIA.

IT may be a matter of interest in connection with the suit of the Edison Electric Light Company against the United States Electric Lighting Company on Mr. Edison's filament patent No. 223,898, which was argued before the Court of Appeal in this city in April, and on which a decision is soon expected, that the corresponding patent in New South Wales, Australia, was sustained in that country in October last.

A report of the case taken from the Sydney *Morning Herald*, of October 12 and 14, 1891, states that the Australian patent was dated March 2, 1880, and corresponds with the patent granted in the United Kingdom November 10, 1879. This patent is owned by the Brush Electrical Engineering Company, Limited, and suit was brought against H. H. Kingsbury, a former agent in New South Wales for the Edison Indian and Colonial Electrical Company, the original proprietors of the patent. It was alleged that in selling Thomson-Houston incandescent lamps Mr. Kingsbury infringed the right of the plaintiff to the exclusive use and sale of lamps constructed on the principle of the filament patent in that colony.

The defendant did not dispute the utility of the invention, but contended that the patent was invalid on the ground of want of novelty, as the subject-matter of the invention was published in New South Wales in several different papers which were, it was alleged, circulated in the colony before March 2, 1880. In other respects the decisions of the English courts in previous years seem to have been binding in the colony, and this position was not impeached by the defendant.

His honor, Mr. Justice Manning, held that there had not been such a prior publication as to invalidate the patent, and granted to the plaintiff an injunction with costs.

College Notes.

McGILL UNIVERSITY, MONTREAL.

THIS university now provides a course of instruction of high standing and completeness, both of a theoretical and practical character, in electrical engineering at Montreal. The course extends over four years and for the first two years is essentially the same as that in mechanical engineering, including practical instruction in the use of tools, etc., in the workshops. After the preliminary mathematical and other needful branches, the remaining years are devoted principally to the practical and theoretical study of electricity. The object being to give the student a general training, as well as to inculcate those principles upon which alone he can base success in his professional career.

In electrical engineering proper, neither the theoretical nor practical sides of the subject are neglected, as appears from the following brief outline of the course of instruction, which includes: The theory, construction, calibration and use of measuring instruments. Magnetism and the design of electromagnets for special objects. The laws of induction. Electrical mechanisms, meters and arc lamps, etc. The general design and construction and testing of dynamos and motors. The distribution and transmission of electricity. Lighting systems. Electric traction. Transformers, accumulators, etc.

This department is under the direction of the Faculty of Applied Science, of which Professor Henry T. Bovey is the dean, Professor C. A. Carus-Wilson being the professor of electrical engineering.

The fine laboratories in the new buildings are being fitted up with an extensive and carefully selected collection of apparatus, chosen to represent the best types in use on this continent and in Europe. The equipment of the testing laboratories includes a very complete set of measuring instruments, comprising not only those for practical use, but standard instruments with which the correctness of the others can be ascertained. In addition, there is a variety of apparatus for special purposes, such as determining the coefficients of mutual and self-induction.

For measuring the mechanical power supplied to the dynamos and furnished by the motors there are the various forms of belt, rope and transmission dynamometers, with a very perfect form of hydraulic absorption dynamometer for checking the readings of the others.

The dynamo-room, when fully fitted up, will contain commercial and experimental dynamos and motors of the best modern types. Every convenience has been provided for varying the speed of the dynamos and in the other laboratories as well. Special facilities have been furnished for conveniently making tests, conducting investigations, etc. A peculiar and noteworthy feature is that delicate tests and experiments will be made in the Physics Building, three or four hundred feet distant from the Engineering Building, where the dynamos and engines are located, thus securing for the delicate apparatus entire freedom from any disturbing influence occasioned by the machinery. The two buildings will be connected by underground cables, by which current will be transmitted to the Physics Building for light and power, and also for experimental work in physics.

The laboratories of chemistry, mining, mechanical and civil engineering, of the other departments of applied science, are equally as well equipped with apparatus and facilities for practical and theoretical instruction.

Announcements of the different courses and other information may be had upon application to the dean of the faculty, Prof. Henry T. Bovey.

THE JOHNS HOPKINS UNIVERSITY ELECTRICAL ENGINEERING COURSE.

THE programme for 1892-93, just issued gives an outline of the course which extends through two years and includes instruction in theoretical and applied electricity, steam and hydraulic engineering, machine design, mechanics of engineering and mechanical drawing. An important feature is laboratory work, to which much attention is paid, and original investigation is especially encouraged. The instruction is given by Associate Professor Louis Duncan, Ph. D., Mr. Hermann S. Hering, M. E., Mr. Wm. S. Aldrich, M. E., and Mr. Percy Matthews.

The course is primarily intended for graduate students, who are not formally examined for admission, but are required to satisfy the instructors that they are fitted for the work. Students who have received the degree of Bachelor of Arts on completing the Mathematical-Physical group in this University, are well prepared to take up the special studies of electrical engineering. Special students may be admitted to the course after completing the studies of the preparatory year. Special students who are not ready for the regular work in electrical engineering, may be admitted to a preparatory course including the first year undergraduate course in mathematics (plane analytical geometry and differential and integral calculus), in physics, and in chemistry, and a year of drawing. These students must pass an entrance examination covering the matriculation requirements in mathematics, French or German (first division), English, United States history, and science. Near the close of the year the class will conduct a test of a central station and electric railroad and prepare a complete report on the same.

Personal.

MR. ADOLPHO ASCHOFF, of Rio Janeiro, who was here some months ago investigating telephones and electric railroads, and has done much to promote the interests of both in Brazil, has now returned as secretary to the Brazilian Commission at the Chicago Exposition. He will make his headquarters in Chicago, and proposes to prepare a creditable representation for his country.

MR. JOHN BOGART has been appointed by the Rapid Transit Commission chief engineer of the commission, and now that the Supreme Court of this State has approved the plans for the new rapid transit system of New York, he will assume his new duties at once. Mr. Bogart is well known in electrical circles. He was at one time secretary of the American Society of Civil Engineers, and later became State Engineer and Surveyor.

MR. W. C. FUCHS, E. E., has resigned his position with the Milwaukee Street Railway and has become the electrical engineer of the Cicero and Proviso Street Railway Co., Oak Park, Ill., with full charge of all their electrical work. Mr. Fuchs is a graduate of the City and Guilds of London Institute, where he studied under Profs. Ayrton, Perry and S. P. Thompson.

MR. WILLIAM H. BRYAN, M. E., late general superintendent of the Pond Engineering Company, and formerly secretary of the Heisler Electric Light Co., will in future devote his time exclusively to the practice of his profession of mechanical and electrical engineering, at 56 Turner Building, 304 North Eighth street, St. Louis. He writes that he will do no selling or contracting of any nature, but will endeavor to serve the best interests of the purchaser. Associated with Mr. Bryan are Messrs. Winthrop Bartlett, C. E., and N. W. Perkins, M. E., who are specialists in cable and electric railways, and machinery and shop design, respectively.

Letters to the Editor.

THE STRENGTH OF THE McINTIRE JOINT.

IN THE ELECTRICAL ENGINEER of June 22, Mr. McIntire claims that his joint was not given a sufficient number of twists in the tests that formed the basis of Mr. F. W. Jones' recent article on "Breaking Strains of Joints." Three twists was the number determined upon, after careful inquiry as to the usual practice in actual construction work. I hope to make further tests in the near future, and will be glad to try the McIntire joint at five twists.

MINOR M. DAVIS.

NEW YORK, July 1, 1892.

Society and Club Notes.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

BY invitation of the city of Rochester, as expressed through the scientific, educational and civic organizations, the forty-first meeting of the American Association for the Advancement of Science will be held in the city of Rochester, N. Y. The official time given for the association meeting will be from August 16th to August 24th inclusive. The hotel headquarters of the association will be the Powers. The meeting will be held at the University of Rochester (corner Prince street and University avenue), where will be the offices, the hall for general sessions, and the rooms for the several sections.

For information relating to membership and papers, address F. W. Putnam, permanent secretary, Salem, Mass. For all matters relating to local arrangements, hotels, railway rates and certificates, address Professor H. L. Fairchild, local secretary, University of Rochester, Rochester, N. Y.

THE NEW YORK ELECTRICAL SOCIETY AND "SINBAD."

THE annual meeting of the New York Electrical Society, for the election of officers, reception of reports, etc., will be held on Thursday, July 14, 1892, at 7.45 p. m. sharp, at the Electric Club, 17 East 22d street. The business will be taken up at the time named without a minute's delay by the members, in order that the second part of the evening's program, which is open to all, may be carried out. Special arrangements have been concluded with the management of the Madison Square Garden, through the kindness of Mr. David Henderson, whereby the members of the society will attend the performance of the successful extravaganza "Sinbad" in the Garden Theatre at 8.15 p. m.

This opera includes a large number of brilliant spectacular effects, utilizing the projection arc lamp in a way and to an extent never before attempted. After the performance members will be at liberty to ascend the tower and to enjoy the attractions of the roof garden, which include, not only a fine concert, but some beautiful decorative uses of the electric light. The price of the coupon ticket covering the whole entertainment, and ensuring the best seats in the theatre, will be only $1.00. The invitation includes ladies as well as gentlemen, and it is hoped that there will be a large gathering of members and their friends. Applications for tickets, with remittance, must be received at the office of the secretary, Mr. Geo. H. Guy, 533 Temple Court, Beekman street, at once.

CHICAGO ELECTRICAL ASSOCIATION.

MR. W. B. SPEIR addressed the meeting on June 28, with some "Notes on Pole Line Construction," referring more particularly to the metallic circuit lines used for telephone purposes. He showed how these had changed from an almost haphazard assembling of crude parts to the carefully systemized construction which gives us the neat and lasting overhead lines of to-day. After a discussion of this paper, the association adjourned until the second Tuesday in September.

FRANKLIN EXPERIMENTAL CLUB, NEWARK, N. J.

AT a regular meeting of the Franklin Experimental Club held Tuesday, June 21, it was decided to discontinue the meetings during the summer months. The next meeting is to be held the second Tuesday in September. The laboratory and reading-room will continue to be open for the benefit of members.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JUNE 28, 1892.

Accumulators :—

Secondary Battery, W. L. Silvey, 477,914. Filed June 15, 1891.

Claim 9 follows :

In a secondary battery a plate or element electrode consisting of a central grating of wires of aluminum, an outer covering for the central grating of a soft metal such as lead, and an active material consisting of a metallic oxide supported thereby.

Electrode for Secondary Batteries, H. G. Osborn, 478,018. Filed April 7, 1891.

Employs independent slotted receptacles and thin connecting pliable webs.

Alarms and Signals :—

Automatic Test for Burglar Alarm Systems, A. Stromberg, 477,712. Filed Mar. 17, 1892.

Pickpocket and Coat Thief Detector, J. F. Hurd, 477,940. Filed Oct. 2, 1891.

Electric Alarm, S. M. Matthews, 477,950. Filed Nov. 16, 1891.

A low-water alarm for boilers.

Conductors, Conduits and Insulators :—

Method of Insulating Electric Conductors, A. V. Abbott, 477,782. Filed Mar. 12, 1892.

An insulation composed of vitreous enamel held in place by a wrapper of organic substance, which is afterward destroyed by firing.

Insulator, F. D'A. Goold, 477,753. Filed Oct. 24, 1891.

Consists of a single strip of metal bent to form a base and two spring arms, constituting a holder for the insulator.

Electric Conductor, C. T. Snedekor, 477,787. Filed Oct. 17, 1891.

Employs a fireproof compound of calcined magnesia, china clay and silicate of soda, a coating of rubber and a final coating of the same fireproof compound.

Composite Electric Conductor, C. A. Mezger, 477,951. Filed Oct. 30, 1891.

A concentric arrangement providing means for the compact assemblage of two or more conductors in parallel and the complete insulation of each from the others,

Insulator, H. C. Wirt, 477,980. Filed Feb. 21, 1890.

An insulator having a knob at each end around which the wires are wound and a central base portion for attachment to the wall.

Dynamos and Motors :—

Dynamo Electric Machine, J. J. Wood, 477,729. Filed Dec. 1, 1891.

Employs a commutator brush yoke, having a concentric cylindrically projecting flange, an armature shaft bearing having a groove to receive the flange, and a removable fastening at the end of the bearing and overhanging the yoke for the purpose of holding the latter in the groove.

Galvanic and Thermo-Electric Batteries :—

Battery, W. A. Childs, 477,645. Filed Dec. 27, 1888.

Claim 1 follows :

In a battery a metal screw bolt or rod having a carbon head, said bolt or rod passing upward through an opening in the negative element and through the battery cover.

Lamps and Appurtenances :—

Socket for Incandescent Lamps, E. L. Smith and G. C. H. Foster, 477,786. Filed Sept 7, 1891.

Has for its object to reduce the resistance of the socket and to secure the socket screw against independent axial rotation.

Receptacle for Portable Electric Lamps, H. Molendo, 477,810. Filed April 21, 1892.

A wall or ceiling connection for portable incandescent lamps.

Electric Lamp or Conductor Support, C. Bell, 477,984. Filed March 28, 1892.

Employs an eye bolt with a threaded shank and an insulator formed of two parts having notches in the lower part for receiving the ends of the hanger.

Measurement :—

Electrical Measuring Instrument, E. Weston, reissue 11,250. Filed Feb. 5, 1892.

Claim 1 follows :

In an electrical measuring instrument a stationary coil, a coil movable in the field of said stationary coil, and a spring opposing and counterbalancing the impressed action of said movable coil, the said coils and spring being connected in circuit.

Miscellaneous :—

Electric Regulating Apparatus, J. M. Bradford, 477,637. Filed Sept. 29, 1890.

Provides automatic means for regulating and maintaining the current strength at a certain degree or at a uniform intensity.

Lightning Arrester, F. Haselwander, 477.656. Filed Oct. 2, 1891.

Employs an explosive cartridge interposed between the circuit terminals and the earth connection.

Electric Current Regulator, C. D. Sigsbee and T. S. Hayward, and F. S. Anderson, 477,708. Filed Sept. 11, 1891.

Employs a resistance device composed of conductive material and one or more perforated regulating plates of lower conductivity.

Elevator, P. Wright, 477,730. Filed May 18, 1891.

A safety device for an electric elevator consisting of a grip normally held out of action by a fragile pin, and a governor connected by a rope to the gripping lever.

Electric Telemeter, C. T. Barrett, 477,853. Filed Nov. 5, 1891.

Process of Making White Pigments, J. Blair, 477,735. Filed July 17, 1891.

An electro-chemical process of paint manufacture.

Electric Current Transformer, N. T. Wilcox, 477,879. Filed Aug. 20, 1891.

Employs a direct current generator, a direct current motor, a transformer and collecting rings to which one of the windings of the transformer is connected, a single commutator having opposite segments connected to the collecting rings and commuting the current flowing through one part of the motor.

Electric Lock, W. H. Hollar and F. S. Holmes, 477,897, Filed Feb. 3, 1 90.

Electric Lock, W. H. Hollar and F. S. Holmes, 477,898. Filed Feb. 3, 1890.

Voltaic Body Battery, W. P. Potter, 477,913. Filed April 4, 1892.

Electric Bath Apparatus, H. E. Waite, 477,975. Filed May 17, 1892.

Electrical Stop Motion for Knitting Machines, A. Beyer, 477,986. Filed Oct. 5, 1891.

Automatic Electric Change Maker and Check Receiver, T. Mangan, 478,011. Filed Sept. 26, 1891.

Electrical Organ, R. P. Strand, 478,082. Filed March 23, 1892.

Railways and Appliances :—

Electric Railway, J. W. Bates, 477,734. Filed Mar. 17, 1892.

Employs a series of posts projecting above the surface of the ground between the tracks and having side openings in which are contained the contact pulleys.

Device for Suspending Trolley Wires, J. Sachs, 477,781. Filed Oct. 28, 1891.

Conduit for Electric Railways, C. T. H. Schwieger, 478,026. Filed Sept. 16, 1891.

Employs two V-shaped conductors placed opposite one another in the same horizontal plane, and a contact device having corresponding V-shape bearing surfaces.

Switches and Cut-Outs :—

Electric Switch, H. M. Pilkington and R. S. White, 477,869. Filed Oct. 8, 1891.

Employs several switch blades movable together or independently and having a common operating handle and separate handles for operating the members separately.

Mast Arm Electric Switch, T. Dillon, 477,890 Filed Mar. 31, 1892.

Has for its object to automatically cut off the lamp current when the arm is lowered.

Telegraphs:—

Electrical Keyboard, W. E. Blodgett, 477,635. Filed Mar. 17, 1890.

Has for its object the closing of a large number of independent circuits by means of a small number of keys.

Writing Telegraph System, H. Etheridge, 477,652. Filed Sept. 10, 1890.

Enables any one subscriber to operate the receiver of the other subscribers without first calling up by a signal.

Individualizing Cut-Out for Printing Telegraphs, S. R. Linville, 477,665. Feb. 10, 1892.

Consists in short-circuiting the electromagnets controlling the type wheels by means of individualizing cut-out mechanism so that an operator may not only short-circuit the electromagnetic devices without interrupting the line, but also can restore such circuits when desired.

Phonoporic Telegraphy, C. Langdon Davies, 477,835. Filed Apr. 20, 1892.

Employs a primary circuit, including a vibrating tongue and primary coils, secondary phonopore coils, a key for opening and closing the primary circuit and devices for closing the circuit through the primary coils excluding the battery.

Telephones and Apparatus :—

Telephony, R. Hope-Jones, 477,866. Filed Sept. 17, 1891.

Has for its object the magnifying of minute vibrations in a vibratory body.

Anti-Inductive Device for Telephones, S. Pollak, 477,870. Filed Nov. 11, 1891.

Provides means whereby any one using a telephone may regulate the instrument from time to time to overcome inductive effects.

THE NEW DYNAMO OF THE DETROIT ELECTRICAL WORKS.

THE description of the new type of machines of the Detroit Electrical Works, which will be found on another page, demonstrates the care with which these machines are built; and as a result they are being rapidly introduced. Thus among the recent orders received for these machines are the following:

Times Building, Chattanooga, Tenn., two 30 K. W. generators, one 9 and one 15 K. W. motors. Bagley estate, Detroit, one 400 K. W. generator and five 9 K. W. motors, This contract also includes five freight elevators and controlling devices for motors, so that each elevator is operated by one 9 K. W. motor, which is controlled, started and stopped by means of the starting rope of the elevator, the motor only running when the elevator is in use. Detroit Dry Dock Co., two 250-light generators for lighting machine shop, boiler shop, dry dock, engine-rooms and offices. One 40 K. W. generator to furnish current for electric cranes. Also, Detroit Dry Dock Co., for boats which they are building, one 125, one 150 and one 250-light plants, complete. Detroit Foundry Equipment Co , Detroit, one 9 and one 17 K. W. motors, complete, with controlling devices, etc., for electric cranes.

THE ROSE POLYTECHNIC INSTITUTE.

THE Rose Polytechnic Institute, of Terre Haute, is one of the few well-endowed and well-equipped schools of a college grade in the United States devoted exclusively to the professional education of mechanical, electrical and civil engineers and chemists. Very special attention is devoted to electricity. It is the strongest possible evidence in favor of this school that for several years the applicants for admission have exceeded the limited number that can be admitted. Those intending to study engineering should address Rose Polytechnic Institute, Terre Haute, Ind., for catalogue.

MR. A. J. CORRIVEAU, Montreal, Can., is doing all he can to interest the public in electrical novelties and improvements. The *Star* says : "A very pretty exhibit of electrical appliances is at present shown in the *Star* window and is much admired by the passing public. The exhibit is composed of elegant electrical fixtures, brackets and lamps of brass, copper, iron and onyx. Several electric fan motors are also exhibited, some suspended from the ceiling, mounted in polished brass, and others resting on bases, with rotating fans. They are pretty little machines, which can be set on a desk, table, mantel-piece, etc., and keep a room cool. This fine exhibit was loaned by Mr. A. J. Corriveau."

TRADE NOTES AND NOVELTIES

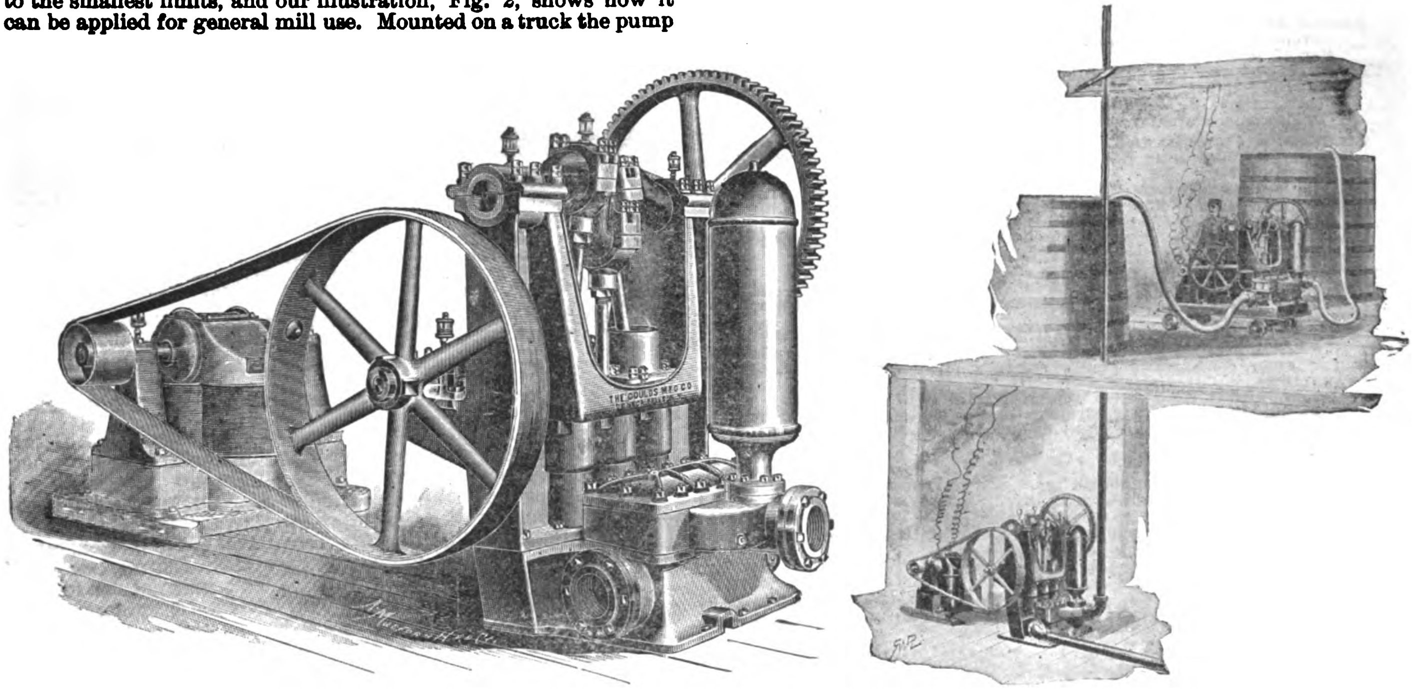
AND MECHANICAL DEPARTMENT.

Continuous advertising and continuous returns are cause and effect.

THE GOULDS TRIPLEX ELECTRIC PUMP.

Recognizing the great value of the electric motor as an auxiliary in the innumerable situations where pumps are required, the Gould's Manufacturing Company, of this city, early devoted themselves to the building of combination electric pumps for which their well-known Triplex pumps were admirably adopted on account of the smoothness of their action. One of the most generally applicable combinations of this kind is shown in the engraving, Fig. 1, which illustrates the Triplex pump driven by a belt from the pulley of an electric motor. The pinion of the pump gear is of rawhide, thus insuring noiseless operation.

The combination permits of bringing the space occupied down to the smallest limits, and our illustration, Fig. 2, shows how it can be applied for general mill use. Mounted on a truck the pump combination can be readily moved from place to place, thus making it specially convenient for tank pumping and pumping mash in breweries, etc. The motor shown in the cellar supplies a water tank used for general purposes.



The Goulds Triplex Electric Pump.

ENLARGING THE BRUSH PLANT AT GENEVA, N. Y.

Mr. C. H. Avery, the manager of the Geneva Brush Electric Light and Power Co., is about to begin extensive additions to the station and plant of that concern. The increase of floor space will be about 2,100 feet, which will be taken up by two new boilers, two 100 h. p. engines, generators for railway and stationary motor work, switchboards, etc. A large new brick smokestack with four boilers of 600 h. p. capacity is to be erected, and a new 200 h. p. compound condensing engine has been ordered, to replace the present 60 h. p. engine. Countershafting, pulleys, condensers, steam pipe, feed-water heaters, etc., are to be put in at once, to the full capacity of the plant as now designed, and the new investment will represent about $70,000.

HEAVY SALES OF BALL ENGINES.

The Ball Engine Co., Erie, Pa., report the following large shipments in the last four weeks: F. H. Leggett & Co., New York City, one 80 h. p.; Lowell M. Palmer, New York City, one 130 h. p.; H. Ward Leonard & Co., New York City, one 130 h. p.; Electric Light Co, Coulee City, Wash., one 25 h. p.; Cooley & Vater, Minneapolis, Minn., one 100 h. p.; Silver Bow Electric Co., Butte, Mont., one 150 h. p. tandem; Hotel St. Louis, Minnetonka, Minn., one 60 h. p.; Oakland Street Railway Co., Stockton, Cal., one 200 h. p. tandem; Edison General Electric Co., Joplin, Mo., one 35 h. p.; Baltimore Traction Co., Baltimore, Md., one 130 h. p.; Washington Park, Chicago, Ill., one 35 h. p.; Pittsburgh Iron & Steel Engineering Co., Pittsburgh, Pa., one 50 h. p.; Risdon Iron Works, San Francisco, Cal., one 35 h. p.; Brooklyn Cooperage Co., Brooklyn, N. Y., one 130 h. p.; Hotel Vendig, Philadelphia, Pa., one 50 h. p.; Schuylkill Electric Railway Co., Pottsville, Pa., one 300 h, p.; Rome Street Railway Co., Rome, Ga., one 130 h. p.; Duluth Street Railway Co., Duluth, Minn., one 50 h. p.; Pittsburgh Locomotive Works, Pittsburgh, Pa., one 100 h. p.; Curtis & Dean, New York City, one 80 h. p.; Risdon Iron Works, San Francisco, Cal., one 200 h. p. tandem.

THE WATERTOWN STEAM ENGINE CO.

The handsome catalogue published by this company, of Watertown, N. Y., embraces a large variety of steam engineering products, chief among which, as of interest to electric light and power companies or for isolated plants, are their automatic cut-off engines, for which are claimed the features of great simplicity, few parts, extreme durability, quick sensitiveness in meeting changes of load, freedom from variation in speed, equal efficiency at different points of cut-off, and low cost. The engines are well built and capable of severe test. The Watertown Company build, also, a line of boilers.

THE BALL ELECTRIC LIGHT COMPANY.

A **very** handsome and interesting catalogue has just been issued by the Ball Electric Light Company, of 404 West 27th street, New York City, illustrative and descriptive of their apparatus. The designs on the front and back covers, printed in blue, white and gold, are so arranged that the lamp on the front, as it hangs up, is in direct circuit with the Ball machine on the back. The effect is very pretty and pleasing. The frontispiece of the pamphlet is a fine engraving of the celebrated Ball machine, once the subject of so much animated controversy, and the first part of the contents explains the merits of the Ball system, the Ball dynamo, the Ball communtator, armature, arc lamp, reciprocating carbon, all-night lamp, long-distance series incandescent system, etc., all of which are clearly illustrated. Then follows a big batch of testimonials, and this is supplemented by a very long list of users of the Ball system, many of whom have plants that have been in constant operation for years, the plants being of all sizes from 25 lights up to several hundred.

Mr. W. Scott Sims, the torpedo inventor, has been making an inspection of the Baker submarine boat on behalf of the Bureau of Ordnance, and is reported to speak very highly of what he saw at Detroit. He says it is the first boat that has been made of the kind that will ride upon an even keel.

KIND WORDS FROM THE PACIFIC.

THE PELTON WATER WHEEL Co. of 121-123 Main street, San Francisco, in a letter of recent date, say: "Permit us to congratulate you in getting into such elegant and commodious quarters. Such a move certainly affords evidence of success and prosperity. Your patrons have also reason to congratulate themselves on your ability to furnish them with unfailing regularity, information of so much value and interest."

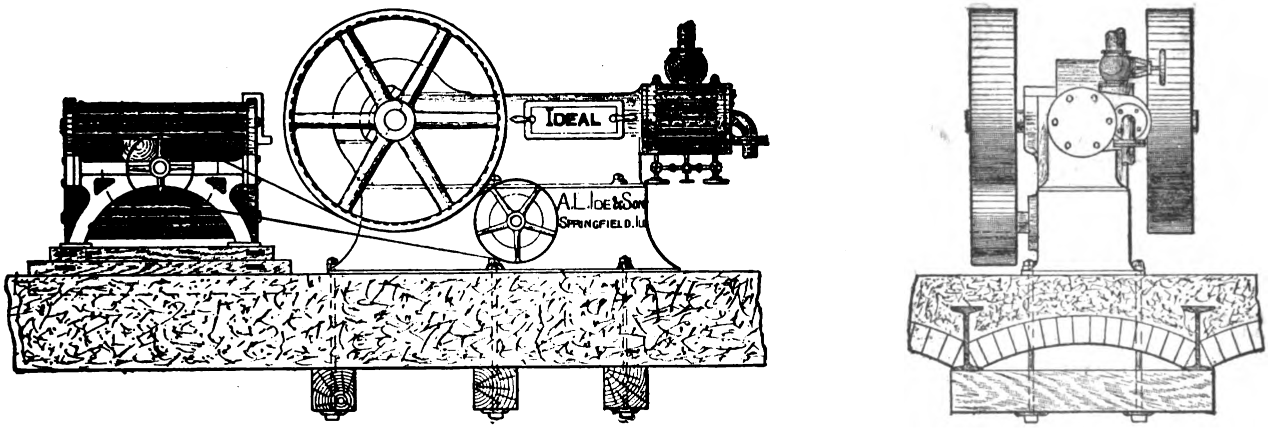
THE IDE METHOD OF DYNAMO DRIVING.

COMPACTNESS in electric central stations is desirable, not only on account of the lessened first cost of buildings and interest thereon, but also for the reason that a compact plant can be more easily supervised and maintained in good condition.

In order to reduce the space required for the engine and dynamo within as small a compass as possible, Messrs. A. L. Ide & Son, the well-known engine builders of Springfield, Ill., recently designed a method of power transmission which will be readily understood by referring to the accompanying engravings, Figs. 1 and 2, which represent respectively a side and end elevation of the plan adopted.

As will be seen, it consists of a pulley supported by a stud, which is secured to the base of the engine and requires no additional foundation or fixtures. On account of the small space required, it is especially adapted where space is limited. Two dynamos may be driven from one engine by placing a pulley on each side of the base, and either dynamo may be stopped or started, without interfering with the operation of the other machine, by sliding the dynamo on the base so as to bring the belt in contact with the lower surface of the engine pulley.

Messrs. Ide & Son have recently installed one of their 8 x 10 35 h. p. "Ideal" engines with this transmitting device driving a Thomson-Houston 250-light incandescent dynamo, for lighting the Keeley Brewing Co.'s plant, Chicago, Ill. The engine and dynamo are placed on the floor, which is composed of eye-beams or brick arches, as shown in the engravings, having no foundation or support. The engine runs at 360 revolutions per minute, and is so perfectly balanced that there is no perceptible vibration of the floor or building.



FIGS. 1 AND 2.—THE IDE METHOD OF DYNAMO DRIVING.

NEW BILLINGS & SPENCER TOOLS.

THE accompanying illustrations show two of the latest productions in small appliances of the Billings & Spencer Co., of Hartford, Conn. Fig. 1 is what is what is known as the Billings wire cutter, a device which will be appreciated by any one connected with electrical industries. It is drop forged from the best tool steel, and provided with four cutting edges on the rim, and two which are enclosed. It also has an adjustable gauge so that wire can be cut accurately to any length. The workmanship is of the same high quality which characterizes all the appliances made by the Billings & Spencer Co. The total length of the tool is ten inches.

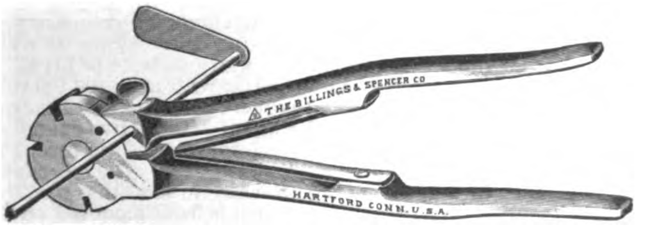


FIG. 1.—THE BILLINGS WIRE CUTTER.

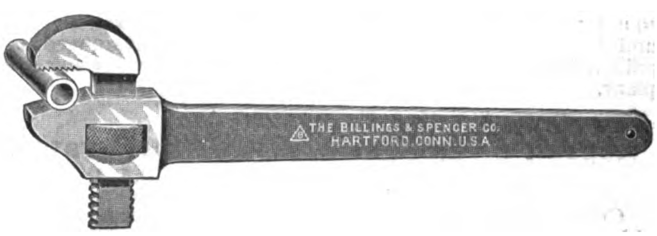

FIG. 2.—THE BILLINGS PIPE WRENCH.

Fig. 2 represents the Billings pipe wrench. The jaws of this wrench are drop forged of the best tool steel, and the handles of the best grade of machinery steel. This wrench offers many advantages, being simple in design with few parts, and characterized by the best workmanship and finish. A special feature is found in the fact that no matter how large or small the size of pipe for which it is adjusted, the angle of the jaws always remains the same. The total length is 14 inches, and is made to take pipe from ¼ inch to 1½ inches.

WARREN WEBSTER & CO.

WARREN WEBSTER & Co., manufacturers of the Webster vacuum feed water heater and purifier, 491 N. Third street, Philadelphia, Pa., during the past few weeks have booked the follow, ing orders: Cleveland Axle Manufacturing Co., Cleve land, Ohio-one 250 h. p. vacuum heater; Edison Light & Power Co., San Francisco, Cal., one 1,500 h. p. vacuum heater; Armour Packing Co., Kansas City, Mo., one 1,500 h. p. vacuum heater, 3d order; Ostrander Fire Brick Co., Ostrander, N. J., one 150 h. p. vacuum heater; Standard Kiln Dried Lumber Co., Norfolk, Va., one 500 h. p. vacuum heater; Lowenberg Knitting Co., Norfolk, Va., one 150 h. p. vacuum heater; Armour Industrial School, Chicago, Ill., one 500 h. p. vacuum heater; American Tube & Iron Co., Middletown, Pa., one 1,500 h. p. vaccuum heater; Central Iron Works, Harrisburg, Pa., one 1,000 h. p. vacuum heater; Illinois Steel Co., Milwaukee, Wis., one 1,500 h. p. vacuum heater: Joliet Enterprise Co., Joliet, Ill., one 1,500 h. p. vacuum heater; Standard Iron Co., Bridgeport, Ohio, one 750 h. p. vacuum heater, 2d order; Hydraulic Machine Co., Pittsburgh, Pa., one 100 h. p. vacuum heater; Asbury Park Electric Light & Power Co., Asbury Park, N. J., one 600 h. p. vacuum heater; St. Augustine Gas & Electric Light Co., St. Augustine, Fla., one 40 h. p. vacuum heater; Allentown Gas Co., Allentown, Pa., one 40 h. p. vacuum heater; Cleveland Rolling Mill Co., Cleveland, Ohio, one 3,000 h. p. vacuum heater, 5th order; W. F. & F. C. Sayles, Saylesville, R. I., one 1,800 h. p vacuum heater, 3d order; Cudahy Packing Co., S. Omaha, Neb., one 1,500 h. p. vacuum heater; Anhauser-Busch Brewing Association, St. Louis, Mo., one 1,500 h. p. vacuum heater; Republic Iron Works, Pittsburgh, Pa., one 1,500 h. p. vacuum heater; Edison Illuminating Co., Detroit, Mich., one 1,500 h. p. vacuum heater.

They have also booked orders from the following parties for the Williames vacuum system of steam heating, during the past few weeks: Royal Baking Powder Co., New York; Basch & Greenfield, Newark, N. J.; Eureka Fire Hose Co., Brooklyn, N. Y.; Alsip Brick Co., Chicago, Ill.; Lowenberg Knitting Co., Norfolk, Va.;

Armour Industrial School, Chicago, Ill.; Ostrander Fire Brick Co., Ostrander, N. J.; Brunswick, Balke-Collender Co., Chicago, Ill.; De La Vergne Refrigerating Co., New York.

They furnish a descriptive catalogue, and send a representative to any part of the United States at their expense, to examine plants and to explain to intending purchasers, |the advantages to be gained by adopting their system in connection with any steam plant.

MESSRS. SWINBURNE & CO. AT THE CRYSTAL PALACE ELECTRICAL EXHIBITION.

ONE of the most interesting exhibits at this exhibition is that of Messrs. Swinburne & Co., of Teddington, who show a transformer, giving nominally 130,000 volts designed for commereial use on cables. In order to test a cable of, say, 0.5 microfarad, under 50,000 volts, with a frequency of 100, a current of 12½ amperes must be available; 50,000 volts and 12.5 amperes require a 625 kilowatt dynamo. A large adjustable choking coil, however, takes or gives nearly the whole 12½ amperes. The dynamo and step-up transformer then supply quite a small current. Messrs. Swinburne & Co. are supplying a large testing plant of this kind to one of the leading cable makers, for testing a mile of cable at one time under high pressure. Fig. 1, shows a low-pressure transformer, as employed in electric welding and similar work.

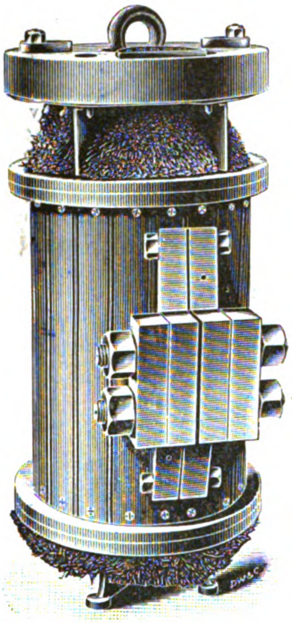

FIG. 1.

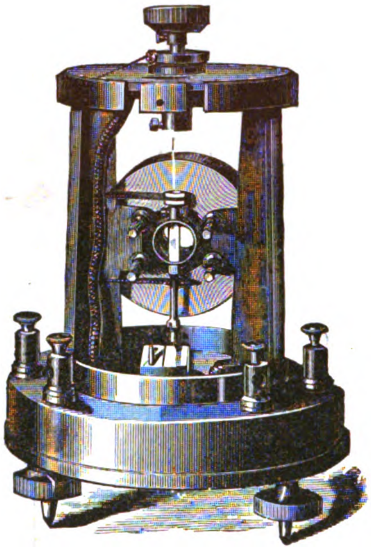

FIG. 3.

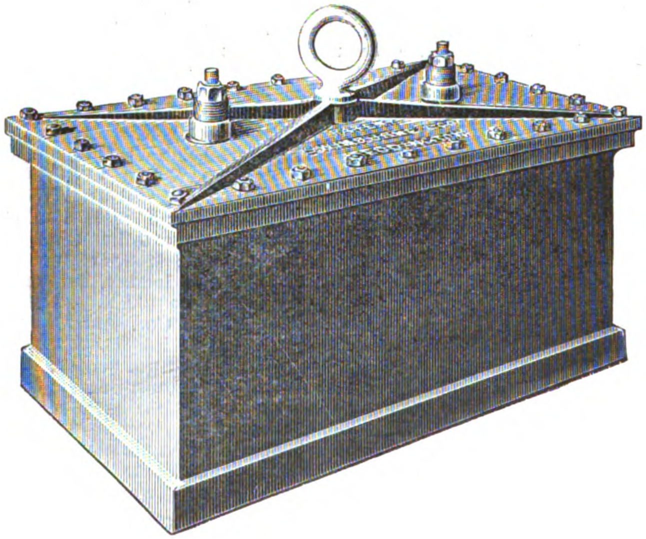

FIG. 2.

Several alternate-current condensers, Fig. 2, are also exhibited. One of these is designed for 130,000 volts for performing experiments with the high-pressure transformer for exhibition purposes. Among laboratory instruments is shown a non-inductive wattmeter, Fig. 3, designed to give accurate readings in such work as measuring power absorbed by iron in transformers. It is a dynamometer so designed that the self-induction errors are quite inappreciable. Another form of laboratory instrument for similar purposes is illustrated in Fig. 4. This is a direct-reading electrostatic wattmeter. This instrument can be used either as a wattmeter or as a voltmeter. The particular instruments exhibited were made for some interesting researches on power measurements, on which Dr. Fleming has been engaged. The Bourne form of Thomson reflecting galvanometer, Fig. 5, is designed to fulfil special requirements. The moving system consists of two vertical needles, so that the instrument is truly astatic, and is not affected by external fields.

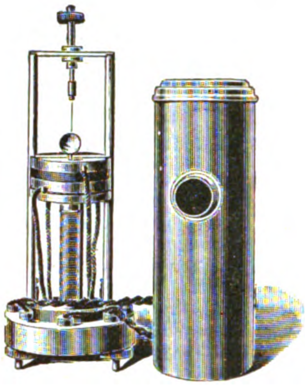

FIG. 4.

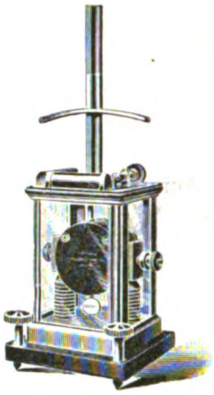

FIG. 5.

Messrs. Swinburne also exhibit a resistance box shown in Fig. 6, which differs from the ordinary form in being worked by switches, instead of plugs. The makers hold that the dial form of bridge with many coils, and a small but constant number of contacts, is more accurate than a plug with fewer coils, and a large and varying number of contacts. This form of bridge box is, of course, much quicker to use. An object of interest is a reflecting moving coil galvanometer compactly arranged in a small brass case, and having automatic gear which grips the moving system when the galvanometer is lifted. A voltmeter is also shown for measuring currents up to 100,000 volts. This instrument is on the co-axial cylinder principle, and the cylinders are immersed in heavy insulating oil. The active cylinder is connected to one terminal, the wire being carried up through a little glass tube till it is quite clear of the case. The mechanism and the other two cylinders are attached to the other terminal, and are mounted on a glass plate, which is itself mounted on corrugated ebonite pillars. The striking and creeping distances are thus very great.

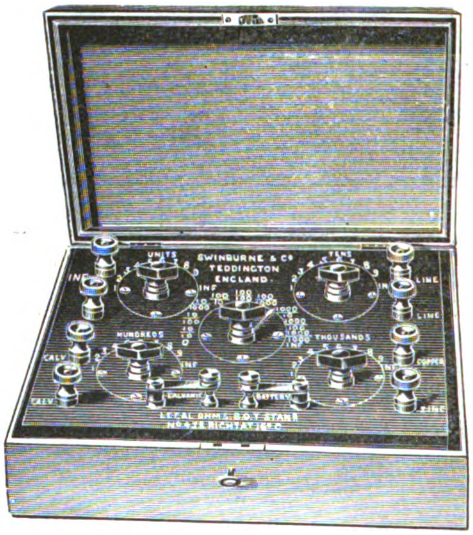

FIG. 6.

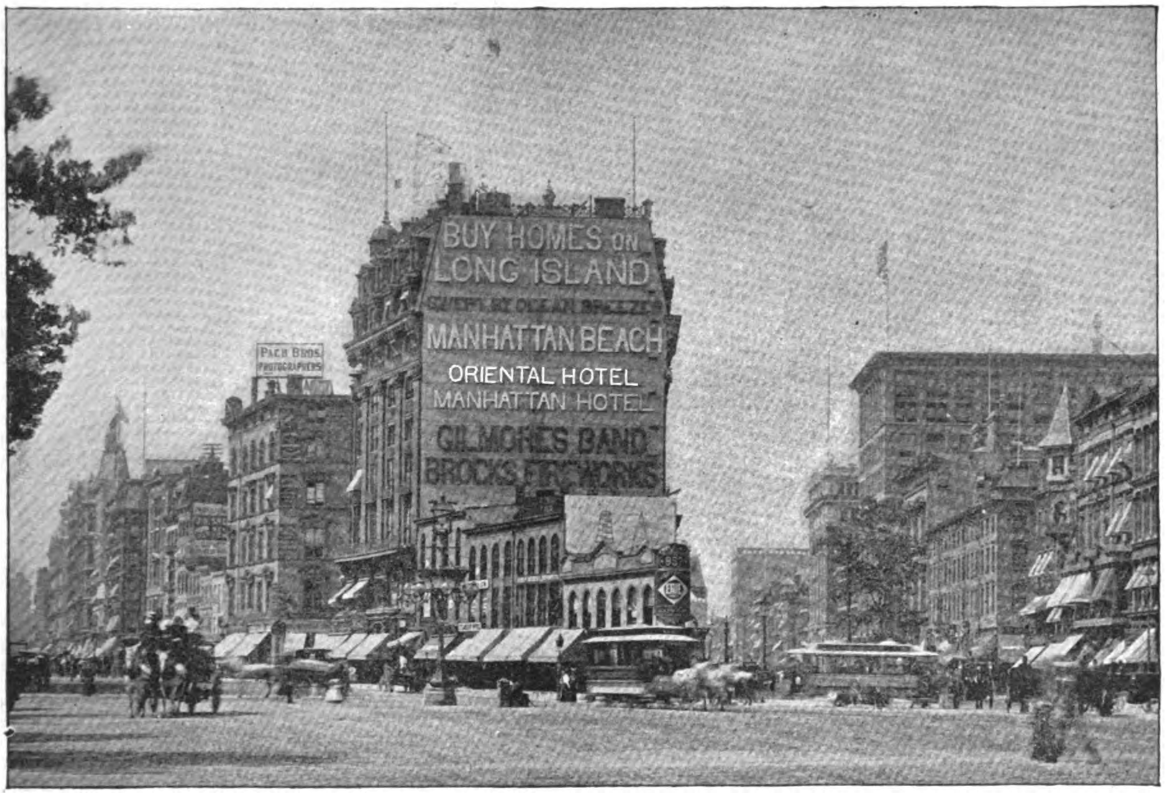
THE BALL ENGINE CO., Erie, Pa., have recently shipped to the Westminster & Vancouver Tramway Co., Vancouver, B. C., three 150 h. p. engines.

THE CORBIN ILLUMINATED ADVERTISEMENT ON WEST TWENTY-THIRD STREET, NEW YORK.

THE beautiful exhibit at Madison Square Garden, during the recent, Actors' Fund Fair, as illustrated in THE ELECTRICAL ENGINEER, of the novel developments in electric lighting by means of new small lamps, formed the initiative and experimental effort on a grand scale of a new department of the Edison General Electric Company—the Sign and Decorative Lamp Department.

The adaptability of the electric incandescent light to ornamental sign work was considered as fully proved by the success encountered at the Actors' Fund Fair, and the president of the Long Island R. R., Mr. Corbin, while viewing the many pretty effects obtained, decided to have a sign of his own, and commissioned the new department to realize his ideas.

On the corner block on 23d street, formed by the junction of Broadway and Fifth avenue, stands a small building behind which rises a huge overtowering construction nine stories high exposing a plentiful surface of blank wall over the top of its dwarf neighbors. This surface sixty feet wide by sixty-eight feet high has for the past few evenings been the study of the eyes of everybody coming down Broadway or Fifth avenue or walking East or West along 23d street. Upon the surface of this wall is erected perhaps the largest illuminated sign in the world, and certainly the largest and most conspicuous electrically illuminated sign.



THE CORBIN ILLUMINATED ADVERTISEMENT ON WEST TWENTY-THIRD STREET.

By means of this sign, Mr. Corbin brings, on these hot days, to the attention of a sweltering public the fact that the Coney Island or the well-to-do Manhattan Beach, is swept by ocean breezes, and emphasizes the various other special attractions to be found on Long Island.

In this sign, there are one hundred and seven letters, some six feet, some four feet and some three feet high, each one of which is, in reality, a box of galvanized iron. In the interior of these boxes arranged in the outline of the letters are a number of small Edison porcelain series plug cut-outs which are here used as lamp receptacles. At the lower end of each letter is a small sliding door, giving access to a plug cut-out which serves to protect the lamps in that letter. Each letter is suspended, and clasped top and bottom to two iron rods formed of strong steam piping which are securely attached to the wall by expansion bolts.

The illumination of the sign is obtained by the use of no less than 1,457—16 c. p. Edison lamps of different colors—white, frosted, red, blue and green. The current is taken from the mains of the Edison Electric Illuminating Co. There are seven sentences, each of which is on a separate and distinct circuit controlled by a lever switch. The switches are arranged temporarily on a rough wooden frame, and as the primary object of the sign is to keep the different sentences constantly appearing and vanishing, the operator is in a state of activity from dusk untill eleven o'clock at night, when all the circuits are opened and the performance ends. It is a strange fact, but true, that so long as the changes are being rung, the public is attracted and stands agape watching the sign, but as soon as the whole seven sentences are lighted and allowed to remain so, the people move on their way and the crowd disperses; 5,040 changes can be rung on these seven sentences.

From the switchboard, along the roof of the smaller building, the line is led to the base of the wall, whence the different wires run up to their respective sentences.

At the end of each line is a small platform, and between each line a long rod of bicycle steel, fastened securely to the wall, as are the letter supports, by expansion bolts. A flying ladder 8 feet long, with small wheels, fits top and bottom to two of these rods and enables the attendant to run himself along each line and replace any broken or burnt-out lamps or blown fuses, in a very few minutes. As an additional protection to the wires outside, they are run through conduit tubes thoroughly taped at their junctures, and are carried up the wall on porcelain insulators.

The great difficulty with this sign, as in the case of all outside electric lighting work, lay in preventing the deleterious effects of rain and moisture. This has been overcome by fastening to the galvanized iron box letter covers, over each hole through which the lamps are thrust into the receptacles, small pent-houses of iron which project out over the lamps, and carry off the rain, without interfering in any way with the effect of the sign. Any rain which might collect on the lamp surface is prevented from running down into the receptacle by a small projecting brass ring fastened to the outside of the lamp near the screw shell.

Each sentence is painted a different color, so that during the day the only thing lacking is the brilliancy of the illumination.

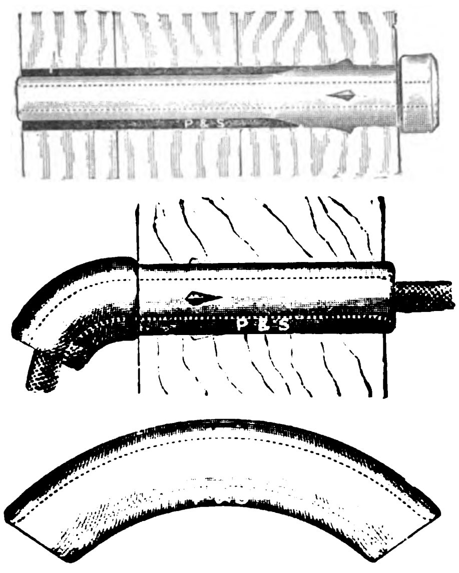
The entire work was completed in about fifty days. It was designed by and constructed under the supervision of Mr. F. R. Upton, Mr. A. D. Page and Mr. McAllister of the Lamp Works of the Edison General Electric Co.; Mr. Corbin having practically given them carte blanche.

This illuminated sign is not only a commercial success, but when all the lamps are lighted is really a thing of glory. Its splendor is visible from far away up town, and its glow on the sky can easily be seen from the East and North rivers.

MR. NEWTON L. SCHLOSS.—Increasing demands for the well-known Ries regulating socket have necessitated an increase of the selling staff, and to further the interests of their fast increasing trade, the Ries Electric Specialty Co. have secured as general sales agent for New York and the New England States Mr. Newton L. Schloss, formerly of New York, and well known in electrical circles. All will wish him continued success, and the company are to be complimented on securing his services.

PASS & SEYMOUR WINDOW TUBES AND AWNING INSULATORS.

A new catalogue has just been brought out by Pass & Seymour of Syracuse, N. Y., manufacturers of the famous Syracuse china, and in it are mentioned a number of electrical novelties and specialties in the porcelain line. Three of the minor pieces are illustrated herewith. Fig. 1 shows the new "Window Tube" intended for use where wires enter a building through windows or doors. They require a much smaller hole than the ordinary glass floor insulator now generally used, and are, it is said both better and cheaper than glass or rubber tubing. Fig. 2 shows another form of the tube, with a curved end to prevent any water entering through the tubes and complying with the insurance rule requiring a "water loop" in the line. Fig. 3 shows their "Awning Insulator," for use where wires pass awnings or over cornices or around the corners of buildings, as they give perfect protection against abrasion of the insulation. As will be seen, the insulator is very strong and is in no danger of breakage.



FIGS. 1, 2, and 3.—PASS & SEYMOUR INSULATORS.

ELECTRIC MINING IN UTAH.

MR. R. M. JONES, of Salt Lake City, Utah, has put an electric mining plant in at the Reed & Benson mine, owned by Reed & Goodspeed of Boston, and located at the head of the Big Cottonwood Cañon. The plant consists of a water power generating station with one 15 kilowatt Edison generator, from which current is transmitted three miles up into the mining district to the face of the tunnel; thence about 1¼ miles in the mine where current is supplied at 500 volts for lighting and ventilation. Mr. Jones has also supplied a rotary diamond drill of his own devising, which, he says, has exceeded in rapidity and ease of operation any other that has been tried. He has also just received another which is to go in the same mine.

NEW ENGLAND NOTES.

THE WRIGHT ELECTRICAL ENGINEERING COMPANY, of Boston, are installing the new plant of the Economic Electric Light, Heat and Power Company, at Augusta, Me. The building will be 80 feet by 42 feet, and will contain at present a 125 h. p. compound condensing Westinghouse engine, one 72 inch return tubular boiler, and two 500-light direct incandescent dynamos. The station is being built large enough for double the present capacity, and is conveniently situated on the Kennebec River, with good water and coal privileges, and ample space for future increase. Mr. C. H. Herrick, manager of the Wright Company, is on the ground himself, making all necessary plans, and looking after the construction work.

THE BOSTON BRAID MANUFACTURING CO., of Boston, the well-known manufacturers of silk braid for the filaments of incandescent lamps, have removed to much larger quarters to accommodate their growing trade, namely, from No. 28 to No. 27 Beach street, where they will continue to manufacture the same line of goods. Mr. Fiedler, the manager of the company, will be glad to see his friends at the new address.

THE ELECTRIC GAS LIGHTING CO., of Boston, are calling attention to the marvelous success of the Samson battery when used to make sparks for igniting the gas in the cylinders of gas engines, and have received some of the strongest kind of endorsements of its success in this line. The Regan vapor engine requires 125 sparks a minute, and yet with only six Samson cells and a 10-inch spark coil, the manufacturers of the engine state that they can run the engine from six to nine months without renewing the battery. Five manufacturers of gas engines in San Francisco have united in giving an unreserved testimony in favor of the Samson cell for this purpose, and state that they had never been able to use batteries successfully until they tried the Samson; now they use no other, and recommended it to all users in this line. Truly, the Samson battery is well named. Battery users should send to the Electric Gas Lighting Company for their latest circular relating to its application for gas engines. Col. Burnham has just returned from a long business trip in the West, and is now enjoying much more robust health.

THE ASHTON VALVE COMPANY, 271 Franklin street, Boston, announce that they have bought the entire plant, material and business of the Boston Steam Gage Company, together with a series of valuable patents and have consolidated the businesses. They have secured the services of the former manager of the business, Mr. H. L. Willard, long and favorably known to the trade. They will manufacture all classes of steam pressure and vacuum gauges, hydraulic gauges, water pressure and ammonia gauges and all similar instruments used in connection with steam plants, being more particularly the sole manufacturers of the Boston patent steam gauge. The reputation gained by nearly twenty years of experience in the manufacture of safety valves, and the widely recognized quality of the product of the Ashton Valve Co. will be the only guarantee needed for the quality of the goods put upon the market.

THE SUFFOLK ELECTRIC COMPANY, of Boston, has been incorporated under the laws of Maine, with a capital of $300,000, with the following gentlemen as officers: A. W. Reynolds, president; A. W. Rounds, treasurer and manager; and H. W. Body, A. C. Davies and Joseph Bennett as directors. The Suffolk Company will manufacture the Russell arc lamp, which has already attained a wide reputation, and which is the only lamp on the market using a disc form of carbon, but in addition will manufacture a new lamp, having a single pair of pencil carbons, which will nevertheless burn fifteen hours on a 10-ampere circuit, without any change of carbons. Both these forms of lamps will be ready for the market in a very short time, and the company in issuing its circular print a number of very warm testimonials as to the excellent service which has been given by the Russell lamp wherever used.

THE GOULD AND WATSON CO., of Boston, who have been long and favorably known to the electrical trade as dealers in mica, have issued a circular stating that they have disposed of their entire mica stock and the good-will of the business to the American Mica Company, who will in future conduct the main business in all its branches. Mr. George B. Watson, the former treasurer of the company, will be general manager of the new company, a sufficient guarantee that the business will be conducted with the best of care, that the interests of customers will be carefully attended to, and that the first quality of material will be furnished them at the lowest prices. The headquarters of the American Mica Company will be at Room 62, 620 Atlantic avenue, Boston.

THE AMERICAN ELECTRICAL WORKS, of Providence, R. I., inspired with the feeling of true patriotism, and remembering their numerous friends all over the country, have sent out once more their welcome 4th of July token of good fellowship—this year in the shape of a neat little miniature of the "Star-spangled Banner," with the good wish that the day might be an enjoyable one to us all. It came just in good time, and our thanks are due this enterprising firm for another very pretty decoration for the walls of the editorial sanctum. We reciprocate the good wishes, and hope that 1892 may be a banner year in the history of the American Electrical Works.

CLAFLIN AND KIMBALL, of Boston, have incorporated under the laws of Massachussetts, with a capital of $135,000, as "Claflin and Kimball, Incorporated." The officers of the new company are as follows: Adams D. Claflin, president; Marcus M. Kimball, treasurer; and George Walker, clerk. This company will continue to act as general selling agents for the Mather Electric Company and the Perkins Electric Light Company, and will also continue as electrical engineers and contractors.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

VOL. XIV. JULY 20, 1892. No. 220.

NEW ELECTRIC CRANES AT THE BRUSH ELECTRIC CO.'S WORKS.

BY

Fred A. Scheffler

THE application of electric motors to traveling cranes is assuming such proportions that this class of work can fairly be said to be a business which should require careful attention to the details in the construction both of the motor and its attachments, as well as the mechanical design of the crane itself. The latter we can leave to the crane manufacturers to take care of, and several firms have already shown great engineering skill in such designs.

A single motor crane has almost as many disadvantages in its operation and construction as the old-fashioned crane operated with a wire rope, or the improvement on it—a square shaft. Either of these three methods of operation can only be utilized by introducing a complication of double-friction clutches for reverse motion and consequent double gearing, and these are again multiplied for the required movements, provided the crane is desired to be operated by power in more than one of the three directions necessary to a traveling crane—longitudinal, transverse and hoist movements. Therefore there are usually no less than six, and sometimes many more, clutches to be operated and repaired, in the old-fashioned (this term is perfectly proper at the present writing) cranes.

Electric motors have revolutionized the crane business, and to-day the three-motor cranes (one motor for each motion) are in demand in preference to all other methods, for any kind of work whatsoever. Some work even requires an extra motor for hoisting light loads, where the main hoist is not rapid enough except for heavy loads,

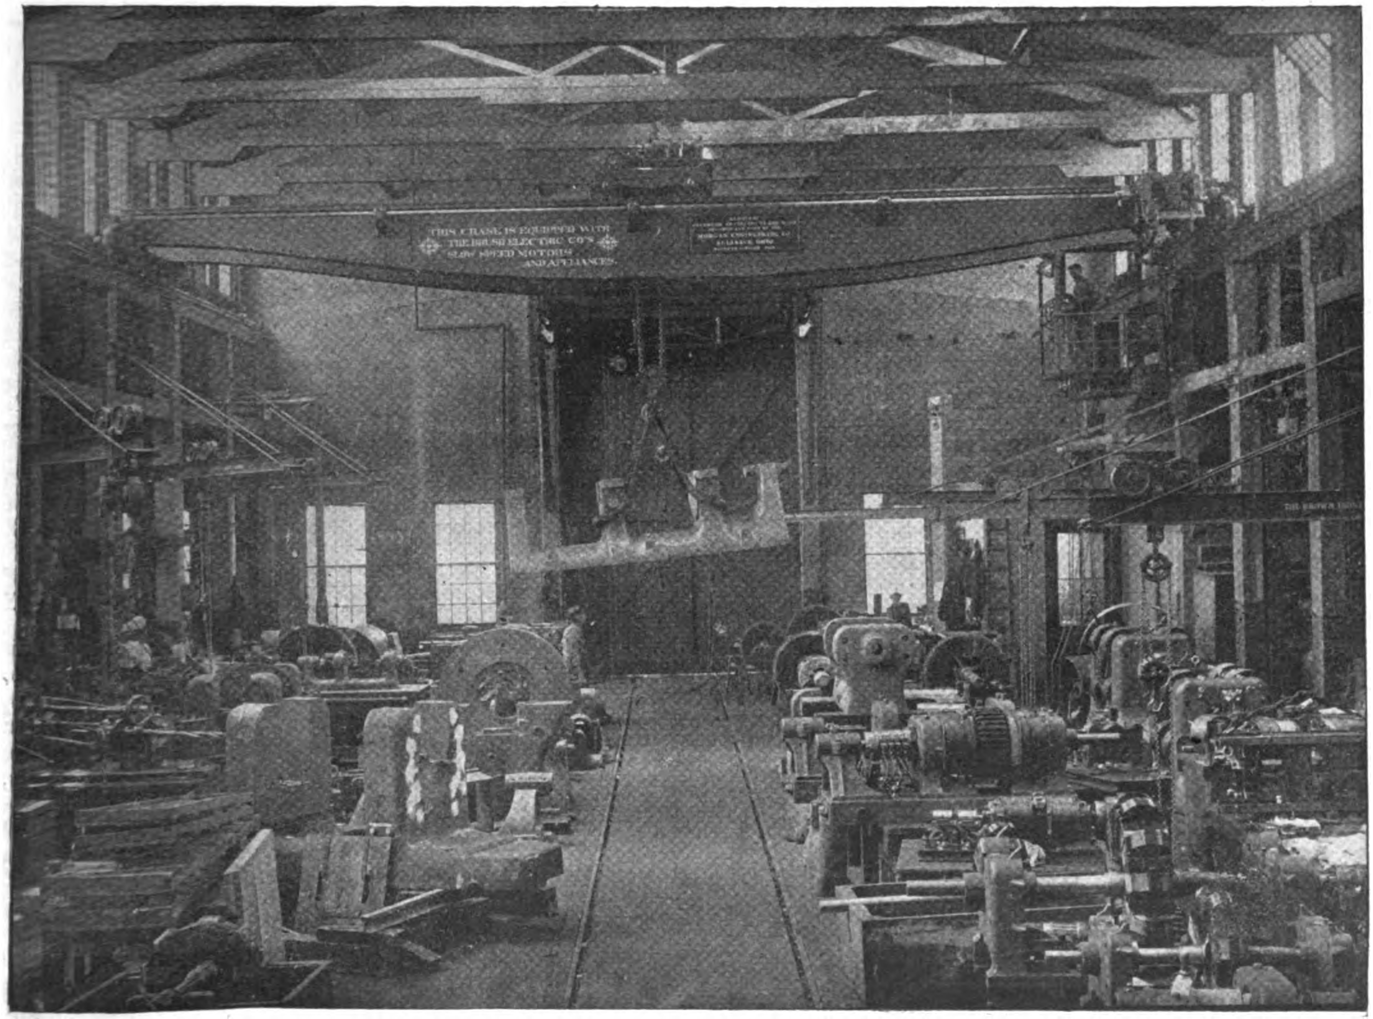

FIG. 1.—TRAVELING CRANE IN THE BRUSH ELECTRIC CO.'S ERECTING SHOP.

The custom has generally been to use the ordinary high-speed motors and by a system of a train of gears reduce the speed to a few revolutions per minute. In general the reduction has been from a belt speed of from 3,600 to 4,000 feet per minute to 150 feet of longitudinal travel and to 15 feet for hoist. The gearing necessary to do this is, therefore, considerable, and consequently the loss by friction in the gears and bearings must be very large. The writer has a decided objection to using gearing in any form where the work can possibly be accomplished by some other means, and when it was found necessary to provide the Brush Electric Company's new erecting-room at Cleveland with a traveling crane, the opportunity for developing a motor which would be specially applicable to such purposes, and others where comparatively slow speed is required, presented itself.

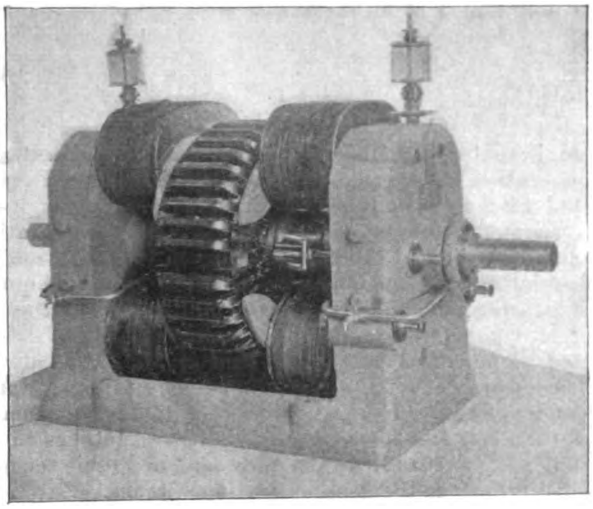

FIG. 2.—10 H. P. SLOW SPEED BRUSH MOTOR.

Fig. 2 shows the motor used for this purpose, which at 200 revolutions gives 10 h. p. with an efficiency equal to that of a high-speed motor. The crane which is shown in Fig. 1 is equipped with two 10 h. p. motors of this type (longitudinal and hoist) and one 5 h. p. for transverse movement of the trolley. The latter motor only makes 100 revolutions when developing 5 h. p. Each motor is furnished with a standard in the cage on which is mounted a hand wheel operating the rheostat for changing the speed and the reversing switch. The crane is operated on a 500-volt circuit, and can be inspected at any time by parties interested.

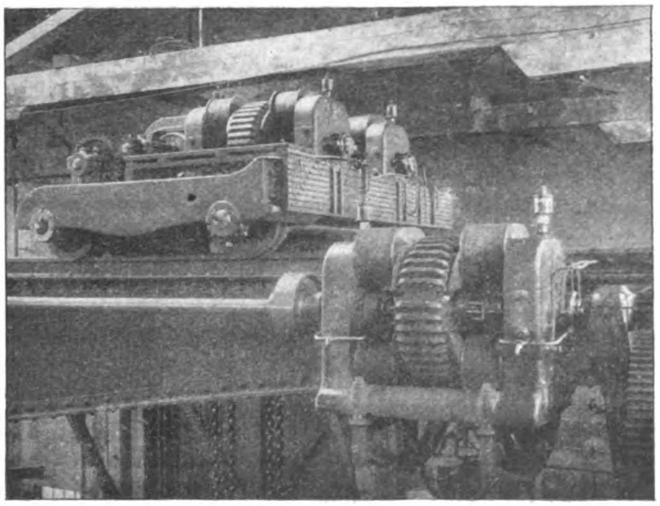

FIG. 3.—SLOW SPEED MOTORS ON CRANE.

Fig. 3 is an enlarged view showing the three motors in their respective positions for longitudinal, transverse and hoist movements. The motors are self-contained, and deviate from the usual construction of the Brush incandescent dynamos and motors in that the commutator is enclosed between the upright pieces forming the supports for the magnets, and there is therefore no out-end bearing required. This reduces the space occupied by the motor very materially. The brush holders are fixed, the motors being so proportioned that the position of the brushes on the commutator will not have to be changed when the load is varied, no rocker, therefore, being required. Carbon brushes are employed, and there is practically no sparking whatever at the commutator. The motor for longitudinal travel, as seen in the cut, is coupled directly to the shaft running across the bridge, each end of which shaft is furnished with a pinion gearing directly to the truck wheels carrying the crane so that there is no possibility of the crane being thrown out of its proper position on the track when traveling. The power for hoisting is transmitted by a simple worm and wheel, the latter being keyed to the hoisting drum shaft and meshing in the worm on the end of the motor shaft, making the reduction in speed with only one set of wheels.

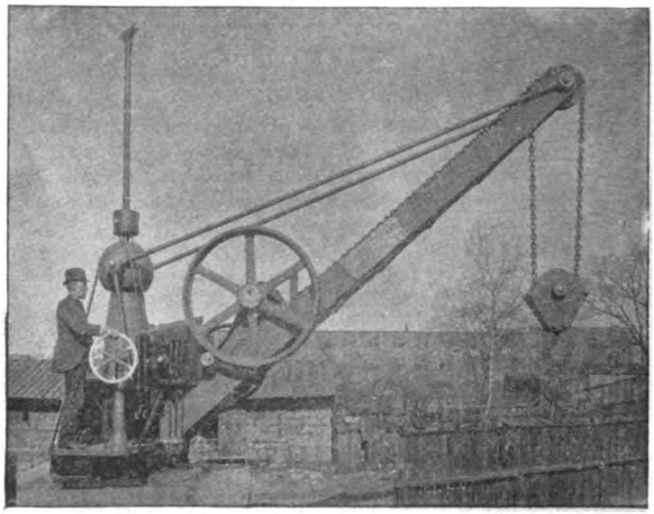

FIG. 4.—15 TON PILLAR CRANE, EQUIPPED WITH 10 H. P. MOTOR.

These motors are especially applicable also to pillar crane work, and Fig. 4 shows a 15-ton crane of this type fitted with a 10 h. p. motor running at 200 revolutions, which gears directly to the intermediate shaft, and from that to the drum shaft. The crane is fitted with the same hand-wheel contrivance and rheostat and reversing lever, and is operated on the same circuit as the traveling crane. The motor and the electrical appliances are carefully boxed in to protect them from the weather, so that the crane can be used for out-of-door work when desired.

While the above description showing the application of the slow-speed motors only applies to crane work, they are extremely well adapted for pump, elevator, general shop work, and all places where stationary motors are desired.

LIGHTNING ARRESTERS.

WE have received an inquiry as to the existence of any lightning arrester based on the principle of a discharge through vacuum in glass bulbs or tubes, and will be glad to hear from our readers who may possess information on the subject.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY—IX.[1]

BY

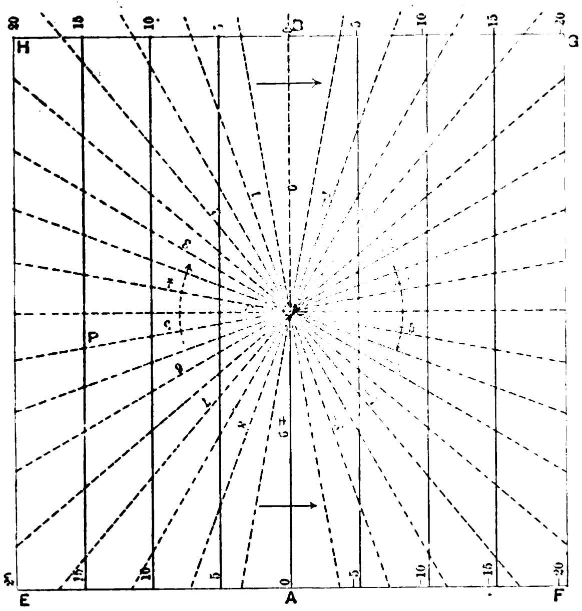
A. E. Kennelly

STRESS DISTRIBUTION.

The flux in a magnetic circuit is accompanied by a condition of stress. In a perfect fluid at rest, the stress at any point is equal in all directions. Magnetic stress, however, varies from a negative value or tension in the direction of the flux, to a positive value or pressure in the perpendicular plane. Assuming then that ether is a perfect fluid, this observed condition is an argument for the existence in it of motion for which flux is the origin, associate, or result. This is the basis of Maxwell's theory of molecular vortices.

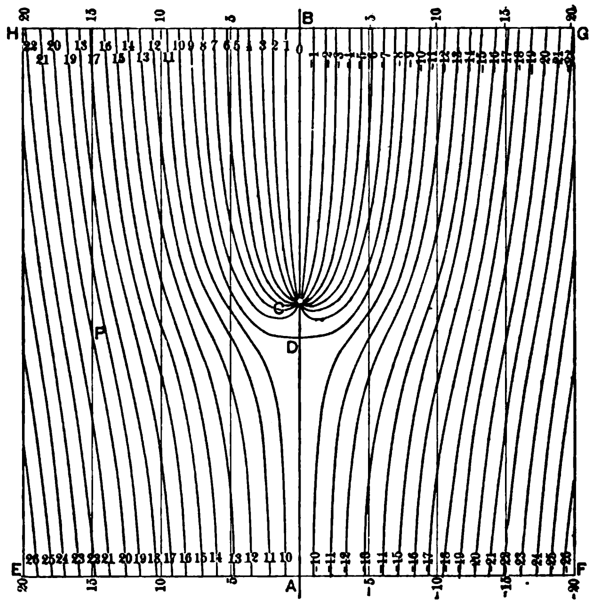
Whatever may be the ultimate cause of this stress, all the observed moving forces that are exerted between currents or magnets may be attributed to its existence. If we consider any point in the magnetic circuit where the intensity is B, the stress will be represented by a pressure of $\frac{B^2}{8\pi}$ dynes per square centimetre in all directions, like a simple fluid pressure, with a superimposed tension of $\frac{B^2}{4\pi}$ dynes per square centimetre in the direction of B. The resultant pull in this direction will therefore be a tension of $\frac{B^2}{8\pi}$, and, broadly speaking, the lines of flux tend to shorten themselves, while repelling each other sidewise. This is the fundamental moving power in nearly all electrodynamic machines.

Strictly speaking, all substances appear to have some capability for magnetization. The effect is ordinarily so feeble that it can only be discovered by placing two substances in a powerful flux, so that the difference of their magnetic properties may enable them to exert a relative displacement. Excluding therefore the magnetic metals and their principal chemical derivatives, matter is apparently unaffected by permeating magnetic flux, and the stress may be said to exert as negligibly little disturbing influence upon the substances in its path, as hydrostatic stress might effect upon a sponge immersed in the cylinder of a hydraulic press.



SCALE, ⅜ FULL SIZE.
FIG. 18.

Considering the case of a long straight wire at rest, far removed from all magnetomotive forces, it is evident that the stress set up when a current passes through the wire cannot tend to displace it bodily, for we know that the flux, and consequently the stress, is symmetrically distributed in concentric cylinders round the axis. There will be a uniform pressure on the surface of the wire tending to compress it and reduce its diameter, keeping the axis at rest. But any flux from neighboring magnetomotive forces, or from portions of its own circuit, not in its own straight line, will in general disturb this symmetry, and give the wire a tendency to move.



SCALE, ⅜ FULL SIZE.
FIG. 19.

This pressure in the case of a wire of radius r carrying a current c will be $\frac{2c^2}{\pi r^3}$ dynes per cubic centimetre of the wire's substance. Thus a straight wire carrying 30 amperes and having a radius of one millimetre would have a pressure exerted on its surface due to the stress from its own flux of $\frac{2 \times 3 \times 3}{3.1416 \times (0.1)^3} = \frac{18,000}{3.1416} = 5,730$ dynes per cubic centimetre of its volume, and a small element in or near the surface of any shape occupying $\frac{1}{1000}$th of a cubic centimetre would be forced towards the axis by a pull of 5.73 dynes. Three-fourths of this stress is due in a round wire to side pressure and one-fourth to the tension along flux paths encircling the surface.

Fig. 18 represents two systems of potential. One, indicated by the parallel straight lines, belongs to a uniform intensity. The other, shown in radial dotted lines, is due to a long, straight, current-carrying wire appearing in section at C. If the parallel lines are one centimetre apart $B = 5$ in the first system over the 64 square centimetres of space included in the diagram. Also since $4\pi c = 18$, the current establishing the second system has a strength of 1.432 or 14.32 amperes.

For numerical convenience, the cyclic elevation of potential round the wire is indicated as taking place at the line A O B in the surface of zero potential for the first system. The arrows indicate the respective directions of the flux in the two systems and are assumed to lie in the plane of the paper. The current c must therefore be flowing down the wire from the observer, since the nut on a right-handed screw rotating with the arrows would move in that direction.

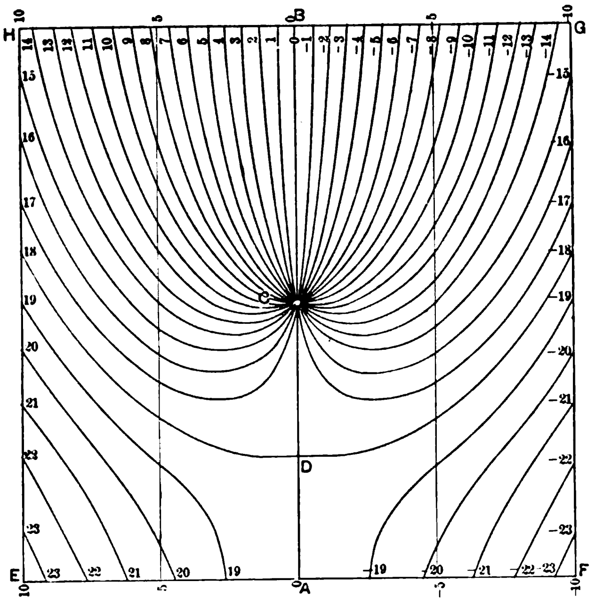
If these two systems coexist, their effects will necessarily be combined. Fig. 19 gives the resulting system, the curves representing the sections in the plane perpendicular to the wire, of the equipotential surfaces surrounding a current of 14.32 amperes in a uniform prime intensity of 5. The faint straight lines indicate the surfaces of the first system. The point P for example, which stood in Fig. 18 on the surfaces of + 15 and + 5, now resides on that of + 20. The general effect is a crowding of the contours between B and C, with a more sparse distribution between C and A. The intensity is increased above C at the expense of the region below. The potential is numerically discontinuous at the line CAD, but the gradient is uniform on the sides of the gap so that there is no discontinuity in B.

---

[1] *Copyrighted, 1892, by A. E. Kennelly.*

At the point D, the perpendicular intersection of two equal gradients there is absolute neutrality, and here the fluxes from the two systems, equal and opposite, disappear in union. The distance of this point from the centre of the wire we know to be $\frac{2c}{B}$, or, in this instance, 0.573 cm. Generally, if B represents the prime intensity, and C the vector current, the resultant intensity B^1 at any point whose axis vector is ρ in the plane outside the wire will be defined by the relation

$$B^1 = B - \frac{2}{\rho^2}\, V.\, C\rho.$$



SCALE, ⅜ FULL SIZE.

FIG. 20.

The combined influences of the tension along the lines of flux that bend over the wire, and the side pressure from the more crowded flux above, are to press the wire down from C towards A with the force expressed in dynes by the equation

$$P = V.\, CB;$$

and this relation holds in all cases for a steady, straight current C making any angle with a uniform intensity B. In Fig. 19, B and C are mutually perpendicular, their influence is a maximum, and $P = 1.432 \times 5 = 7.16$ dynes acting along CA, upon every centimetre of the wire's length. In 3 metres of this wire, the total magnetic pull would amount to 2,148 dynes or 2.19 grammes weight.

The simple equation last stated is practically important. It shows that when the straight wire is not perpendicular to the flux, but is inclined to this at an angle θ, the pull is reduced to $C\,B \sin\theta$ dynes per cm. The wire may be considered in such a case as having two components, one $\cos\theta$ along the direction of flux, and uninfluenced by stress; the other $\sin\theta$ across the flux perpendicularly. From this point of view, the whole pull is exerted upon the virtual component of the wire's length at right angles to the flux. Again, if the wire is not straight, or the flux not uniform, it becomes necessary to subdivide the length into such a number of smaller sections that the wire may be considered straight and the field uniform in these narrowed limits without sensible error. The pull must then be found for each section separately, and the resultant of all the actions determined. In some cases it will be possible to avoid this tedious process by finding an average by inspection; in others the rules of the integral calculus will be applicable. But however complex the arrangement in the number of wires or the difference of strengths of current they carry, the fundamental principle is the same,—the pull on each element $d\,l$ of conductor carrying a current c in an intensity B making an angle θ with its direction, will be $d\,l\,.\,c\,.\,B \sin\theta$ dynes directed perpendicularly to the local plane of B and C; and each element acts independently of all the rest. The direction of motion is perhaps best remembered by Fleming's rule, often useful in dealing with motors. If the *f*irst *f*inger of the left hand points in the direction of *f*lux (that is by following the north-seeking end of a compass needle), and the bent middle finger, the current,—the outstretched thu*m*b perpendicular to these will point out the direction of *m*otion.

We have hitherto assumed that the prime flux was not altered by, but merely compounded with, the flux due to the currents in the wire or wires. If, however, the flux of the currents alters the prime distribution, as might take place in the vicinity of iron by the establishment of induced M. M. F.'s, these alterations would have to be accounted for and effected in B, if they are of sufficient importance to affect the result, in order to arrive at the true moving forces.

Fig. 20 gives the resultant potential system for a straight wire with $C = 2.864$, and uniform prime intensity $B = 2.5$. P has the same value as in the preceding case of Fig. 19, the prime flux being halved, and the current doubled. It is to be observed that notwithstanding the equality of forces in the two instances, the distributions of potential and therefore of flux differ materially.

NOTE ON THE NATURE OF ELECTRIC CURRENTS.

BY

William James Morton, M.D.

It has long been noted that when a piece of cardboard is pierced by the disruptive discharge or spark, a burr or protuberance is produced upon *each* of its faces. No satisfactory explanation, so far as I am aware, has been offered of this phenomenon, but the experiment is often cited as furnishing an inference that something has acted upon the cardboard in opposite directions at the same instant. The experiment does not prove that the forces acting pass by each other. Mascart, in giving expression to the commonly accepted view, says:

"The paper appears to have become electrified by induction, and each of its two surfaces seems to have been attracted by the nearest point of the two metallic conductors."

And Sprague says: "If a discharge be passed through a card by pasting upon its two sides pointed pieces of tinfoil with their points not quite opposite, there will be a burr produced upon both sides, indicating that the force is not a penetrating one but a pulling one, acting by attraction from each pole." A simple experiment, which I here outoutline, throws, it would seem to me, a new light upon the nature of the disruptive discharge, and possibly upon the nature of electric currents in general.

If, in place of a single piece of cardboard, a pad consisting of numerous sheets, say fifty or more, be caused to be perforated by the spark of an influence machine, to each of whose prime conductors is attached a Leyden jar whose outer tinfoil coatings are electrically connected, a new set of appearances from any described may be found upon careful examination of each sheet. The disruptive spark discharge has, in its progress, left a record of certain peculiarities of its passage, like the imprints found of fossils. The two outside sheets will exhibit the characteristic burr or protuberance, of a conical shape, but as successive sheets are lifted (the entire pad is united like a book at one end) it will be observed that each exhibits a hole, one-half of whose rim is an indentation and the other half a lip or projection. The appearance is as if two needles had been thrust by each other in making the same opening, each one thrusting the paper before it in opposite directions; or again as if two express trains had been rushing by each other throughout the length of the same tunnel, scraping along fragments of plastic walls, one in one direction the other in an opposite direction. The two trains must be supposed to be practically frictionless as regards each other, but accompanied by friction as regards the tunnel.

The deduction may be indulged in that the spark discharge consists in like manner of two elements corresponding to the two polarities, which travel in opposite directions and in relation to each other.

But further examination discloses that the two opposite moving forces have not traveled in the same plane, as is the case with the trains, but that, being free in space and untrammeled by gravity and a fixed track, they have spiraled around each other for a certain distance, then abruptly and mutually changed the direction of their spiral turns to an opposite direction, and repeating their sudden changes several times in the distance of an inch. This fact is demonstrated by lifting the perforated sheets of the pad one by one and observing that the projection (or the indentation) upon their face is found to progressively change its point of compass. Starting, for instance, at the left or west end of the paper, Fig. 1, the burr will be found, as each sheet is lifted, to be more and more to the east, or may extend even to beyond the south; its direction then suddenly changes, passes back again by way of the south, even to the west, and so on, presenting several such alternations in a distance of half an inch.

Fig. 2 indicates the usual appearance of a single sheet of paper perforated by a spark. Fig. 3 represents in a schematic manner that upon any of the inside sheets of a large number, closely approximated as in a writing pad; each face exhibits both a projection and an indentation.

I may here also mention another simple experiment pointing to a rotary action of the current. If a piece of moistened fine cotton thread, say about 4 inches in length, be tied to the ends of each discharging rod, the thread will, upon approximating the rods (the influence machine being in motion), twine about each other several times. If the threads are dry this action will not take place, nor will it if they are too wet; when dry, they fly together and apart without twisting, when wet, upon the first contact they adhere and convey all the current without further movement.

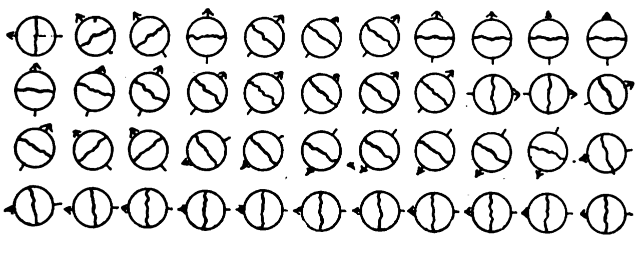


Fig. 1.

The experiments suggest:

1. That the electric disruptive discharge or spark consists of two parts traveling in opposite directions, together constituting a current.

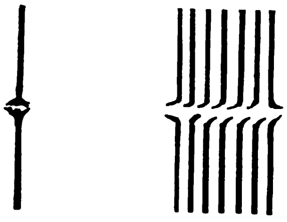
2. That these two parts move in opposite spirals around each other.

3. That, in the spark form, the direction of the spirals is frequently and mutually alternated.

5. That the angular, broken, or zigzag appearance of lightning and of large and long sparks represents the point at which the alternations in direction of the double spirals occur.

5. That if in the air-gap part of an electric circuit a "current" consists of two parts oppositely spiraling around each other the same may be true of the current in the metallic or "conducting" part of the circuit.

6. That two spirals moving in opposite directions and upon each other must be subject to friction and thus occupy time in their progress as well as present other phenomena of friction.



Figs. 2 and 3.—Paper Perforated by Sparks.

But whatever deductions may be indulged in, the experiment itself would seem to be new and, as pointed out, possibly suggestive.

THE CITY AND SOUTH LONDON ELECTRIC RAILWAY.

BY

Edward Hopkinson

In the present session of Parliament no fewer than six bills have been introduced authorizing the construction of new underground railways in London to be worked electrically or the extension of those for which acts of Parliament have already been obtained. Three of these bills have passed through the House of Commons and are in an advanced stage in the upper house. The present time, therefore, is opportune for drawing attention to the results which have been attained with electric traction on the only railway in the world on which it has been adopted on an extensive scale; and the working of which during the eighteen months it has been open for public traffic is the basis upon which the promoters of the present schemes found their application for parliamentary powers; and from which they must in the future seek the confidence of the public.

That the City and South London line has been a success in the system of traction adopted is conclusively shown by the mere fact of the present schemes being brought forward, and has moreover been abundantly proven by the evidence given before the joint committe of both houses, appointed to consider the proposed lines from the general point of view of their public utility and also by the evidence given as the bills passed through committee in the lower house; but it has been pointed out that no authentic information has been forthcoming as to the actual results achieved nor any explanation of any shortcomings in its working, which must be obviated in the future.

The limits of this communication do not permit the discussion of the engineering features of the electrical plant adopted, but as my firm designed and constructed the whole of the electrical equipment of the railway, the present occasion is not inopportune either in time or place for me to give a brief account of the history of the first year's working and of the results achieved, leaving for some other occasion a discussion of the technical details.[1]

The City and South London Railway Company, then known as the City of London and Southwark Subway Company obtained its first Parliamentary powers in 1884 for the construction of a subway from King William street, in the City to the Elephant and Castle in Southwark. The success, however, of Mr. Greathead's beautiful system of constructing the tunnels, now familar to all interested in engineering matters, had been so conspicuous that the directors obtained powers in 1887 for an extension to the Swan Inn at Stockwell. Further powers have since been obtained for an extension southwards to Clapham, but this portion of the line has not yet been constructed. It was originally intended that the Subway should be worked on the cable system and contracts were actually entered into for this purpose, but the progress of electrical traction in the interval, made it necessary to reconsider the system of traction to be adopted. The Bessbrook and Newry tramway (more correctly described as a railway) had been equipped with electrical plant by Messrs. Mather and Platt and had been running with perfect regularity for three years. The weight of the trains on this line was but little less than the weight of the trains proposed for the South London line, but the cost of haulage had been proved not to exceed 4d. per train mile, although the mileage was small and consequently fixed expenses high in proportion.

The success attending the Bessbrook line induced Messrs. Mather and Platt in 1888 to approach the directors of the City and South London line and to make definite proposals to them for working their line electrically, instead of by cable. After long consideration the cable system was finally abandoned and Messrs. Mather and Platt's scheme accepted in its entirety. Their proposal was accompanied by an offer to work the line for a limited period or to guarantee the cost of traction for two years. The locomotives were to be designed for drawing trains consisting of three carriages accommodating 100 passengers, and weighing 4¼ tons each, and the generating plant was to be sufficient for working a service of 20 trains per hour. A contract was entered into with Messrs. Mather and Platt in January, 1889, and their guarantee accepted, that the cost of haulage exclusive of drivers' wages should not exceed 3½d. per train mile for the maximum service proposed, viz., 384,800 train miles in the half year, and according to a sliding scale, if the mileage were more or less, increasing up to 7½d. per train mile for 188,666 miles, the actual mileage accomplished. The works were completed in November, 1890, and on the 4th of November were formally inaugurated by the Prince of Wales accompanied by the late Duke of Clarence.

On December 18, 1890, the line was opened by public traffic; and has now completed eighteen months' running. During this time Messrs. Mather and Platt's locomotives have run more than 500,000 miles and have provided for a traffic of more than 7,000,000 people; but this statement alone does not fully represent the work which has been demanded from them. Owing to the carriages being made stronger and heavier than originally designed, the actual load of each carriage being 7 tons instead of 4¼ tons, the weight of the loaded train was increased to 42 tons, or more than 40 per cent. heavier than the trains for which the locomotives were designed. Of this great increase in the loads which their locomotives were to draw, Messrs. Mather and Platt had no intimation until after all the locomotives were constructed and delivered, and arrangements had been made for the opening of the line. Under such unexpected circumstances the locomotives have at times been overstrained, and delays to the traffic resulted, and the wear and tear has proved somewhat greater than originally anticipated, yet the record of work done by the electrical locomotives in comparison with the work done by steam locomotives is extraordinary. Leaving out of consideration one of the locomotives of special type made for the purpose of testing its comparative efficiency, the average mileage made by the remaining 13 locomotives during the first year of work exceeded 27,000 miles. On the Metropolitan district railway the yearly average of their locomotives appears to be less than 20,000 miles.

The cost of working has proved equally satisfactory. Although the formal guarantee of Messrs. Mather and Platt was not taken up on account of the carriages failing to comply with the specification upon which they were requested to base their calculations, yet their estimate of cost has been amply justified. During the second six months of working, according to the published half-yearly accounts, the cost of locomotives and generating power, including wages, repairs and renewals, was £6,199, for a mileage of 188,666, or less than 8d. per mile. If allowance be made for the drivers' wages, which were excluded from the original estimate, this is equivalent to about 5½d. per train mile, 25 per cent. less than the amount guaranteed by Messrs. Mather and Platt, although the weight of the trains had been increased 40 per cent. These facts are the more striking when the difficulties of adequate and regular inspection of the rolling stock of a line entirely underground are considered; difficulties which do not obtain in the case of any ordinary railway, and when it is further remembered that the entire system of working was novel, to which the employees of the company were unaccustomed, and for which they had received no special training. Under the able management of Mr. Basil Mott, the company's engineer and Mr. T. C. Jenkin, the general manager, it is probable that the working expenses will be still further reduced, while the mileage and traffic receipts are being steadily increased.

The distinguishing feature of Messrs. Mather and Platt's locomotives is that the armature is constructed directly upon the axle, and the magnets supported partly upon the axle and partly upon the frame. Probably this design, obviating all gear and reducing the mechanism to the simplest elements, has contributed more than anything else to the successful working. For the heavier trains which will be required for the working of the new lines there will be no difficulty in designing heavier and more powerful locomotives on the same principle. In the schemes now under consideration Mr. Greathead is proposing larger tunnels 12 feet in diameter, instead of 10 feet, as in the case of the City and South London line. This will greatly facilitate the construction of larger locomotives and more commodious and comfortable carriages, which are the chief points necessary to ensure the success of the new undertakings.

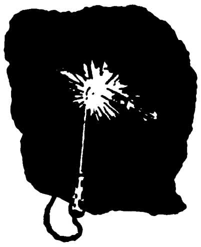
AN EIGHT-FOOT SPARK.

At the recent Royal Society conversazione Mr. James Wimshurst, says *Engineering*, gave another proof of his fertility of invention by an entirely new demonstration. He had a number of metallized surfaces 9 feet long, covered with copper, tin, brass and other metals. At each end of such a surface he placed a Leyden jar; some of the jars were coated with tin and others with brass. When the jars were charged from one of his large machines they threw out sparks over the coated surface, the color depending on the metal employed. With brass they were a vivid green, with tin a dazzling white. At first the sparks appeared at the edges of the jar, and as they gathered strength, radiated beyond them. Gradually they became like adders' tongues darting in all directions, and beating themselves on the metal surface in a futile attempt to get away to earth. At length the tension rose until the electricity found itself able to fling itself over the entire distance from jar to jar, and the magnificent spectacle of an 8-foot spark was seen.

---

[1] A complete, illustrated description was given of the road and plant in THE ELECTRICAL ENGINEER. Vol. X, No. 134, Nov. 26, 1890, p. 585.

MODERN STAGE LIGHTING.—"SINBAD" AT THE MADISON SQUARE GARDEN.



"*Lightning.*"

THE importance of good lighting upon the stage is only second to that of a good cast, and a very clever piece, well set, well costumed and well acted may be marred at its first presentation by inadequate lighting effects. The average theatre goer, in fact, has no idea of the amount of light used, nor how ingeniously it must be thrown exactly on the right spot at the right moment to produce the proper effect. There must be no sudden glare when dawn breaks; no jerky gradations of twilight when the sun sinks behind the hills; the whole system must be so perfectly under the control of the person in charge that it will instantly respond to the requirements of the piece, as circumstances demand, and leave the spectators with a pleased sense of completeness in the whole. To be perfect it must be as unobtrusive as the daylight, and suggest its mechanism as little.

It seems singular, in view of these facts, that the electric light has not been used more extensively in the theatres of this country, at least where managers are certainly unsurpassed in enterprise in other directions. Incandescent lamps in footlights and borders are, of course, almost universal, but there has been no serious effort made until very recently to supplant the clumsy, noisy and expensive calcium by an electric arc lamp, though the latter is easier to control, much cheaper to operate, takes less space and is practically noiseless.

The first spectacular production in this city where such a system has been wholly and successfully adopted is the extravaganza "Sinbad," now running at the Garden Theatre under the management of Mr. Wemyss Henderson, of Chicago. The lamps used are the invention of Messrs. W. O. Meissner and Martin Krueger, and are under the direction of Mr. P. Armstrong, who, by the way, is so deeply impressed with their usefulness that he has disposed of his interest in the Chicago Calcium Light Co. and thrown his influence on the side of electricity *vs.* lime. There are fourteen in use, each of 4,000 c. p. but toned down considerably by refracting shades of ground glass. They are run on the regular incandescent street circuit from the Edison mains, and hence the current can be taken from the regular bunch light pockets, no extra wiring being necessary.

A comparison of the relative merits of the arc light as compared with the calcium is of especial interest. Each of the latter requires a man to operate it, while the whole set of arcs may be controlled by one man at the switchboard; the calciums are practically stationary, while the arcs are perfectly portable; and last, but none the less important to the management, the cost of one calcium is from $1 to $1.50 per night while that of one arc is from 19 to 20 cents. These lamps, by the way, are used successfully in St. Louis for racing at night, and it is intended to use about 100 of them on floats at the dedication of the World's Fair.

In addition to the lamps on the stage, there are two similar ones in the color box in the centre of the gallery, and close beside them, so that all may be readily operated by one man stands the "vision light," a lamp of the same character, but provided with an adjustable lens and a reflector, and capable of being turned about in all directions. The switches for these three lamps are fixed upon the gallery rail at such a height from the floor that the operator can throw them with his knee while his right hand is occupied with the color box and his left with the lens.

These gallery lamps play an important part during the shipwreck scene in the second act. The twilight is made by four stage lamps and the reflector; for the moonlight that follows, one stage light is used, covered with a green gelatine shade, the border lights being turned low; then comes darkness, followed by the storm, and as this clears and the ship is seen sinking, the green shaded stage lights are supplemented by both of the color-box lights, while the reflector is concentrated upon Sinbad slowly rising from the bottom of the sea.

The lightning during the storm is particularly well done, and the apparatus for producing it is absolutely unique. It consists of one old file, one equally old piece of brass rod and one dead short-circuit. Real lightning is the result, and the effect is perfect.

The remainder of the play offers no other opportunity for such a striking piece of work, but notwithstanding, one cannot but be impressed with the evenness of it all. It is to the credit of Mr. Henderson and his assistants that they have been the first to give to electric stage lighting an impetus which is bound to bring it into favor at no distant day with other managers who wish to keep abreast of the times.

SOME NOTES ON THE EXECUTIVE MANAGEMENT OF STREET RAILROADS.

BY

A. K. McCay.

THE importance of this branch of railroad operation will not be gainsaid by any one. Executive ability is born, not bred, and as a manager has this quality so also is his worth. By the executive branch of the management may be understood the whole management of employees, from the officer directly under the manager, to the day laborer on the track; also the management and direction of all supplies bought, promotion of travel, accidents, and the dealings with the municipal government.

The writer will assume that an entirely new road is being built ready for the executive officer to take charge and will briefly refer to the departments and to the problems to which a manager should particularly apply himself. But before going into details the writer wishes to impress upon owners and directors of street railways the absolute necessity of allowing the manager *full* and *free* control; he should be the absolute and not the nominal head, directing and guiding its policy in every branch. It has been demonstrated too often that a board of directors *cannot* sucessfully operate a street railway. Choose your man, in whom implicit confidence can be placed and who has the best and permanent interests of the road at heart, whose zeal and experience are known; then allow him to exercise unhampered and unfettered control.

When these powers have been conferred, the manager will begin by appointing his assistants, namely, the electrician and superintendent; these two offices can be combined in small roads. The conductors, motormen, car cleaners, and inspectors will be under the superintendent, and should be engaged by him. The engineers, firemen, oilers and linemen will be under the electrician and he should be allowed to engage them. This matter of allowing the superintendent and electrician to engage their own men is a great help to them in maintaining the discipline of the road. The men will work better, have more respect, and be more strictly obedient to the man who engages them than to one they recognize as subordinate to the manager. The moment they see that the manager reposes confidence in the electrician or superintendent, the same moment will they accord him additional respect and prompter obedience.

A time-table should be prepared and submitted to the manager, together with a code of rules, and conductor, engineer and car inspector reports. Every day these various reports should be handed to the superintendent and electrician, so that each morning they can in person report to the manager, noting in detail anything which may have occurred the previous day.

Having then thoroughly organized his force, through his two lieutenants, and having gone through and sifted the rules and reports and satisfied himself as to their usefulness and practicability, the manager can turn to the purchasing of supplies. These should all be bought from the manager's office; the superintendent and electrician inspecting whatever comes to their respective departments, recommending or disapproving, together with reasons, in writing, their supplies. In this manner the best of coal, oil, grease, etc., as suited to the exigencies of the occasion, will be secured.

The question of travel will next engage the manager. It is assumed that the road is situated in some city of moderate size where the cars are not overcrowded and that travel must be more or less created, or at least encouraged. Having made the schedule, and having operated the same for a short while, the conductor reports should be examined. From these can be readily obtained the hours of the day when travel is the heaviest. Extra cars should be run during these hours, and during the lightest hours cars may be taken off.

Of course on some days of the week travel will be lighter than on others. These should be noted and if possible special attractions should be offered to promote travel. During the summer months this can be very easily done by concerts held in some park or hall at the end of the line. The manager should exercise every ingenuity to furnish attractions of one sort or another which can be obtained without *too much cost,* which shall attract crowds. The writer knew a case in which a manager spent some five dollars on a set of negro camp-meetings, feeding the colored people till they became self-supporting, which was in a day or so, and receiving back some three hundred dollars in car fares during the time the meetings were held. A manager must be quick to grasp the opportunity of carrying the crowds on such occasions, giving full and ample accommodations for riding, as nothing will detract from amusements so much as a poor return service. If he has insufficient car capacity, try to move them in sections, prolonging the entertainment to hold part of the crowd while a portion is being moved.

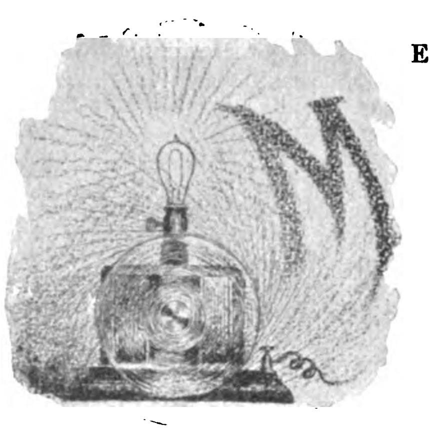
In winter the same plan should be pursued; a skating carnival, a dance, or a concert in some hall towards the end of the route will prove attractive and increase receipts. Too much attention cannot be paid to this branch, with liberal assistance to any enterprising individual who wishes to open a pleasure ground at the end of the route.

Accidents will happen on the best regulated roads; and only one piece of advice is necessary, that is, to compromise. The writer knew of a road which was unfortunate enough to run over a capitalist and kill him. The widow had ample means to fight the company; but by excellent management of the case, it was compromised at *two hundred* dollars!! The road should endeavor to pay such claims by tickets, or privileges granted; actual cash being the last and final resort. Delay is a very potent factor in the settlement of such cases, and the collection of evidence *at the time* may be *invaluable.* The rules should state, that in case of an accident, the conductor and motorman should get the names and addresses of *all eye-witnesses* and make a written statement of the affair to the superintendent, who in turn will report to the manager.

Every manager will be called on to cope with the city fathers, either in getting a new franchise, a side track, or placing a pole. A general piece of advice which may prove useful is to meet and conquer them individually before being called before them collectively. Count noses, only be sure they are counted correctly. A manager who requests a grant from the council and who does not consult them individually before presenting the same, is not wise, and will oftener be denied than granted the privilege.

An executive officer who is thus equipped, with a pair of good lieutenants, the best men obtainable as employees, a ready and facile ingenuity for promotion of travel, and a mild form of diplomatic ability in dealing with the aldermen, cannot fail to render a good report both for himself and for his road.

THE DAY OF THE FAN MOTOR.



MERCY is certainly not strained in quality this weather when it takes the form of a cooling breeze from a fan motor, for it would be hard to imagine anything more grateful and refreshing. The appreciation of the benefits of a steady flow of air has become very keen, and it seems likely that the public will in due time expect fan motors and free breezes as a matter of course, just as it now does ice water. In fact there can be no question that the use of electric fans invites business, and we know of one large New York restaurant down town that suffers loss of patronage because it is without them. One of the customers remonstrated with the proprietor the other day, and was told that the reason was that he had had trouble with the electric light 10 years ago. Thus do the sins of the pioneers come back on those who have a good thing to sell!

Be that as it may, the reports as to a good "fan motor" season are very general. In many parts of the South, it has ceased to be a "season" trade, and a man now on taking a store thinks of his fan motors as among the first fixtures to be secured. The number of fan motors sold in the South this year is very large, and throughout the country the demand has been excellent. It would have been even larger, were there more circuits to put the motors on. For alternating fan motors the inquiry has been peculiarly brisk, while 500-volt motors especially for railway circuits, which it is already the custom to tap, have become a standard article.

Now that the fan motor has won its place, and bids fair soon to be as numerous as the sewing machine, some makers are seeking to win attention by novelty. In this line, the pivoting fan which travels around its base distributing a breeze in every direction with the strictest impartiality, has made a decided hit, and we may look for changes to be rung on the idea. A popular novelty is the little motor in the shape of a ball or globe; and this is ingeniously hung sometimes from the ceiling by chains, so that it can be swung in any direction or can send its breeze down or up at any angle.

Not only are the makers aiming at novelty, but the users are striking out after novel advertising effects with fan motors. It is confidently expected that before long, hotel proprietors will make a special card of having a fan motor in every bedroom. But it has also been found that very funny effects can be created with the breeze. Hence the pretty device is often seen of red, white and blue streamers flapping and fluttering like pennants in a gale, the current of air that keeps them up coming from the adjacent fan. Just to watch them gives a feeling of coolness. A startling variation on this idea has lately been tried by an enterprising storekeeper, who filled up his window with a lot of white feathers and then set an electric fan running near by. The appearance of the window was fantastic in the extreme, and two policemen were required to keep moving the crowd of those who wanted to see the "feather-dance."

A very amusing scheme to pique public curiosity in this way has been hit upon by J. H. Bunnell & Co. at their electrical supply store on Cortlandt street, this city. In the window are displayed a number of fan motors of various sizes. It is clear to all that they are without electrical connection, yet some are moving in one direction, and some in another, and all at different speeds. An inquisitive crowd may be seen around the window at all times, wondering and expressing admiration like so many exclamation points. Others in the throng discuss the question : "What makes them go?" Among those who stopped to see the sight recently was the editor of an electrical journal, who explained loftily—as editors often will in such cases when their superior wisdom is appealed to—that there was a concealed connection somewhere. He felt taken aback, on going inside to prove his theory, to find that the motors had no connection at all with any circuit. The explanation of the mystery is simple. At one side of the window is an alternating current motor whose fan revolves so quickly that it is not easily noticed. The other fans are stationed opposite to it, and in places of the best advantage to catch the breeze. They revolve according to the pitch of their fan blades, and each makes obeisance to the master fan like the historic sheaves of wheat around the central one. The trick is clever, and deserves all the success it meets with in drawing the gaze of the public that way.

EXHAUSTING INCANDESCENT LAMPS BY MEANS OF MERCURY PUMPS.

BY

J W Packard

I do not wish to enter into a discussion regarding the relative merits of mechanical versus mercury pumps as used in exhausting incandescent lamp bulbs, but simply to correct a generally accepted opinion that the cost of lamp making will be materially reduced by the adoption of the mechanical pump. The following are the actual figures of the cost per lamp in the pumping department of a medium sized factory, exhausting about 2,000 lamps per day:

Labor, pumpers	$0.00727
" glass blowers	.00583
Repairs and supt	.00191
Material	.00077
	$0.01578

This gives a total of a trifle over one and one half cent per lamp.

These figures are from actual practice, and will of course vary slightly, but are neither above nor below the average, and represent the total cost of pumping for finished lamps. In some larger factories I have no doubt that the cost is materially less than this, while in others it probably runs up as high as three to four cents per lamp. There is a mistaken impression that mercury pumps as at present used require a great deal of attention. In the case of the factory mentioned above and in any well-equipped modern lamp factory, using the so-called Geissler pump, the pumps are absolutely automatic, the mercurial pistons rising and falling with clock-like regularity during the entire time that the factory is in operation, the labor of the pumpers consisting solely in placing the lamps on the pumps, in turning on and regulating the current and in removing the lamps at the proper time. It is manifest that this labor cannot be reduced by the employment of the mechanical pump, however perfect and rapid its action. The labor of the glass blowers, too, in attaching the lamps to the pump connections and in sealing off the tubes through which they are exhausted must be the same, whatever kind of pump is used. It is difficult to see how the items above mentioned, of repairs and superintendence and of materials which consist of acid, oil waste, etc., can be much reduced.

In the above-mentioned system of pumping, which is in almost universal use in this country, it is of course understood that the atmospheric pressure is never admitted to the operating bulb of the pump and that the preliminary exhausting of the lamp before connection with the mercury pump is established, is done by means of a mechanical pump, this operation consisting in the mere opening and closing of a stop-cock. The mechanical pump used for this purpose is almost without exception the Packard pump, which is a modified form of the Ritchie and gives in regular use a vacuum approaching to within ½ inch of the barometric pressure. The size of the mercurial pumps used is limited not so much by the difficulty of constructing and operating them, as by the undesirability of attempting to exhaust more than a certain number of lamps on one pump at a time, as a leak or defect in one would destroy the vacuum in all of the lamps on that pump. The pumper's most difficult task is, when a leak is developed on a pump, to discover the defective lamp in order that it may be removed and the exhaustion of the remainder proceeded with. This difficulty would be greatly increased in the case of the mechanical pump, where it is claimed 600 lamps are pumped at one time, and it would be impossible to secure a perfect vacuum until all leaky lamps had been removed.

The time taken for exhausting too, is dependent as much upon the slow and careful electrical treatment to which it is necessary to subject the carbon at this stage, as upon the displacement effected by the pump piston.

From the considerations and figures given above it is manifest that the claims made by the inventors of mechanical vacuum pumps for the complete exhaustion of incandescent lamps, that a saving of 8 cents, or more, per lamp, can be effected by the substitution of mechanical for mercury pumps, are absolutely without foundation since, supposing that the entire operation and cost of pumping were done away with, a saving of but 1½ cent per lamp could be effected.

In one of the mechanical vacuum pumps for this purpose the inventor states that he uses a non-volatile liquid and that a vapor of oil or hydrocarbon is left in the bulb, presumably from this liquid. The claim is made too, that a vapor of mercury is left in lamps exhausted by the old process, which is very injurious to the lamp, causing a rapid blackening. I am unacquainted with any authority for, or any evidence which would tend to sustain, this statement. In the recent test by Prof. Thomas at the Ohio State University, the "Packard" lamps, which are exhausted by the mercurial process, showed considerably less blackening than any of the other makes, among which was the "Beacon" which is exhausted by the mechanical process. The leaving of a vapor of hydrocarbon in a finished lamp has often been tried and at one time was quite extensively practiced at one of the largest lamp factories in the country, but was soon abandoned as being of no utility. The presence of any vapor in a finished lamp imparts a dull appearance to the carbon and makes the bulb distinctly visible, it appearing to be of a slight yellowish tinge. In all the mechanically exhausted lamps which I have examined, this appearance is quite marked.

PROPOSED ELECTRIC TRANSMISSION OF POWER AT TROLLHOTTAN.

The question of erecting an electric installation for the transmission of power from the large Trollhöttan waterfall to Gothenburg, says *Industries*, has so far advanced that about one hundred firms in the latter town are willing to use electric power from Trollhöttan if conveniently installed and subject to prices being suitable. The amount of motive power and electric lighting required by these applicants amount to respectively 5,262 h. p., and 8,395 incandesent and 178 arc lamps. The plan, if realized, is likely to become the forerunner of many similar installations in Scandinavia.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can 'entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, JULY 20, 1892. No. 220

Every change of condition, every transformation of matter, and every manifestation of life is at the expense of some motive power, which having performed its part, is forever neutralized.—Joseph Henry.

ELECTRIC TRACTION IN GREAT CITIES.

IT is interesting and encouraging to observe how thoroughly the idea of electric traction has found acceptance in great cities. In fact there are few great cities in which it has not been tried, and while the methods are various, the results generally are very satisfactory. The article we publish this week from Dr. Edward Hopkinson tells what has been done on the underground road in London, and shows how bright the prospects are for an extension of the system. So far we have no such road in this country, but there is every promise that New York will soon have one. In the meantime the trolley is making its way, and that method has already given proof of enormous capabilities for passenger transportation, there having been, for example, no fewer than 625 trolley cars running in Boston on the Fourth of July.

At the present moment, storage battery traction again looms up, and both New York and Brooklyn are again discussing the subject. In New York, the proposition is made to operate the Second avenue surface road by batteries, presumably the Waddell-Entz, and if the plan is tried it is to be most devoutly hoped that the experiment will succeed. While the storage battery is steadily gaining ground for lighting and for stationary power work, it still has to demonstrate its commercial utility in traction, especially on roads with grades, subject to frost and snow, and handling such heavy traffic as falls more or less to the lot of all city roads. Our best wishes go with the work now on foot in New York, Cleveland, Washington and elsewhere, but we cannot approve the proposal to employ storage batteries on the Kings County Elevated Road in Brooklyn. Such a road is an ideal place for the trolley system, and all the supposed objections to the trolley on a surface road disappear at once. We can see no advantage in adopting a complex method when a simple one will serve every purpose. Even if it is intended to break up the trains into single car units, the trolley would still seem preferable. But if Genl. Jourdan carries out his ideas, he can count on cordial co-operation for every man in the electrical field.

It is a pity that this co-operation cannot be gained from other men who should be equally interested in the adoption of improved and modern methods of light and power. A conspicuous example of obstruction is found, we are sorry to say, in the person of Mr. David M. Stone, the venerable, but not venerated, editor of the New York *Journal of Commerce*. It is a marvel that the intelligent and informed merchants of this city and Brooklyn can listen tolerantly to the nonsense that he is printing as supposed argument against electricity. Only the other day, attention was called in these columns to his absurd assertion that riding in trolley cars in Brooklyn would cause a large number of cases of palsy. Another effusion of his published in the *Journal of Commerce* last week, holds it to be probable that the present use of electricity is causing the cyclones in the West, and after saying that "as a motive power electricity is winning a most condemnatory record," and alleging that in Boston "several hundred are killed or seriously injured every year by the trolley," winds up as follows with regard to the trolley in Brooklyn: "There never was a more infamous assault upon the peace and safety of a great city than this project carried to a successful issue on the other side of the East River."

After all, this is amusing from a Brooklynite who opposed other benefits his fellow-citizens now enjoy, including gas, ferries and the elevated road. It is, perhaps, no more than could be expected from one who has been prominently interested in a perpetual-motion machine, and who, if report be true, severed his connection with a Brooklyn club because it introduced the electric light. But it is not so amusing when we remember that these wild sayings about electricity appear in a newspaper which has long commanded the respect of the merchant princes of America and still has their ear. Patience is, perhaps, the only remedy. The men who opposed steam railroads have now all disappeared, except in China, and by and by electricity will also be free from the attacks of ignorance and prejudice.

THE PHYSIOLOGICAL EFFECTS OF HIGH FREQUENCY ALTERNATING CURRENTS.

THE harmless nature of alternating currents of high frequency at enormous potential cannot be explained away on the theory of the small quantity involved in their passage through or along the human body, for some of the experiments performed by Mr. Tesla with the current transferred through his body involved electrical energy sufficient to have given positive discomfort, to say the least, if administered in any other way. Prof. Edwin J. Houston, whose ideas on electro-physiological questions are always interesting, in a short paper recently read before the electrical section of the Franklin Institute, suggested that an explanation of the observed phenomena can be found in adopting the modern hypothesis that the electric energy is not propagated through the mass of the conductor itself, but rather through the dielectric or medium lying outside the conductor; that, as it were, the electric energy is rained down on the surface of the conductor from the space outside it, and soaks down into the mass of the conductor, the conductor forming a sink or place where the energy can be dissipated. According to Prof. Houston's conception, in the case of a steady, continuous current, the energy sinks or soaks rapidly through the mass of the conductor, so that the electric current, in the language of the old ideas, passes through all portions of the mass of the conductor.

In the case of alternating currents, however, the energy received from a single impulse or electrical movement, by sinking or soaking moves, say, from the surface of the conductor towards the centre, only while such impulse continues; and, when the direction of the impulse changes, moves in the opposite direction, or towards the surface.

When the human body is subjected to the effects of discharges of alternating currents of enormously high frequencies, the superficial portions only are traversed by the discharges. The more deeply seated, vital organs, being thus free from current, such discharges are necessarily harmless. As the frequency of alternation increases, the body becomes more and more protected, until, when the frequency becomes as great as that of the ether waves, which cause sunlight, they would probably produce on the surface of the body the same genial effects as are produced by the light and heat of the sun, with which they are probably identical.

If these views are correct, it would appear that when the human body is exposed to rapidly-alternating discharges, it is subjected at one moment to a discharge that might produce instant death, were it not for the fact that the bolt is practically no sooner hurled at the body than it is hurled away from it.

THE NATURE OF ELECTRIC CURRENT.

That the ordinarily accepted directional nature of the electric current is a convention adopted merely for the purpose of facilitating the fixing of our ideas, is now so generally understood that all electricians are quite prepared to give respectful attention to theories respecting the progressional nature of electric currents, however they may differ from the conventional. Whether that which we call electric current passes from the positive to a negative pole, or whether there be a mutual interchange between the positive and negative poles, and questions of a like nature, have given rise to much discussion in the past, and the recent addition of the ether has served to introduce another element of strife. But as the facts regarding the nature of the electric current are still confined to a small number of experimental demonstrations, any addition to them must be welcomed as a possible aid to clearing up our ideas on this subject. As such the experiments described by Dr. William James Morton, in a note in this issue, will prove of more than ordinary interest; and as the experiments are easy of repetition they may afford a basis for further work in this direction by others. The experiments of Dr. Morton, it must be borne in mind, are in the nature of alternating currents of enormously high potential, and suggest a possible explanation of some of the phenomena in conductors carrying alternating currents, which have heretofore been explained on a different theory. Dr. Morton also suggests a number of hypotheses, based on his experiments.

TRANSFORMER TESTS.

Although reliable tests of transformers have been published from time to time, the corroboration afforded by the testimony of independent testers of repute is always of value As such we note the recent work of Dr. John Hopkinson, who has just finished an elaborate test of two 6,500-watt Westinghouse transformers. Without entering into the details, we cannot but draw attention to the exceedingly high efficiency obtained which at full load amounted to 96.9 per cent., at half load 96 per cent. and at quarter load 84.7 per cent. The magnetizing current of the transformer amounts to 114 watts, or 1.75 per cent., while the drop of potential from no load to full load is between 2 and 2.2 per cent. The increased efficiency at light load brought out these tests, and more partciularly the diminished drop in potential from no load to full load, show marked improvements in the design of transformers over those produced but a few years ago, and must go far towards establishing the value of the transformer, even as a light load converter of energy.

Cyrus Field.

There can be no question that Mr. Field's death was hastened by the troubles and disasters that have fallen upon him heavily during the last year or two; but so far as his life's work went, that may be said to have ended with his grand achievement in uniting the Old World and the New by submarine cable. All that he has done since that time has gone for little, and in fact it may be said to have deprived him of the fortune that his earlier efforts won. His fame and memory will rest upon the noble work of his earlier years. Such men as he are benefactors of the race, even when their aims are most deeply affected by the commercial spirit. Electricity still has need for many such as he.

Regulating Incandescent Lamps.

One of the reproaches brought against the incandescent lamp by the gas companies in the early days was that no convenient means existed for varying its brightness, and that hence the lamp could never be employed economically or to its fullest advantage in domestic illumination. The rapid introduction of electric lighting proved its immense superiority over gas, but it must be admitted that, so far as the early reproach above mentioned is concerned, there was, until quite recently, much truth in it. The Ries regulating socket, for alternating circuits, which has met with deserved success, has apparently stimulated the direct current workers, with the result that we are able to present in this week's issue no fewer than three different devices for varying the brilliancy of incandescent lamps.

A GRAPHIC REPRESENTATION OF THE MAGNETIC FIELD.[1]

BY PROF. EDWIN J. HOUSTON.

BEING engaged in a study of the magnetic field and desiring to obtain some simple method of fixing and readily reproducing the peculiarities of different fields, I have, after numerous trials, succeeded in devising a modification of an old and well-known plan, so simple and efficient, that I have thought it may be of sufficient interest to others engaged in similar investigations, to describe it in detail. The method consists essentially in forming a magnetic field with iron filings on a plate of glass in the usual manner, and subsequently fixing the filings so as to permit the plate to be used as a positive for obtaining a blue print, a silver print, a platinotype, or any other photographic print.

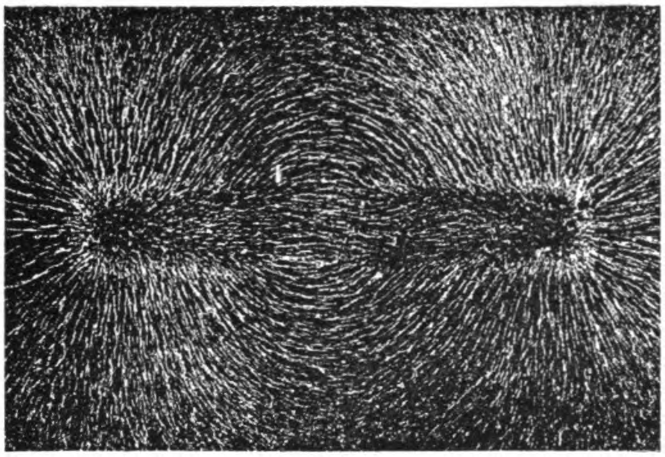

FIG. 1.—FIELD OF BAR MAGNETS.

In order to readily fix the groupings of filings on the glass plate while in the field of the magnet, a thin film of wax is spread over one surface of the plate by any suitable process. A convenient method of waxing the surface of the plate consists in first gradually heating the plate until its temperature is above that of the melting point of wax, and spreading melted wax over its surface by means of a brush. The surplus wax is then allowed to drain off the plate, or it may be wiped off by a piece of warmed paper. The remaining wax is then spread in an even film over the surface by cautiously heating the plate by a Bunsen flame or other suitable source of heat; or, the same thing can be effected by placing the plate in a vertical position in an oven or sand bath, supported on a suitable vessel so as to catch the surplus wax which drains off.

Plates can be readily covered in this manner with an uniformly thin coating of wax sufficiently transparent to permit them to be successfully employed for photographic printing. For such purposes, of course, only pure, white wax is employed.

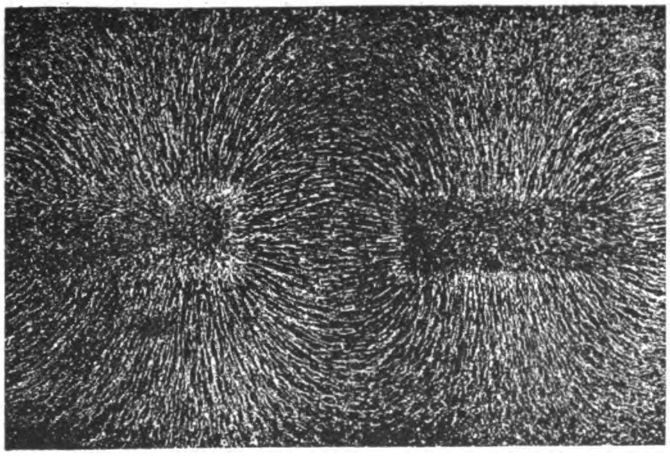

FIG. 2.—OPPOSITE POLES OF BAR MAGNETS.

The wax-covered glass plate so prepared is placed with its waxed surface upward, in a horizontal position over the magnet whose field is to be fixed; and iron filings are sprinkled over its surface. The arrangement of the filings in the characteristic groupings of the field is aided by gently tapping the plate in the usual manner.

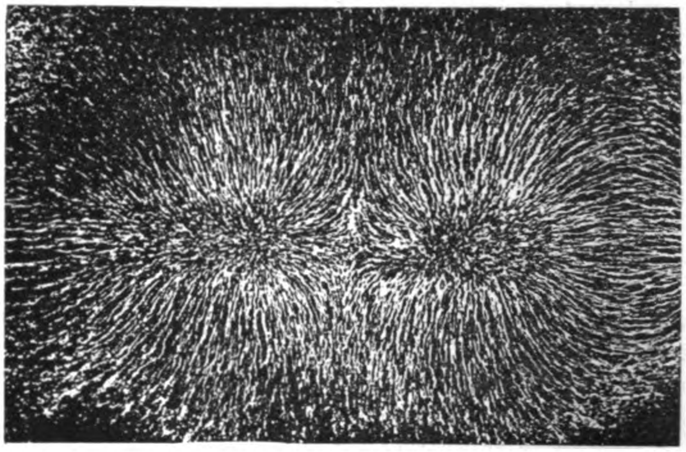

FIG. 3.—SIMILAR POLES OF BAR MAGNETS.

When a satisfactory grouping of filings has been obtained, the field is fixed on the plate by gently warming it so as to melt the wax. At first I adopted the plan of carefully lifting the plate from the magnet and melting the wax by holding it over a source of heat, such as a Bunsen burner; but, no matter how carefully the plate was lifted from the magnet, or how nearly it was raised vertically from the same, so as to avoid lateral displacement of the filings, a change of figure almost invariably attended its removal. Better results were obtained when the wax was melted while the plate was in place over the magnet. This can be readily effected either by holding a heated plate over the warm surface, or more conveniently by cautiously heating it by a Bunsen flame. After a slight heating, the flame may be permitted to play directly on the surface of the filings without displacing them. After cooling, the plate with its fixed groupings of iron filings may be used as a positive for photographic printing. For this purpose it is placed in a printing frame with its surface of wax-fastened groupings of filings upwards, so as to come into contact with the surface of the sensitized paper.

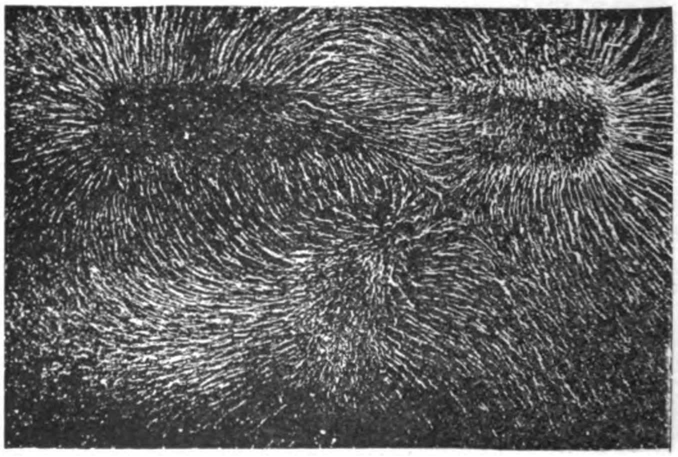

FIG. 4.—BAR MAGNETS AT RIGHT ANGLES TO EACH OTHER.

If the plate has been properly prepared, but comparatively few filings will become detached from the waxed surface when it is brought into contact with the sensitized paper. These should be blown off before taking a second print from the plate. In order to obtain the minimum of roughness of surface, it is necessary to use filings that are as nearly as possible of a uniform size. This can be readily ensured by previously sieving them through a fine-meshed wire gauze. It is advisable that the plates be covered with as smooth a coating of wax as possible. Otherwise, the filings will be prevented from readily arranging themselves in the directions in which the lines of magnetic force pass.

In the case of powerful electromagnets care must be taken to avoid a too great motion of the filings to the poles, since, in this manner, the portions of the surface over which the particles are moved, are swept clean of filings.

---

[1] Read before the Electrical Section of the Franklin Institute on May 31, 1892.

The best results are obtained by sieving the filings over the plate through a sieve whose meshes are sufficiently fine to ensure a small quantity only of filings falling on the plate at any one time. This, of course, is necessary to ensure the uniform distribution of the filings in the field of the magnet.

When the plates on which the magnetic fields are so fixed, are used for positives for photographic reproduction, and negative prints obtained therefrom in black, as by means of a silver print, or a platinotype, such prints can readily be used for the purposes of graphic reproduction for printing by any of the well-known photographic processes. In this way cuts and illustrations of actual fields can be readily had for purposes of illustration, without the introduction of those well-known errors arising from the too great artistic imagination of the copyist.

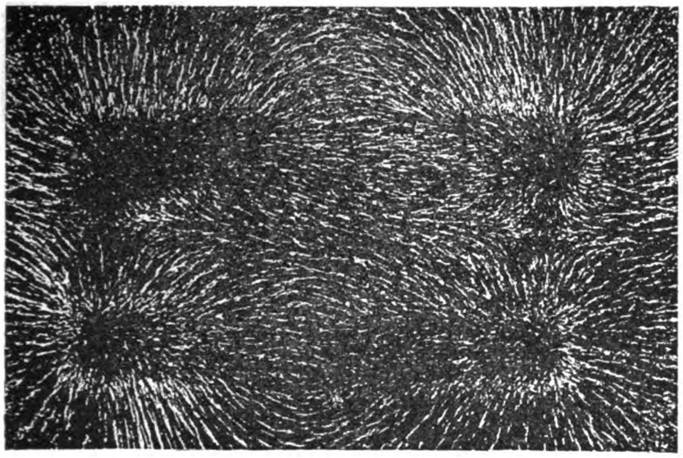

FIG. 5.—PARALLEL BAR MAGNET. SIMILAR POLES OPPOSED.

For purposes of subsequent reproduction I find platinotype paper the best, as it gives dead blacks, that contrasting markedly with the white lines and spaces occupied by the iron filings are readily photographed by any of the well-known processes of reproduction.

When the filings are dusted over the plate from a sieve held a few feet above the waxed surface rather than quite near its surface, a better grouping of the filings is obtained.

I have prepared a number of fields according to the processes described. They have been printed by the platinotype process.

In Fig. 1 is shown the field of a straight bar magnet. The characteristic radiation of the lines of force at the poles is well shown, as well as the curved lines produced by the mutual attraction of the lines coming out of the north and proceeding toward the south pole. The numerous parallel lines at the equator of the magnet show the strength of the magnetic flux at that point.

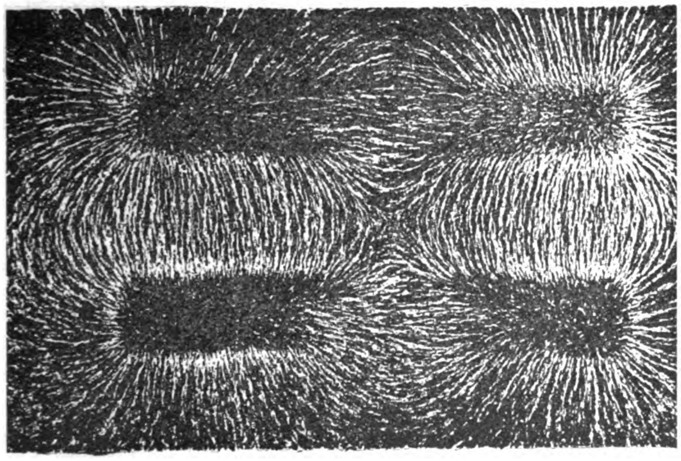

FIG. 6.—BAR MAGNETS. DISSIMILAR POLES OPPOSED.

Fig. 2 shows the field produced by the approached, unlike poles of two straight bar magnets. The attraction of the oppositely directed lines of force in the space between the opposing poles, as well as the increase in the length of space on the bars from which the lines pass off approximately at right angles to the surface, are well marked.

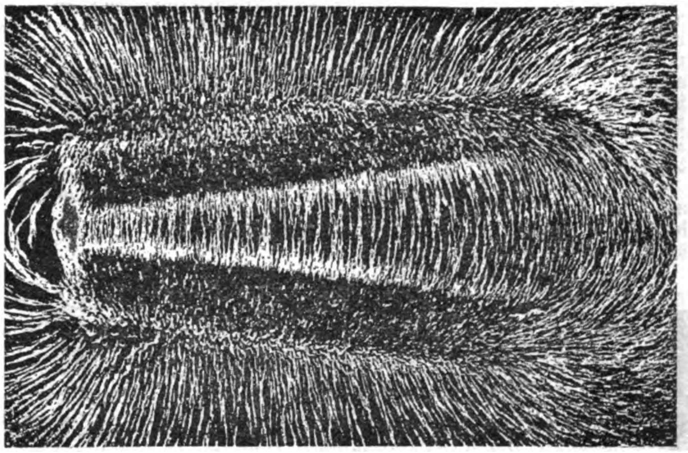

FIG. 7.—FIELD OF HORSESHOE MAGNET.

Fig. 3 shows the field produced by the approached, similar poles of the same straight bar magnets used in Fig. 2. The repulsion of the similarly directed lines of force producing nearly straight paths in lines at right angles to the length of the magnet, as well as a curious space midway between the poles, bounded by apparently hyperbolic curves are clearly seen.

Fig. 4 shows a very curious field produced by two bar magnets placed with their axes at right angles to each other so that one of the poles of one magnet is placed at right angles to the neutral point of the other and at a short distance from it. At the left hand of the field is shown the curved deflections of the lines of force produced by the attractions of opposite poles. The lines of force coming out of a north pole and those entering a south pole mutually attract one another and produce curves similar to those shown in the space between the approached, opposite poles shown in Fig. 2. At the right hand of the field the repulsions existing between the similarly directed lines of force produced characteristic parallel streamings. The curious area bounded by hyperbolic curves is shown in the space between the poles at the right of the figure.

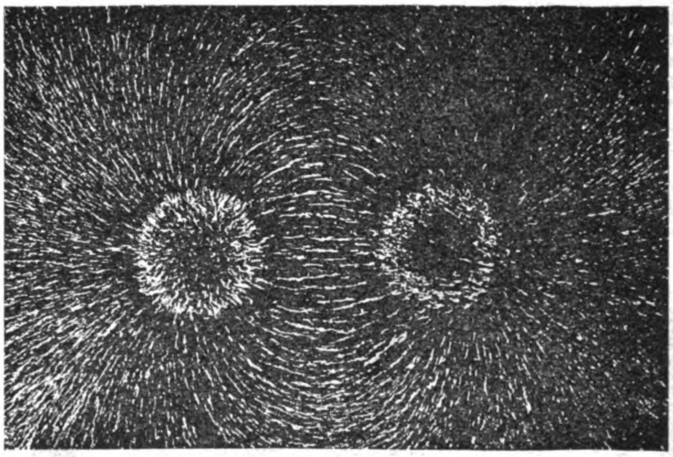

FIG. 8.—FIELD OF ELECTROMAGNET.

Fig. 5 shows the field produced by two straight bar magnets placed with their axes parallel to each other and their similar poles near together. The mutual repulsions of their fields are clearly shown. The curious areas bounded by hyperbolic curves are shown in the spaces at each end between the poles of the magnets.

Fig. 6 shows the field produced by the same parallel bar magnets placed with their opposite poles near together. The attraction of their oppositely directed lines of force is well marked. In the neighborhood of their neutral points, a very marked area bounded by hyperbolic curves is seen. The strength of the magnetic flux near the neutral points is also marked.

Fig. 7 shows the field of an ordinary horseshoe magnet. The magnetic leakage between the sides of the bar is marked, as is also the strength of the magnetic flux in the neighborhood of the equator or neutral point of the magnet.

Fig. 8 shows the field of an electromagnet. In order to avoid the injurious sweeping action of the particles as they are carried bodily forward towards the poles, I found it necessary to use a very weak current, and to place the plate a short distance above the poles. It may be mentioned in this connection that it is in general advisable to avoid resting the plate on the surface of the magnet, since when the plate does not touch the poles it is left free to be gently tapped or vibrated so as to permit the filings to arrange or group themselves while in the field of the magnet.

Fig. 9 shows the field of a peculiarly shaped permanent horseshoe magnet taken in a plane over the poles at right angles to the length of the magnet. I was rather surprised in this case to find that so many of the lines of force passed through extended air circuits shown, rather than through the narrow gap directly between the poles.

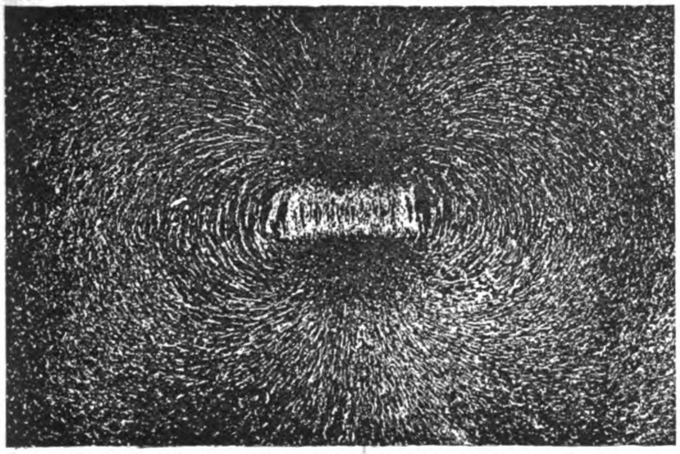

Fig. 9.—Field of Permanent Horseshoe Magnet.

Fig. 10 shows a novel field obtained by short lengths of very thin iron wire, that act as small magnetic needles. The field is that of the bar magnet employed in Fig. 1. Although the separate particles do not possess as great freedom of motion as the shorter and smaller iron filings, yet their tendency to come to rest with the lines of magnetic force passing through their greatest dimensions, so as to reduce the resistance of the magnetic circuit as much as possible, is manifest. The peculiar wire field produced by these means is of especial interest when studied in the light of Ewing's theory of magnetism.

Fig. 11 shows another wire field produced by the same electromagnet as is employed in Fig. 8. The polarization of the minute magnetic needles and their arrangement in groupings of polarized chains is well marked.

Fig. 12 shows a field produced by iron filings and iron wire. The peculiar groupings of the iron wire in chains of polarized particles are clearly shown.

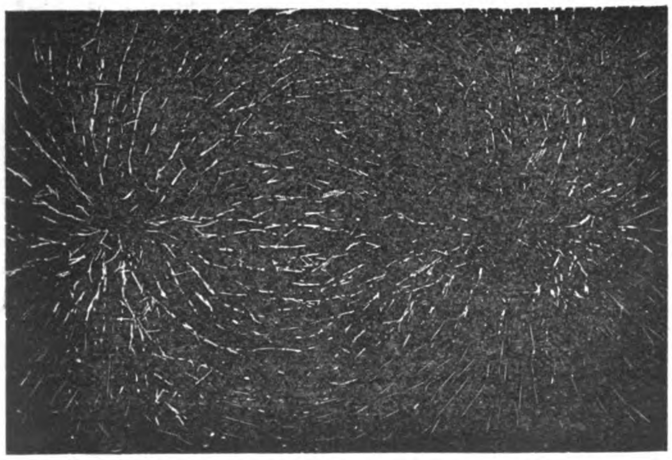

Fig. 10.—Wire Field of Bar Magnet.

A curious resemblance is possessed by this field and other wire fields to the discharge produced by a lightning flash, or other high potential discharge; such, for example, as the recent 500,000-volt discharge of Elihu Thomson. This resemblance quite naturally leads to the speculation, whether the peculiar forked or curved shapes of such discharges are not due to similar causes, viz., to polarized chains of particles of the medium which offers paths of less resistance to the discharge than the spaces adjoining or surrounding them.

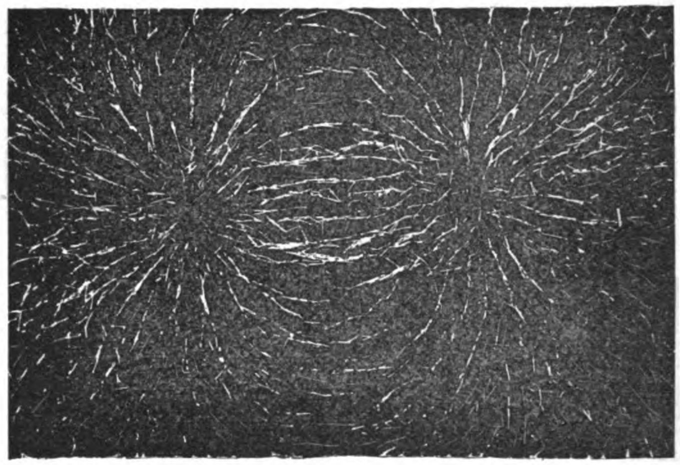

Fig. 11.—Wire Field of Electromagnet.

I am making some experiments in solid fields, *i. e.*, in the peculiarities of the distribution of the lines of force in the space of three dimensions surrounding magnets, which I trust to be able shortly to bring before you.

I desire to express my indebtedness to my assistant, Mr. B. F. Lacy, for valuable aid in preparing the plates.

Since writing the above my attention has been called to the fact that the process above described has been very fully anticipated by Prof. Mayer, in a publication printed in the *Journal of the Franklin Institute*, for May, 1871. As my process differs in some particulars from that described by Prof. Mayer, and as it appears to me advisable to call attention to both processes at this time, I have concluded to permit the paper to go to publication. To Prof. Mayer, however, the credit is due for the first conception of the general process.

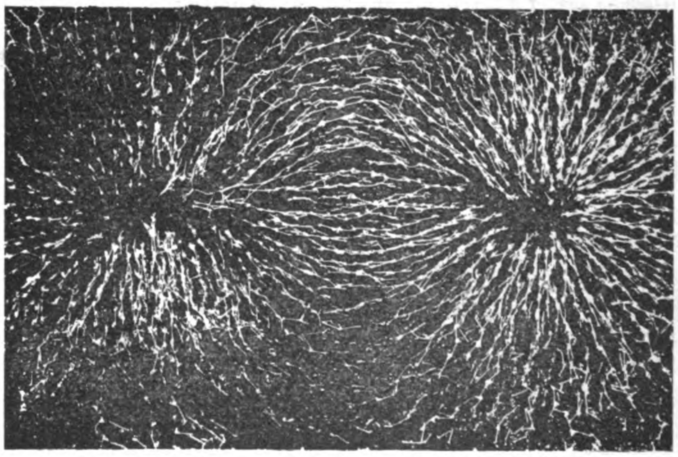

Fig. 12.—Wire and Filings Field.

Since writing the above I have devised a new plan which I believe to be far in advance of what I have just described. According to this plan I place a dry sensitized photographic plate over the magnet whose field I desire to fix and after the characteristic groupings of filings have been obtained, I expose such plate while over the magnet to the light of a gas flame for a few seconds. This operation is necessarily performed in the dark photographic room. After exposure the light is turned out and only the non-actinic red or yellow light left. The filings are allowed to fall off the surface of the dry plate, and the finer particles that still adhere to it are brushed off by a feather or dry camel's hair brush. The plate is then developed and fixed in the usual manner. The removal of the adherent iron dust by the feather or brush is preferable to the use of the breath, as this is apt to produce troublesome spots. I have found that the so-called lightning gelatine dry plates give very satisfactory results when employed for such purposes.

This process of obtaining records of magnetic fields produces true negatives, which when employed for printing by blue print, silver print, platinotype, or similar process produce excellent positives. As the negatives so obtained are more permanent than the positives obtained by the use of the filings themselves, they permit the taking of an indefinite number of photographic prints.

I have thought of forming the field directly on the surface of sensitized paper and exposing such to light. But such paper is apt to curl, and such processes produce but a single impression. The time has been too short to prepare many specimens of fields by this new process. I hope to be able, however, by the next meeting of the section, to present such results in a short paper.

A PRIMARY BATTERY LAUNCH ON THE POTOMAC.

A GREAT deal of interest is being taken in the matter of electric launches, and there is every reason to believe that a great many will soon be seen on American rivers, lakes and ornamental waters. In Europe and England, the number of storage battery launches is already large, but resort to them in this country has been much slower, owing to the initial cost of the outfit and more especially to the absence of charging stations. It is expected, however, that the use made of electric launches on the beautiful and extensive lagoons of the World's Fair at Chicago will lead to the general adoption of such craft all over the continent, wherever a charging circuit is available.

Now that attention has been turned in this direction, it has seemed singular to some that an effort has not been made to utilize the primary battery; and impressed with the idea that something could be done, Mr. Frank Aldrich, of the Hanson Battery, Light & Power Co., determined to equip a launch and run it on the Potomac. We are glad to be able to give herewith illustrations of his launch "Electric," and some account of the manner in which success has been reached. We are indebted to Mr. Aldrich for the figures given below.

The launch, which was built by the Naphtha Launch Co., of Morris Dock, and A. Glose & Son, New York, N. Y., is 21 feet in length and 5 feet beam. She draws 18 inches of water with battery and motor, which are thus, it will be observed, barely sufficient to serve as ballast, instead of being an encumbering dead weight. The propeller is 17 inches in diameter with three blades and makes 250 revolutions per minute. To the propeller is geared a small Riker motor wound for 50 volts and 30 amperes, and weighing 240 pounds. The gear wheels are respectively 2¼ inches and 6 inches. The launch averages 7 miles an hour.

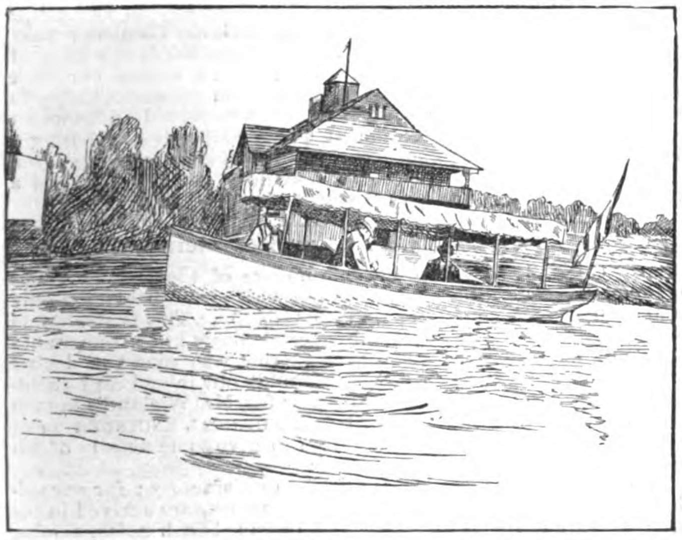

FIG. 1.—THE PRIMARY BATTERY LAUNCH "ELECTRIC."

The battery equipment is very interesting. It consists of 60 Hanson cells grouped as shown in the engraving, Fig. 2, with 30 cells on each side, and so connected that half the required current comes from each row of cells. Each battery box holds two cells. Each cell is 11 x 12 x 3 inches. In each cell is a porous cup 9 x 11 x 1 inches in which is suspended a carbon plate 7 x 11 x ¼ inches. Outside the porous cup are suspended two zinc plates each 7 x 10 x ¼ inches, the surface being thoroughly exposed to the action of the solution. In the porous cup are three pints of strong solution and in the outer cell are six pints of weak solution. The total cost of the solution, including depolarizer, for the 60 cells, is $1.60. From one charge of this battery, Mr. Aldrich gets 180 ampere hours. The cell gives an average of 1⅞ volts, and will yield 50 to 60 amperes on short circuit. The zincs are amalgamated before using, and again after 24 hours' use. The average consumption of zinc is less than one pound per hour when the battery is in use; and when it is not in use the local action is not sufficient to render it necessary to remove the zincs. Each double cell weighs 40 pounds, or 1,200 pounds for the 60 cells, when the zincs are new. The battery cells are of wood treated with a special preparation making them acid-proof.

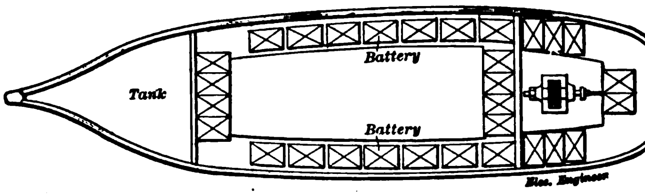

FIG. 2.—PLAN OF PRIMARY BATTERY LAUNCH "ELECTRIC."

From one charge of the solution, Mr. Aldrich gets a good 12 hours' run. In the tank shown at the bow of the boat, he carries extra solution enough for three more charges. The tank is made of prepared wood, as above mentioned, and Mr. Aldrich thinks that it makes a "charging station" that a dynamo and steam engine find it pretty hard to compete with. One man can recharge the whole 60 cells in 1½ hours. Of course the 12 hours of service can be extended over several days, a few hours at a time. The current is thrown on or off by a simple switch that any one can control. The "Electric" seats 12 persons easily, and there is an active competition for seats that keeps her well loaded on every trip.

The Hanson Company has done a great amount of work in and around Washington with its battery and motor outfits, and hence, being well-known its new departure in the launch line has excited very general interest. The trips of the launch have also been watched by the Navy Department, and Lieut. McFarland, U. S. N., has made tests of speed, etc., for Chief Engineer Melville. It is now the intention of Mr. Aldrich to build and equip a launch 30 feet long and 5 feet beam, designed specially for speed, and he hopes to run her at not less than 12 miles an hour. In the meantime, as might have been expected, he is receiving a great many applications for boats from persons who have seen the "Electric" making her graceful, noiseless way up and down the Potomac River.

THOFEHRN'S ELECTROLYTIC COPPER REFINING PROCESS.

M. HYPPOLYTE FONTAINE'S work on electrolysis gives a very full account of M. Thofehrn's process for refining copper by electrolysis. In principle the process does not differ materially from other electrolytic methods, but the arrangement of the parts and the general working out of the details make the method, in the opinion of M. Fontaine, a new, complete and efficient system of copper refining. In the plant at present in operation there are 120 baths in 12 series of 10 each. Each bath is a little lower than the next, and the siphons are placed between them in order to obtain a constant circulation. After the electrolyte has left the last of each series it goes to a collecting basin, from which it is pumped again to the distributing reservoir. Baths are made of concrete. They are lined first with wood, which has been boiled in tar and with sheet lead. The surface of the concrete itself is protected by a coat of a special kind of tar. The electrolyte consists of sulphate of copper, 150 parts; sulphuric acid, 60 parts, and water, 690 parts. In order to oxidize the electrolyte and so remove the impurities which are constantly forming, jets of air are introduced into the collecting basin and the distributing reservoir, and at the same time the liquid is kept at a temperature of 35° C. The rate of production of refined copper is 1 gramme per ampere hour, or in an average of 2½ tons per day. The average drop in potential for each bath is 1.5 volt. The difference in potential at the binding posts of the dynamo is just sufficient to overcome the resistance of the bath and the conductors. The cost of refining copper by this installation is $19.60 per ton. The original cost of the plant was $37,300: the stock in hand has always a value of $84,000, and the annual working expenses are $9,210. The interest on capital and stock and the depreciation amount to $8.130 per annum; this, together with the working expenses, is equal to $17,640.

MR. FRED. SARGENT, the electrical engineer of the World's Fair authorities was in New York last week closing a contract with the Worthingtons for a huge pumping outfit for the Fair, The water required will reach as many millions of gallons as if it were to supply the population of a large city.

Obituary.

CYRUS W. FIELD.

Cyrus W. Field.

THE death of Cyrus W. Field, on July 12, at Ardsley, N. Y., at the age of 73, removes from the ranks of American electrical pioneers the man to whom, more than to any one else, is due the laying of the Atlantic cables and the foundation of submarine cabling as a great modern commercial enterprise. The story of Mr. Field's life and work has been told so often that it long since became hackneyed, but it may be fitting to recapitulate the chief events in his distinguished career. He was born at Stockbridge, Mass, on November 30, 1819, of an old New England family. As a youth he was employed by A. T. Stewart, the great drygoods merchant, then went into business for himself, made money, and at last became interested in a scheme to put a telegraph line across Newfoundland. That naturally led on to the project of an Atlantic cable, which had already been suggested by F. N. Gisborne, then a telegraph operator. Mr. Field had keen foresight, great courage and a genius for organization, and these qualities, as well as his fortune, were soon devoted to the idea which had taken complete possession of him. The New York, Newfoundland and London Telegraph Co. was formed, with the co-operation of such men as Peter Cooper, Moses Taylor and Marshall O. Roberts, and the project was at once pushed on both sides of the Atlantic, Mr. Field crossing the ocean more than forty times in prosecution of it, while preliminary work was successfully attempted in the way of laying a cable between New York and Newfoundland. Two attempts at Atlantic cable laying failed before a cable was actually laid in 1858 and messages were exchanged from shore to shore of the Old World and the New; but the cable snapped at once, and silence again fell, not to be interrupted until July 27, 1866, when, as John Bright said, Mr. Field, as the modern Columbus, had, by his cable, moored the New World alongside the Old. Then, practically, began the development which has to-day resulted in an aggregate of 135,000 miles of submarine cable. Honors came fast and thick to Mr. Field, and a period of financial struggle and stress was swiftly succeeded by one of great riches.

Of late years Mr. Field was interested in other public enterprises, notably the New York Elevated Road, and in this, strangely enough, he lost the bulk of the fortune he had made out of electricity. More recently the failure of his son, Edward M. Field, drained his resources, until at last when he died, Cyrus Field was, it is said, in actual poverty. But of his more solid and lasting acquisitions, no one can rob him, and he will forever remain rich in the esteem of his countrymen and in that of mankind at large, as the great American who, despite all discouragement and delay, had carried to completion and fruition one of the foremost enterprises of the age, that upon which, perhaps, more than any other, the present political fabric of the world depends, while it has done much to improve social intercourse and modify the conditions of commerce.

ELECTRIC LAUNCHES AT THE WORLD'S FAIR.

GENL. C. H. BARNEY writes us as follows from Chicago:

At the official test of electric launches made by the electrical engineers of the World's Columbian Exposition, at Jackson Park, Chicago, Ill., each boat was required to make a ten hours' consecutive run, over a prescribed course, and making designated landings. Two boats entered, the "Electra," owned by the Electric Launch and Navigation Co., of New York, and a boat not named, built by the Columbian Launch Co., of Chicago.

The "Electra" made 45 trips at the rate of 11¼ minutes per trip. The Columbian boat made 32 trips at the rate of 16¼ minutes per trip. Subsequently, a test of several cells of battery, taken at random from the two boats, was had. The cells were charged as fully as the contestants desired and then discharged at the uniform rate of 16 amperes. The Consolidated Co.'s batteries of the "Electra" were charged 160 ampere hours, and gave a discharge of 137. The Columbian batteries (Morrison's) were charged 200 ampere hours, and gave out 100. A second test of the latter resulted: Charge, 235; discharge, 109.

A NOVEL APPLICATION OF STORAGE BATTERIES ON A TROLLEY ROAD.

A MOST interesting exhibition of the application of storage batteries for propelling electric cars was given in Dover, N. H., July 12. At the invitation of the Bradbury-Stone Storage Battery Company, of Lowell, Mass, who made the installation, about 30 gentlemen from Boston and Lowell went up to Dover to witness the test of the application of storage batteries as an auxiliary to the overhead trolley system in that city. The application is extremely novel and very interesting in its details. The road is operated by the Union Electric Street Railway Company, power being furnished from the station of the Great Falls Electric Light Company, situated on the Salmon Falls River. The road is full of steep grades, and in one part about half a mile out of Dover there is a grade of over nine per cent. over the Garrison Hill, which taxes the trolley system to the uttermost at all times, and which on special occasions when the cars are heavily loaded, proves too much for the trolley system to overcome. In the past on such occasions it has been found necessary to employ from four to six horses to aid the electric car in surmounting the grade. The station from which the current is derived is a number of miles away, and much speculation has arisen as to the inability of the cars to surmount the grade. It is accounted for partly owing to the long distance between this hill and the station, and the necessary fall of potential when a car is drawing heavily on the current on the hill. The natural objection to keeping horses at this point led Mr. H. W. Burgett, the general manager of the road, to investigate other methods, and after consulting with Mr. J. T. Bradbury, of the Bradbury-Stone Company, it was at last decided to try storage batteries as an auxiliary. Accordingly in a small outhouse, attached to a house in the vicinity, 238 cells of storage battery were installed. The cells are all connected in series and give a total voltage of from 530 to 540 volts. The trolley wire on the hill was cut off from the remainder of the system, and wires leading from the storage battery were connected to it, so that as soon as the car trolley wheel, comes in contact with this section, which is about 300 feet long, the current is all taken from the batteries. The experiment worked most successfully, the volts only falling off five or ten, when the motors were drawing from 40 to 60 amperes. On Tuesday a very crucial test was made. The special car containing about fifty people was hitched on to one of the regular trip cars, also well loaded, the one car pulling the other, and both ascended the hill without a hitch, the battery registering about 510 to 520 volts, and the current being consumed from 100 to 1[illegible]0 amperes. Mr. Burgett is to be congratulated on his "happy thought" in introducing this auxiliary in the shape of a storage battery, and the Bradbury-Stone Company may well be congratulated upon the extremely successful working of their battery. After visiting the installation, a special car took the visitors to Burgett Park, one of the numerous tributaries to the electric road, where a light lunch was served, afterwards visiting the interesting station at Great Falls. On returning a most enjoyable dinner was served by the Bradbury-Stone Company to their guests, in one of the pavilions in the park, and a return was made to the city about 7 o'clock.

AN ELECTRIC LAUNCH IN THE PACIFIC.

MR. CHAS. S. WIELAND, the commodore of the Pacific Yacht Club, is the owner of a storage launch which is probably the only one in this country now in actual commission. This is strange in view of the popularity enjoyed by electric boats in Europe and in England, but there is reason to hope that very soon the electric launch will soon be a familiar sight on all our inland and yachting waters. In order to ascertain how far Mr. Wieland's launch had proved satisfactory to him, THE ELECTRICAL ENGINEER wrote to San Francisco recently asking him to give some details of his experience. His reply is as follows:

"My experience has been more than satisfactory; far exceeding my highest anticipation. The extreme pleasure derived in the use of this power is its not being attended with noise, smoke, grease or unpleasant odors, aside from the novelty. The electric launch "Magnet" was built and designed by Frederick Reckenzaun, New Jersey, and shipped direct to California to me. The "Magnet" is 28 feet over all, 6 feet beam and 30 inches draft. She carries 56 batteries, "23 M" type, which operate a Reckenzaun motor 2½ h. p. On one full charge of the accumulators the "Magnet" will run 10 hours at the rate of eight miles an hour, and for spurts can attain the speed of 12 miles.

"This "Magnet" is operated with the ease of a boy with a miniature boat in a tub. By the turning of a lever the speed can be regulated. She has electric whistles and a 100 c. p. search light at the bow and 16 c. p. side lights of red and green as well as 12 incandescent various colored lights suspended from the awning. I have a power house on the grounds of the Pacific Yacht Club, from which the "Magnet" is charged by an Edison dynamo.

"If I have not made myself clear on this or any other point connected herewith it will be a pleasure to me to furnish you with any additional data. I am so well pleased with electric motor applied to yachting I have in contemplation in the near future arranging for another launch on a much larger scale."

Letters to the Editor.

DR. JACQUES' EXPERIMENTS IN THE LIGHT OF MAXWELL.

I AM sorry that Mr. Victor M. Berthold should think that I wrote in a spirit of pugnacity, if he means pugnacity toward himself or Dr. Jacques, for, as I do not know either of these gentlemen personally, it is impossible that I should have any such feeling toward either of them. If, however, he means pugnacity toward the paper published under the name of Dr. Jacques, he expresses exactly my feelings, which would not be any different if the paper had borne the name Thomas Jones or Samuel Smith. I am also sorry to have caused him such alarm in regard to my ignorance, but I am not to blame; it is all owing to a typographical error.

The objectionable passage should read "the attraction of *oppositely* electrified plates," which makes sense of what I meant to write, whereas the way it was printed made nonsense. This I had supposed was so evidently a typographical error that I did not think it necessary to write a special letter of explanation any more than in case of the misspelling of a word.

Now if the published report of Dr. Jacques' paper is correct, he expected and obtained (?) an increase of attraction between oppositely electrified plates, where, according to Maxwell's view of the subject, the attraction should be diminished in the same degree as the repulsion of the similarly electrified plates is. Maxwell says: "This moving electrified surface will be equivalent to an electric current sheet." I have already quoted this, but take the liberty of requoting it as Mr. Berthold in his letter leaves it to be inferred that the experiment tried by Prof. Rowland, and described in Maxwell, Art. 770, was the only one founded on that assumption. The above quotation, however, is from Art. 769, where the experiment which Dr. Jacques is supposed to be trying, or at all events improving upon, is described.

Two parallel, similarly electrified surfaces, by virtue of their electrostatic properties repel; but when moving in the same direction they (that is, the electrified surfaces) are, according to Maxwell, equivalent to two parallel conducting "sheets carrying currents in the same direction, and, therefore, by virtue of their electromagnetic properties, will attract." At a certain velocity, namely that of light, the attraction and repulsion will balance. This is Maxwell's idea, the moving electrified surfaces are equivalent to conductors carrying currents; and yet Dr. Jacques deliberately leaves Maxwell at this point and says that the ether current passing between the plates is the electric current, and Mr. Berthold will have it that this is in accord with Maxwell. I think these gentlemen differ with Maxwell by a much larger discrepancy than I do.

In the case of two oppositely electrified surfaces moved in the same direction we have the equivalent of two parallel conducting surfaces carrying currents in opposite directions. The electrostatic action will be attraction, and the electromagnetic, repulsion, again tending toward equilibrium, where Dr. Jacques thinks both should be attraction.

As to the charge of setting myself up in opposition to Maxwell, I must plead guilty. This may indicate that I am very audacious, perhaps very egotistical; but I will say for myself that I am susceptible to conviction by argument, but that the mere assertion of the fact that I differ with Maxwell is not argument. I think I thoroughly appreciate Maxwell's genius and noble character, but I cannot find that he ever made any pretentions to infallibility. On the other hand he himself corrected in the second edition of his work several errors which he had found in the first edition, and had he lived to the present time he would have probably found other errors in his work and corrected them in the third edition. It is even possible that he would have changed Art. 769. My reason for hazarding this rash assumption will presently appear.

I am happy to say that I agree with Mr. Berthold in one thing, that Maxwell describes in Art. 769 the motion of two electrified surfaces relative to some fixed point in space; that is, relative to space itself, which is nothing more than absolute motion in space. Maxwell says in his little work on Matter and Motion, (I quote from memory as I have not the work at hand): "Any one who has once tried to conceive of absolute motion and absolute position in space, will ever after be content with relative ideas."

It may be that this Art. 769 of Maxwell does not involve the idea of absolute motion in space, in which case I will be pleased if Mr. Berthold or any one else will demonstrate that fact.

BROOKLYN, N. Y. TOWNSEND WOLCOTT.

"LEONARD'S THREE-WIRE SYSTEM."

I HAVE noted Prof. Elihu Thomson's letter, published in your issue of July 6th. The question under discussion can only be understood by careful examination of Mr. Rice's patent and mine, but for the benefit of any readers who may take sufficient interest to examine into the matter, I call attention to the following:

Prof. Thomson says: "Mr. Leonard might easily have discovered that the reversal of the field which he lays so much stress upon, means the reversal of the current in the series field." There can be no question that this is what the patent should have said, and it might have been well to add that the less of this series coil we have the better, and that the best result will be obtained by leaving it off entirely. But this is not what the patent *does* say, nor intimate, but on the contrary the greatest stress is laid upon the action of the series coil, and most of the specification is taken up with a discussion of its performance.

In my former letter I called attention to the fact that the reversal of the field was emphasized several times, and claimed distinctly.

Prof. Thomson says of this: "This is decidedly not true." In reply to this statement which would give the reader the impression that I had made my statement without any foundation of fact, I quote from the patent the two following paragraphs, which leave no room for doubt in the matter.

"So that a reversal of the field will occur, and the equalizing machine, becoming a generator, deliver current, etc."

"Said machine being so wound that its field is reversed, according as the shunted side has the lighter or heavier load, thereby causing it to act both as a motor and generator, as set forth."

There can be no question of the fact that any reader of the specification would suppose that the reversal of the field was an essential feature, controlling the change from a motor to a generator, whereas the change from acting as a motor to a generator, and *vice versa*, is totally independent of the effect of the series coil.

At line 100, page 1, of the patent is the following: "The field magnetism of the equalizing machine will be varied in accordance with variations of load in the two multiple arc groups." This statement is clear and unquestionable, yet it will be evident that the field magnetism of the equalizing machine for an operative plant should be totally independent of the variations of the load in the two groups, and that the drop in the conductors is the only cause demanding any change in the field magnetism. The drop in the conductors is not mentioned in the patent, and the series coil was not intended to take care of the drop but to "thereby cause it to act both as motor and generator."

Nowhere is it stated in the patent that the series coil can be dispensed with. No drawing is without it. In fact, every point emphasizes the important functions of this coil which is to cause the reversal of the field.

Further evidence to the same effect is contained in the two later patents of Prof. Thomson and Thomson and Rice, which describe methods of getting over the very difficulties which will necessarily be met with in attempting to operate any system having the series coil upon the equalizing machine.

The most positive way to settle such a question is to try it in practice. The commercial use of my system has proven that the series coil is entirely unnecessary. Upon the action of this series coil Mr. Rice's patent depends.

Prof. Thomson does not say that it has been tried commercially. This seems odd in view of the tremendous interests dependent upon avoiding the Edison 3-wire patent, which, until the recent consolidation, was so threatening to the Thomson-Houston interests.

H. WARD LEONARD.

NEW YORK, July 11, 1892.

Literature.

Eclairage Electrique. Monographie des Travaux Exécutés par le Syndicat International des Electriciens. By Hippolyte Fontaine. *Paris, Baudry & Cie.* 1890. 200 pages, 8½ x 12 inches. Price $10.

IT has come to be a generally recognized fact that the only proper mode of illumination for World Exhibitions, at the present time, is that which can be afforded by electricity, and this was strikingly exemplified in the action of the management of the Chicago World's Fair, which did not for a single instant entertain any other proposition. The magnitude of the illumination to be effected at Chicago is such that any ideas which can be brought forward as to the methods best adapted for work of this kind must be of value, and as such we think no better example can be afforded than the lighting work carried out at the Paris Exposition of 1889. Fortunately an account of the work there accomplished has been gathered together in the volume before us. Under the able and impartial editorship of M. Hippolyte Fontaine, it affords an excellent record and a storehouse of information on exposition lighting methods.

It will be remembered that, unlike the arrangement adopted at Chicago, the lighting of the Paris Exposition was farmed out, as it were, to a syndicate, composed of all the leading electric lighting companies in France, Belgium and Switzerland, and of firms in England, Alsace and Switzerland, and as a result we find a great variety of apparatus in operation at the exhibition. The work gives a complete history of the organization of the syndicate and its arrangement with the Exposition authorities, and then proceeds to describe the installations of the various companies and the apparatus employed by them, giving many details and drawings of dynamos and arc lamps, and thus affording an interesting record of the state of the art in France at that time. We also find a full description of the electric fountain, which was one of the greatest attractions of that exhibition, and various methods of suspending arc lamps in order to obtain the best distribution of light and also means for readily raising and lowering lamps for trimming.

We also note the cost, to exhibitors, of electric lights, which was as follows, the price given being the total cost for wiring and maintaining the lamps during the entire exhibition time: 16 c. p. incandescent lamps 60 francs each; 10 c. p. lamps 45 francs; arc lamps, 500 c. p., 500 francs; arc lamps, 1,000 c. p., 750 francs. This cost was calculated on a basis of 900 hours' burning for each lamp; beyond that time the price was, respectively, .05 franc, .03 franc, .75 franc and 1 franc.

The cost of power up to 500 h. p. hours was .5 franc per electric h. p. hour, or beyond 500 h. p. hours .4 franc. The work now being carried out in Chicago must of necessity be of a character similar to that accomplished in Paris, and for all those engaged in it, as well as those interested in exhibition lighting in general, the volume will prove of great value. The book is fully illustrated by 29 large plates and 32 excellent engravings in the text.

Personal.

Mr. C. D. Shain has resigned his position as manager of the Eastern District of the General Electric Company. This district, under the old regime of the Edison Company was large and did an enormous business, and its success was due in a considerable degree to Mr. Shain's vigor and skill in executive work. Mr. Shain is very reticent as to his future course, but is understood to have received several flattering offers already. His experience in all departments of the electrical field is so large as to make his services of rare value to the concern lucky enough to enjoy them. It is said that Mr. Shain will be at liberty September 1, and his next step, in these stirring times, will be awaited with considerable interest and curiosity.

Mr. H. V. Wille, class of '92 of the Cornell Department of Electrical Engineering, and Mr. E. S. Cary, of Haverford College, class of '92, have accepted positions on the electrical staff of Queen & Co. of Philadelphia.

Mr. Edwin H. Northrup, of Amherst and Cornell colleges, late of Queen & Co., has been appointed Junior Fellow of Physics and Docent at Clark University, Worcester, Mass.

Mr. A. W. Schramm will leave the staff of Queen & Co. this fall to take up the duties of instructor in electrical engineering at the University of Pennsylvania.

Mr. W. D. Weaver, of E. G. Bernard & Co., is resigning to assume a position in the business office of *The Electrical World.* His familiarity with electrical engineering matters will render him very valuable.

Legal Notes.

ALLEGED STEALING OF ELECTRIC CURRENT IN ST. LOUIS.

Gustave Temple, the first man tried on a charge of stealing electricity, has been discharged from the St. Louis Court of Criminal Correction. The judge would not concede that it was petit larceny and the Grand Jury would not allow that it was fraud, so when the case came up Attorney McDonald, for Temple, entered a plea for formal acquittal, which was concurred in.

Temple, who is a hardware dealer, was accused of having tapped a wire of one of the electric light companies to get his illumination free.

A DECISION IN FAVOR OF SWAN ON PAPER FILAMENTS.

The Commissioner of Patents has decided a long-standing controversy between Thomas A. Edison and Joseph W. Swan, as to the priority of right to a patent for an electric-light carbon for incandescent lamps. The dispute had been pending since 1881. Swan laid claim to having invented the parchmentized paper in March, 1880. He filed his application in April following, and the patent was issued in October following. Edison did not file his application until May, 1881, but he said that he had made and used the invention as early as 1879. In 1881 Edison filed the following issues of interference:

> "1. A carbon formed from a straight strip of cardboard paper or parchment paper, and bent to the form of an arch, hoop, or loop, and carbonized by heat while in a bent condition.
>
> "2. A carbon for an electric lamp made of the carbonized parchment paper."

On these, testimony was taken on both sides, and for a time a spirited legal battle was waged. For some time the case has lagged, not being considered of any material commercial value.

Society and Club Notes.

ANNUAL MEETING OF THE NEW YORK ELECTRICAL SOCIETY.

The annual meeting of the New York Electrical Society was held at the Electric Club on July 14, at 7:45 p.m. A prosperous year was shown, the membership having grown from 264 to 292, while the finances are in a sound condition. It was voted that the Society present an honorarium to Mr. Guy, the efficient secretary, who has so long given his services without compensation. It was also voted that the executive committee should be asked to consider the question of lower dues, as connected with an active recruiting of new members. Thanks were tendered to the old officers, and the following ticket for 1892–3 was then unanimously elected: President, Joseph Wetzler; vice-presidents, Prof. F. B. Crocker, Nikola Tesla, J. J. Carty, Charles Cuttriss, T. R. Taltavall and R. S. Dobbie: treasurer, H. A. Sinclair; secretary, George H. Guy.

The Society then adjourned to Madison Square Garden, where about seventy of the members, many of whom were accompanied by ladies, witnessed the performance of "Sinbad," with its wonderful electric light effects, and then enjoyed the concert in the roof garden. The evening was a great success, and added one more to the long list of special entertainments that the Society is so successful in organizing.

THE CLAMBAKE OF THE YEAR.

The Fourteenth Annual Rhode Island Clam Dinner tendered to the electrical fraternity by the American Electrical Works of Providence, R. I., will be given at Haute Rieve, the Union Club country house, on Saturday, July 23, 1892. Lunch will be served at 11.30 and the bake will be opened at 2. As usual, a delightful time may be expected by the veterans and new recruits who hasten to accept the royal hospitality of President Sawyer and his associates.

WESTINGHOUSE ROADS IN NEW ENGLAND.

Mr. R. S. Brown, electric railway representative of the Westinghouse Electric and Manufacturing Co., reports an active demand for apparatus. Among orders recently filled is one for the Natick and Cochituate Street Railway Co., who have equipped and are running four cars with 25 h. p. motors. They are taking current from the electric light station. The road is to be extended to Saxonville.

The Wakefield and Stoneham Street Railway Co. have equipped with four cars, each having two single-reduction motors of 20 h. p. The road is 3½ miles long at the present time, but with extensions will reach about seven miles. It will take current from the local electric light station.

The Fitchburg Street Railway, which has eight cars with Westinghouse motors, is running splendidly. The road has now been open about two months and has been carrying great crowds of passengers all the time.

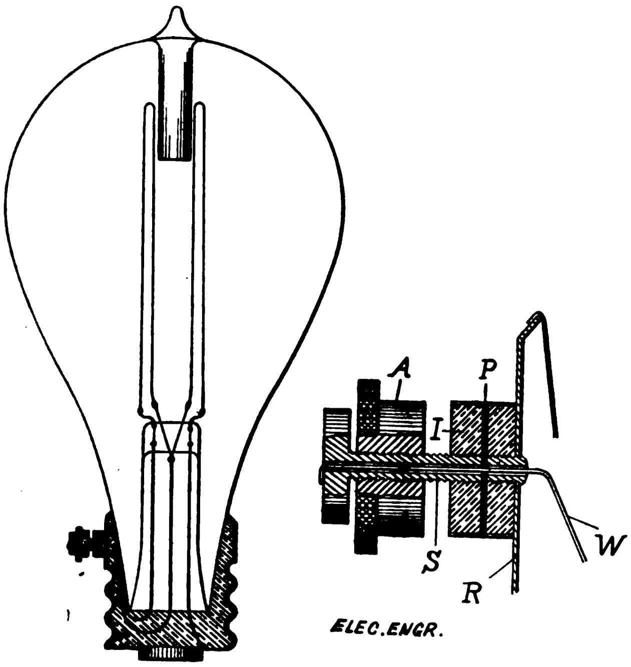
On the 4th of July the Worcester Consolidated Street Railway Co. did an enormous business. Two of its Westinghouse cars earned $100 each. On the whole road they took in $900 more than had ever been paid in fares before. The cars are 36-footers, and one of them during the 4th had on board 185 adults, almost every woman in the crowd having at least one child with her. The capacity of the electric cars is never underrated by the passengers.

QUEEN & CO.

A number of additions to their business and technical staff have lately been made by Queen & Co., of Philadelphia, the better to keep pace with their growing business in electrical instruments. Mr. Nelson H. Genung, a graduate in electrical engineering, of Cornell, has accepted a position in the Queen laboratory, at Ardmore, and his time will be largely spent in designing new instruments and assisting in original work.

THE EDISON NIGHT LAMP.

It is often desirable in interior illumination to run lamps considerably below their normal candle power, as for instance in the case of hall lights burning all night, or in sick rooms and bed-chambers. To accomplish this without loss of energy due to the introduction of external resistances, on direct circuits, the Edison General Electric Co. have brought out what is known as their "night lamp," which is illustrated in the accompanying engraving, Fig. 1.



Figs. 1 and 2.—Edison Night Lamp.

The lamp, as will be seen, is provided with two filaments connected up in the manner shown, and provided with a special switch at the top of the base, which is shown enlarged in Fig. 2. This small auxiliary switch consists of a short brass tube soldered to the screw ring of the lamp and encircling the screw s, the space between the tube and the screw being filled with insulating material I, and the screw s, being kept from turning by means of the insulating pin P. The screw s, is hollow and through it passes the wire w, which is connected to the filaments, which are joined at the centre of the stem.

Mounted upon screw s, is a brass nut A, which, when screwed up, makes connection between the screw s, and the short brass tube soldered to the screw ring. This evidently connects the wire which is soldered to the screw ring of the base R, to that joined to the ends of the filaments at the centre of the leading-in tube, thus short-circuiting one carbon, and allowing the other to give its full brilliancy. When the nut A is screwed back and in the position shown, both the carbons in the lamp are in series and burn at only a fraction of the normal candle power of the lamp. These night lamps as a rule are frosted and shed a mellow light about the apartment.

AN EXTENSIVE SYSTEM OF ELECTRIC ROADS FOR NEW YORK CITY.

The consolidation of the North Third avenue and Fleetwood Park Railroad, the Melrose and West Morrisania Railroad, and the Harlem Bridge, Morrisania and Fordham Railway Company has been completed. This is the combination of horse railroads commonly spoken of as "The Huckleberry Road." Its new corporate title is the Union Railway Company of New York City, and it has $2,000,000 of capital stock, which is more than double the capital stock of the three companies. Following are the names of the directors elected recently: Charles A. Stadler, William Cauldwell, John C. De La Vergne, Thomas W. Olcott, James W. McNamara, and Edward A. Maher of New York; Anthony M. Brady and Robert C. Pruyn of Albany; Albert Shaw of Troy.

The executive officers are: President, Edward A. Maher; vice-president, Charles A Stadler; secretary and treasurer, Thomas W. Olcott.

About seventeen miles of this Union Railway are now in operation by horse power. It is expected that by next November the the entire seventeen miles will be operated by the trolley system. Eight miles of new road will be constructed without delay, making twenty-five miles of road, (all on the trolley plan) which will traverse in many directions the territory lying between the Harlem River and the Westchester county line. The change to the trolley on the main artery will probably be made before the end of August.

The new company will issue bonds not to exceed $3,000,000, to pay for the trolley and the construction of the additional line of road.

THE METRIC SYSTEM IN THE UNITED STATES.

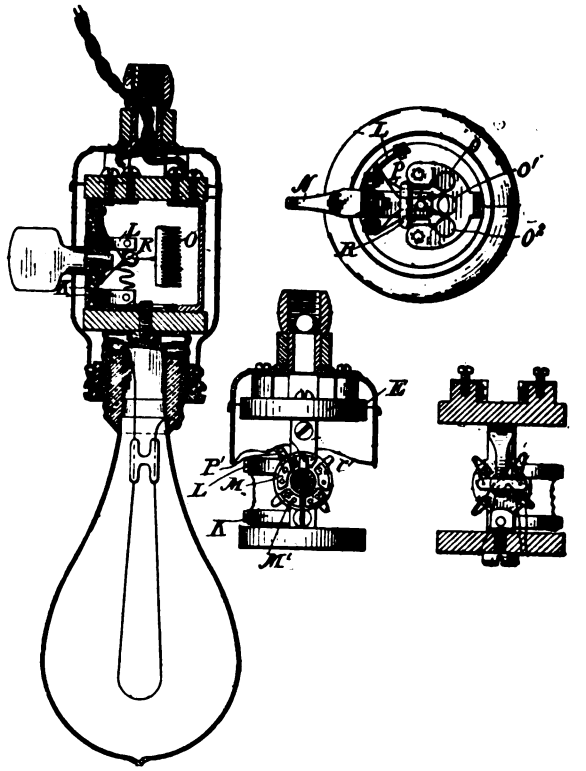
A circular, issued by Prof. John K. Rees, secretary of the American Metrological Society, states that the American Metrological Society has prepared a petition asking Congress to pass the following act:

"That on and after July 1st, 1893, the metric system of weights and measures authorized by the act of Congress approved July 28th, 1866, shall be used exclusively in the customs service in the United States."

Such petition the society desires to circulate widely among those desiring to sign it, and it asks each signer to mail it to his representative in Congress. The American Metrological Society has prepared a simple and excellent chart of the metric system which, for educational purposes, it will mail to any one asking for it for the cost price, 10 cents in stamps. Address secretary of American Metrological Society, No. 41 East 49th street, New York City. Copies of the petition can be had at the same address.

THE WERLINE REGULATING LAMP SOCKET.

The desirability of varying the brightness of an incandescent lamp at will is so obvious that it needs no discussion at this late day. With the object of affording a compact lamp socket, which should contain the necessary regulating device, Mr. Henry E. Werline, electrician of the Werline Electric Specialty Co., of York, Pa., has just brought out the socket illustrated in the accompanying engravings. As will be seen, the handle by which the lamp is turned on and off carries a series of contacts, M, M′, etc., which connect with a corresponding number of carbon helices, O, O′. These small helices are kept apart and thoroughly insulated, and in order to prevent too strong a current from passing through them, by which they might be heated and consumed, they are protected by short fuse wires. The entire set of helices is so mounted that, together with the switch handle, they can be entirely withdrawn from the socket by removing two screws. In this way the socket can be readily inspected at any time. By the protection thus offered to the carbon helices and their arrangement, the use of expensive platinum is avoided and a cheap and effective regulating socket can be produced. At the same time it does away with the necessity of a vacuum chamber for containing the helices.



Werline Regulating Lamp Socket.

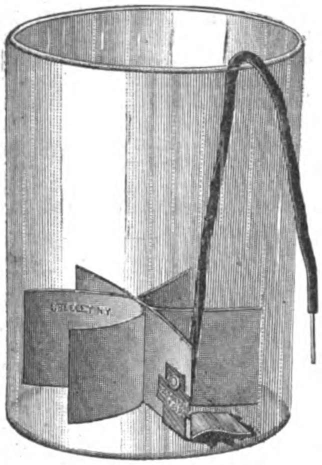
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

Everything comes to him who advertises.

THE GRAVITY COPPER ANCHOR.

THE illustration herewith shows a very valuable improvement which has been lately made in the gravity battery copper, consisting of an anchor attachment for securely and permanently fastening or anchoring the copper to the bottom of the glass jar. The liability to displacement of the copper electrode has always been a serious obstacle in the way of getting the best results from the popular gravity battery.



GRAVITY COPPER ANCHOR.

The new device shown prevents effectually the copper from rising above the bluestone. The copper being held firmly on the bottom of the jar, a uniform distance is had between the two electrodes in all the cells of a battery, and consequently uniformity of resistance throughout, with the highest efficiency.

The "anchor" is made of a piece of sheet copper with a coat of adhesive compound or cement on one side, the upper end being riveted to the electrode, together with the copper connecting wire. When packed for shipping the anchor is rolled up in the shape of a cartridge, with the cement on the inside.

To apply the anchor it is simply necessary to unroll the cartridge, bend it back at right angles parallel with the bottom of the jar, slightly heat the cement over the flame of a match or lamp, and the strip is then ready to be pressed down against the bottom of the jar into position. A little cold water is sufficient to chill and set the cement.

Thus fastened, the cohesion of the cement is sufficient to stand a strain on the wire equal to many times the weight of the jar without dislodging the anchor.

This new copper is now being placed on the market by The E. S. Greeley & Company, sole agents. A patent has been applied for on the device.

NEW YORK NOTES.

MR. **NORMAN HUBBARD**, of No. 93 Pearl street, Brooklyn, N. Y., manufacturer of the Packard vacuum pump, reports that there are now upward of 150 of these pumps in use in incandescent lamp factories in this country and abroad. Among recent shipments are one No. 3 pump to the Edison Lamp Company, Harrison, N. J., and one No. 3 and one No. 4 to the Dominion Electric Company of Montreal, Canada. Recent improvements in the Packard pumps have rendered them capable of continuous use without any danger of break-down or a diminution in the uniformly excellent vacuum they produce.

MR. **E. E. RIES**, president of the Ries Electric Specialty Co., was in New York last week. He reports that the company are not only very busy with their celebrated regulating socket, but are now preparing some new and valuable lighting specialties for the market. Mr. Ries is also very sanguine as to the ultimate success of his induction railway system, which dispenses with all overhead wires, slots or contacts. The model road in the company's factory works like a charm, and Mr. Ries is now after an opportunity to give the system an open-air test.

THE ASTORIA ELECTRICAL MANUFACTURING CO. are running a storage battery car daily on the Steinway & Hunter's Point Railway with a new type of battery weighing 27 lbs. per cell where the usual types of the same capacity weigh 40 lbs. per cell. The battery stands heavy discharges with very small drop in voltage and is therefore well adapted to car work. The positive grids are more durable than those of the usual types, as they are not attacked by the acid and are elastic enough to expand without breaking. The performance of the car is perfectly satisfactory, and the company are going ahead on a commercial basis and are already negotiating with three different roads with a view to equipping them with battery cars.

MR. **LUKE LILLEY**, who for some time past has been the city electrician of Cincinnati, but is now out in the field again for himself, owing to recent changes in city affairs, was a caller in New York last week. Mr. Lilley was one of the pioneers in commercial electric lighting, and has an unequaled fund of experience. He has already had several offers to engage in lighting and railway enterprises, but may spend a little time in developing two meritorious inventions that he is interested in.

PROF. GEO. D. SHEPARDSON, of the Department of Electrical Engineering, University of Minnesota, has been spending his vacation in the East. After visiting Cornell, he made his way to New York last week and looked up a number of friends in the trade and profession. He is mapping out a very interesting line of work for his electrical classes in the fall.

THE EDISON MANUFACTURING CO., which handles the Edison Lalande battery, etc., has removed its offices to 110 East 23d street, this city, where all communications should be addressed. Mr. A. O. Tate is general manager.

HALL & BURDICK are a new firm who have established an electrical supply business at Dansville, N. Y. They find a good opening for local trade and bid fair to succeed.

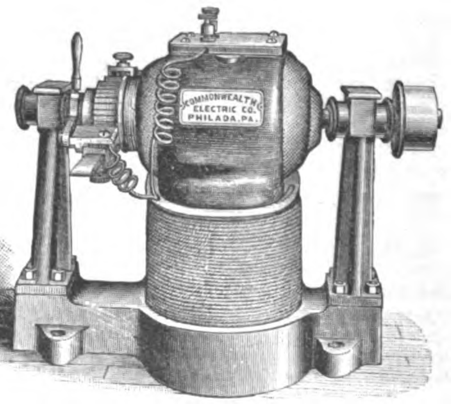
PHILADELPHIA NOTES.

MR. **NEWTON D. HARSH**, formerly with the electric light company at Lancaster, Pa., has opened a wholesale and retail electrical supply house on the third floor of 17 Centre Square, that city, where he will carry on a general electrical business.

CAMPBELL & ZELL CO., of Baltimore, Md., makers of the Zell improved safety boilers, etc., write us that Mr. Robert R. Zell is no longer connected with the active management of their company.

THE COMMONWEALTH DYNAMOS AND MOTORS.

THE accompanying illustration shows the generator of the Commonwealth Electric Co., of 606 Arch street, Philadelphia. As will be seen it is of the Kapp type with oval fields, self-oiling bearings and sliding bed. One peculiar feature of this machine is the construction of the armature, which is wound on a wooden core, each layer being perfectly insulated. The generators are made in sizes of from $\frac{1}{8}$ to 100 kilowatts, and the motors from $\frac{1}{4}$ to 50 h. p. The speed of the arc motor is only 1,000 revolutions per minute, while that of the incandescent is but 1,200 for motors up to three h. p.



COMMONWEALTH ELECTRIC CO. PHILADA. PA.

COMMONWEALTH DYNAMO.

Mr. Charles Bockmeyer, the manager of the company, has had several years' experience in the manufacture of electrical apparatus, and has equipped the shops with machinery of the most approved pattern. His men also are skilled workers, and nothing has been left undone to make the dynamos and motors equal in every respect to the best.

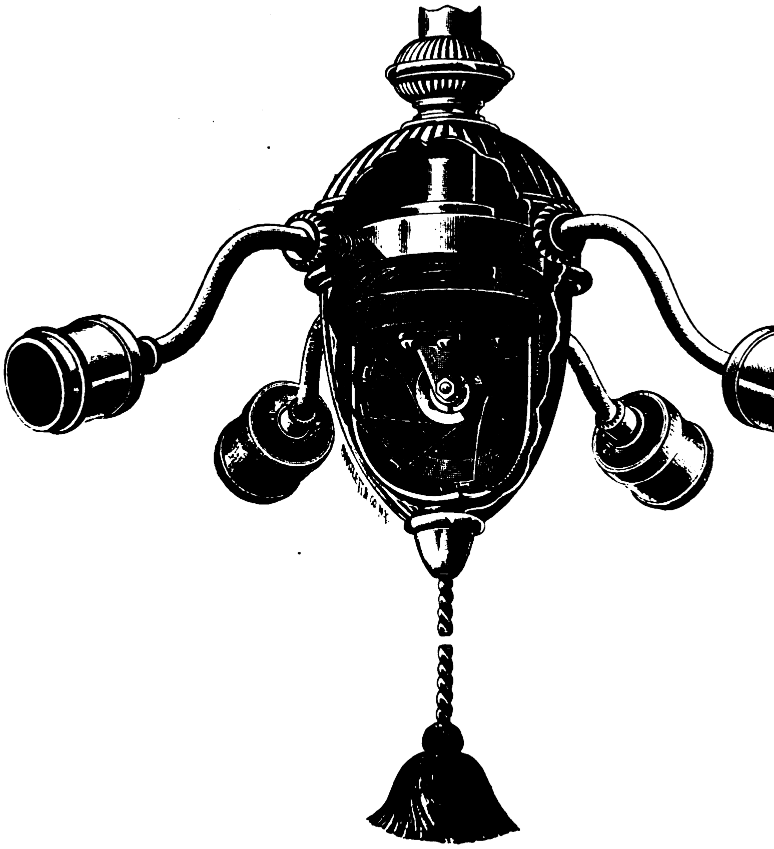
THE QUEEN RESISTANCE TESTING SETS.

Queen & Co., Philadelphia, are having a great "run" on their standard portable testing sets, as the distinctive merits of these goods make them very popular. In every central station, no matter how small, it is real economy to have accurate apparatus for measuring resistance of lines, dynamos, lamps, etc., and the Queen set "1891" type with its wide range, accurate adjustment, and dead beat galvanometer proves wonderfully efficient. Although introduced less than one year ago it is to be found all over the country, and indications point to a steady and increasing demand.

A few years back a commercial resistance set, correct within one or two per cent. was considered very "close," but such finds little sale now in comparison with the improved forms made by Queen & Co., who guarantee them absolutely to ⅛ of one per cent. Electrical engineers as well as central station superintendents will do well to examine these sets before ordering such apparatus. They are fully described in circular No. 285, which can be had by writing to the makers.

THE INTERIOR CONDUIT CO.'S CHANDELIER SWITCH.

The accompanying illustration represents the new combination chandelier switch manufactured by the Interior Conduit and Insulation Company, of New York. As many lights as may be required can be controlled by the device, which embodies the same principles as are contained in the Greenfield pull-down switches manufactured by the same company, and recently described and illustrated in The Electrical Engineer. The mechanical arrangements of this new switch are most ingenious, and are contained in the shell or body of the chandelier. A pull on the cord turns on or off at will one or more lights consecutively, thus dispensing with switches on the wall or key sockets in the chandelier. No extra wiring for the switch and chandelier is required, each light is under direct control by simply pulling the cord, and the switch can be incorporated in the body of any chandelier, as it merely intersects the stem. This ingenious and useful article is said to have attracted instant and favorable notice.



Interior Conduit Co.'s Chandelier Switch.

Mr. Robert Mackie, formerly of the Fort Wayne and Secret Service Electric companies, and lately practicing as an electrical engineer in Cincinnati, has now been appointed city electrician of that place. He has entered upon his new duties.

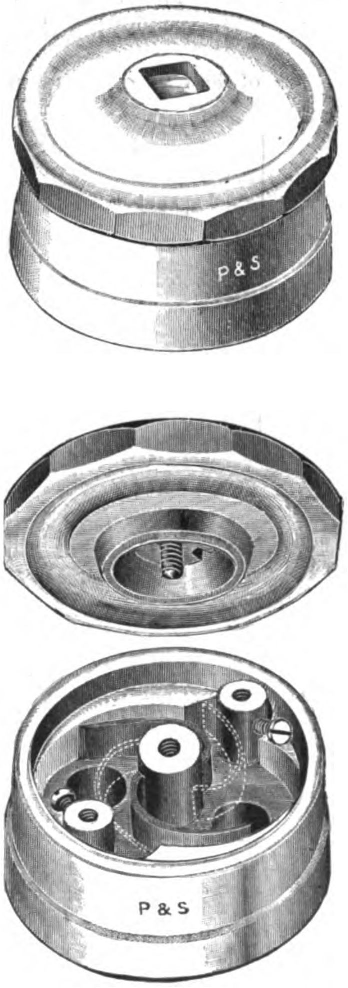
McGUIRE MANUFACTURING CO.

Mr. J. A. Hanna, who for the past eight years has been with the J. G. Brill Car Co. has accepted a position with the McGuire Manufacturing Co., of Chicago, as general traveling salesman. He will hereafter represent on the road their specialties in railway equipment. The McGuire Co. have recently closed large contracts with the South Chicago City Railway Co., Kankakee Electric Railway Co., Toledo, O., Consolidated Street Street Railway Co., and the Pueblo City, Col., Railway Co.

NEW PASS & SEYMOUR WALL SWITCH.

The accompanying illustrations, Figs. 1 and 2, show an exceedingly neat and simple form of switch recently introduced by Messrs. Pass & Seymour, of Syracuse, N. Y. It is made entirely of Syracuse china, the only metal parts being the binding posts, shaft and contact spring, and is operated by turning the cap instead of employing a key. It has a quick, double make-and-break, with rubbing contacts, the break being exceptionally long.

This switch is made for 5 or 10 amperes, and is furnished either plain or decorated in a variety of styles. Its simplicity renders any further description unnecessary.



New Pass & Seymour Wall Switch.

BALL ENGINE CO.

The North Hudson County Railroad Co., Hoboken, N. J., in March, purchased a 300 h. p. latest improved Ball engine from the Ball Engine Co., Erie, Pa. They have been so well satisfied with the performance of the engine that they have ordered an additional engine of the same power from the same company. The Englewood, Ill., Electric Light Co., Englewood, Ill., have ordered a 500 h. p. latest improved Ball cross-compound engine through the Chicago office of the Ball Engine Co. The Port Huron Electric Railway Co., Port Huron, Mich., have awarded an order for one of their latest improved engines to the Ball Engine Co. The engine is a 400 h. p. cross-compound of the latest type.

A PERRET PRINTING PRESS PLANT.

THERE has recently been installed in the press-room of the Brooklyn *Citizen* a system of power transmission of unusual interest to engineers, mechanical as well as electrical. The room contains two Hoe presses, a wetting machine, and several small jobbing presses, etc. These have all been taking power from a single line shaft extending the entire length of the room, except the wetting machine, which was belted to a countershaft, and run as usual by an engine.

When it was decided to change the power from steam to electricity, Mr. Paul T. Kenny, sole agent on Long Island for the Perret dynamos and motors, took the matter in charge and carried it through under his personal supervision. The arrangement adopted is shown in the accompanying diagram.

The line shaft was cut at a point between the two Hoe presses and again between the second one and the jobbing presses, and the sections were connected by clutches. The presses are belted to these shafts and are run by independent motors fastened overhead between the arches that support the ceiling. Each Hoe press has a 15 h. p. motor, and the group of jobbing presses, etc., has a 7 h. p., while the wetting machine is operated by one of 10 h. p. placed overhead like the others and belted to its countershaft.

The flexibility of the whole system is perhaps its most noticeable point. In case of accident to any motor, it may be thrown out and the machine to which it belongs may be run by any or all of the others, by means of the clutches. Thus there is no possibility of a general break-down, even under the most adverse circumstances, and, as an extra precaution, there is a double service from the Edison mains on two different streets, either of which can be thrown on at a moment's notice.

As the entire steam plant of the building has been abandoned, the steam table is now supplied with live steam from the central station of the Edison Electric Illuminating Co., of Brooklyn, while the building is heated by exhaust steam from the same source.

It is claimed that the total expense saved by all these improvements is at least 50 per cent., and as the slow speed of the Perret motor makes it particularly adaptable to this class of work, we expect to hear shortly of other journals coming into line and following the good example set by the *Citizen*. It will be remembered that at the beginning of the year we illustrated the Perret plant of the New York *Commercial Advertiser*.

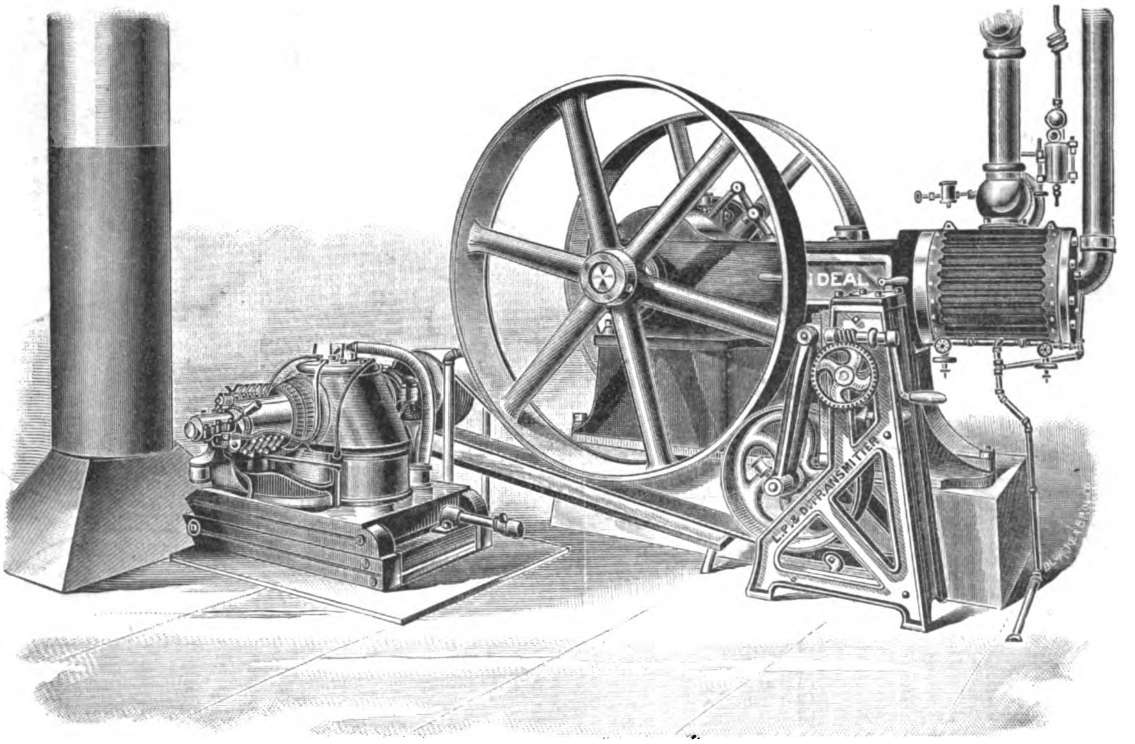
GETTING READY FOR THE ELECTRIC LIGHT.

ONE of the most beautiful parts of the newer New York is the west side from Fifty-ninth street to One Hundred and Twenty-fifth, and it is rapidly filling up with fine residences and handsome apartment houses and hotels. It is still without any central station, but the fact is recognized by foresighted owners of property there that the want will very soon be supplied. An instance of this appreciation of electricity and desire to enjoy its benefits has just been afforded by Dr. A. L. Root, a leading and well-known west side physician, who is building a costly house on West Eighty-first street. Although the electric street mains are still two miles away, he has had the building tubed and wired, for about 120 lights, and hence as soon as the current is available can switch it on without disturbing walls or decorations. He has also made ingenious provision for the use of electric light and power not only as part of the domestic economy, but as a special feature of convenience and assistance in the consultation-rooms. The work has been carried out by H. Ward Leonard & Co. who have used the Interior Conduit system throughout. It is to be hoped that many other residents in the locality will follow the excellent example thus set them, and get ready to enjoy modern methods of illumination, ventilation, etc.

"L. P. & D." POWER TRANSMISSION.

THE accompanying illustration shows an "L. P. & D." transmitter installed by Messrs. Perry & Demeritt, of Montpelier, Vt., in the establishment of Messrs. Siegel & Cooper in Chicago, where the space in which the engine and dynamo had to be placed was so small that the ordinary method of belting was impossible.

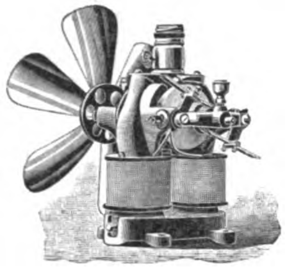
The dynamo is a 400-light incandescent Western Electric, driven by an Ideal high-speed engine with a 72-inch driver. The belt is a light double, 19 feet long by 8 inches wide. The space between the dynamo and engine pulley is 6 inches. The whole space occupied by dynamo, engine and transmitter is 8 x 11 feet. This has been in operation since April 29, 1892, and has given perfect satisfaction.



"L. P. & D." POWER TRANSMISSION AT CHICAGO.

THOMSON-HOUSTON CONTRACTS.—Among the recent installations reported by the Philadelphia office of the Thomson-Houston Electric Co. are the following: Pennsylvania R. R. Co., Pittsburgh, Pa., 100 arc; Carlisle Gas & Water Co., Carlisle, Pa., 50 arc; Norristown Electric Co., Norristown, Pa., 50 arc; Carnegie, Phipps & Co. Pittsburgh, Pa., 300 arc; West End Electric Co., Philadelphia, Pa., 1,300 inc.; Northern Electric Co.. Philadelphia, Pa., 1,000 inc.; Akron Electric Co., Akron, Ohio, 4,000 inc.; Dennison Electric Co., Dennison, Ohio, 2,000 inc.; Duquesne Electric Co., Duquesne, Pa., 1,500 inc.; Wilmington Electric Co., Wilmington, Del., 3,000 inc.; Wyoming Traction Co., Wilkesbarre, Pa., 10 cars; Easton Street Railway Co., Easton, Pa., 12 cars; East Harrisburg Street Railway Co., Harrisburg, Pa., 2 cars; York Electric Street Railway Co., York, Pa., 9 cars; East Harrisburg Street Railway Co., Harrisburg, Pa., 400 h. p. generators; Camden Horse Railway Co., Camden, N. J., 100 h. p. generators; North Hudson Railway Co., Hoboken, N. J., 16 cars; Neversink Mountain Railway, Reading, Pa., 2 cars; Rochester Street Railway, Rochester, Pa., 6 cars; Baltimore & Ohio R. R. Co., Baltimore, Md., three 1,200 h. p. electric locomotives.

THE SIMPSON NOISELESS MOTOR.

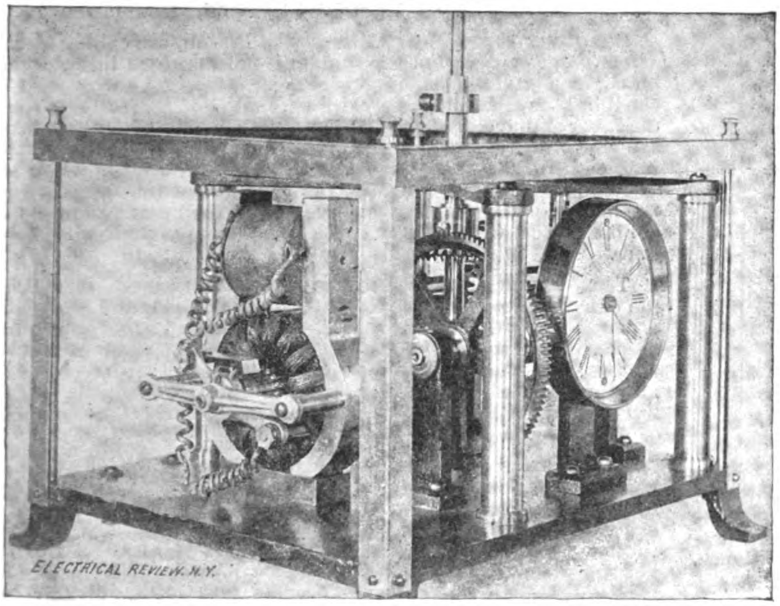


Simpson Noiseless Motor.

ONE of the latest candidates in the motor market is the Simpson Electric Mfg. Co., of 41 West Washington street, Chicago. This company is placing on the market a motor claimed to be second to none. It is noiseless, perfectly automatic and runs without any perceptible sparking whatever. Motors are furnished for arc, incandescent or storage battery circuits as desired, as well as for any voltage. The smallest of these motors receives every attention to ensure perfect construction; all boxes are babbitted, and fitted with automatic feed oil cups. The commutator is made of a fine grade of phosphor bronze and it is much larger than is generally used in small motors. In fact this machine is one that commends itself to intending purchasers. The prices are very reasonable, and the facilities of the company allow of prompt filling of all orders. The cut here shown gives a good idea of one of their fan outfits, which is very complete, and makes a veritable whirlwind.

NEW TOWER CLOCK OF THE STANDARD ELECTRIC TIME CO.

THE new electric tower clock of the Standard Electric Time Co., of New Haven, Conn., which has recently been put on the market by that company, is quite a departure from the usual means of operating tower clocks. It is operated by an electric motor with suitable gearing, so arranged as to be controlled by a self-winding regulator which starts the motor in operation once every minute. After the motor has carried the hands just one minute, it breaks the circuit automatically, allowing the hands to rest at this point until the next minute is completed, when the same thing is repeated. The arrangement of the mechanism is so positive that there is no possibility of a variation from the correct time given by the master clock.



NEW TOWER CLOCK OF THE STANDARD ELECTRIC TIME CO.

The ordinary tower clock is operated by weights, and the movement being exposed to the extremes of temperature it cannot possibly keep such good time as a clock that is finely adjusted and placed in a room where the temperature is more uniform. Besides, the ordinary tower clock must be wound up every week, which requires the full strength of one man, while the electric tower clock never requires winding.

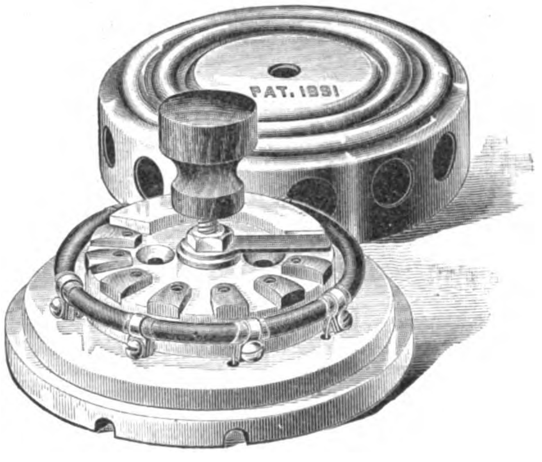
One of the very important features about this clock is the operation of the motor by open circuit batteries. It has required a great many experiments by the Time Company to arrange a motor in such a way that the battery would stand the work, and it is sufficient to say that from ten to fifteen cells of open circuit battery will drive the motor moving the hands to this clock for at least one year without any attention whatever. It will deliver more power to the hands than the ordinary tower clock will with its heavy weights.

This company has just shipped one of these tower clocks to Newport News, Va., where it is to be placed in the new depot of the Chesapeake & Ohio Railway Company. Dials will also be placed in the waiting-rooms, so that uniform time will be given throughout the building. One of these tower clocks has been in operation during the past winter and was not interrupted by any of the storms, while other tower clocks were motionless.

THE McCREARY RHEOSTAT SWITCH.

THE demand which has long existed for a means by which incandescent lamps could be turned down in the same manner as a gas jet is so obvious that a simple device to accomplish this purpose must evidently meet with a wide application. One of the neatest and most compact arrangements of this kind is that just brought out by the McCreary Electrical Specialty Co., of 136 Liberty street, this city. The rheostat switch, as it is called, is shown in the accompanying engraving, and, as will be seen, consists of a series of contacts over which passes the tongue of the switch, the carbon resistance being in the shape of a ring. By changing the switch contact the lamp can be brought from full brilliancy down to total extinction, the last contact breaking the current. The device is thus a combined rheostat and switch.

The McCreary Co. assert that by the use of this switch, and the manner by which it permits the current being turned on, the filaments are spared the shock due to the sudden turning on of full current, as usually effected, and that blackening is thereby also largely prevented. The switches are also adapted for regulating the speed of fan motors. A full line of sizes up to sixteen lights will soon be ready for the market, the rheostat switches for single 16 c. p. lamps for any voltage up to 115 volts being now ready.



McCREARY RHEOSTAT SWITCH.

THE OSHKOSH ELECTRIC LIGHT & POWER CO. have just placed their order with the Rice Machinery Company, 63 and 65 South Canal street, Chicago, for the entire outfit of shafting, floor stands, friction clutch pulleys, etc., to be used in their plant now in process of construction at Oshkosh, Wis. This plant when completed will be one of the largest generating stations in the country, and thoroughly representative in every way. The Rice Machinery Company are general Western agents for the Dodge Manufacturing Co., of Mishawaka, Ind., and the appliances are to be of the latter company's manufacture. The Dodge patent split disc clutches, and wood split pulleys will be used throughout. The main shafting is six inches in diameter, and is to be supported on the Dodge improved adjustable floor stands, and bearings to be of the late improved chain-oiling pattern. The main receiving pulleys from the engines are the Dodge Manufacturing Co.'s celebrated wood split pulleys, of sufficient capacity to transmit 500 h. p. each. The Rice Machinery Company, the contractors of the above plant, are making a special effort in the electrical field, and have installed some important plants, among them the Bessemer Electric Co., at Bessemer, Ala., 400 h. p. plant, and the plant at the Grant Locomotive Works, near Chicago, furnishing the motive power for their 30-ton electric cranes.

ONE ORDER.

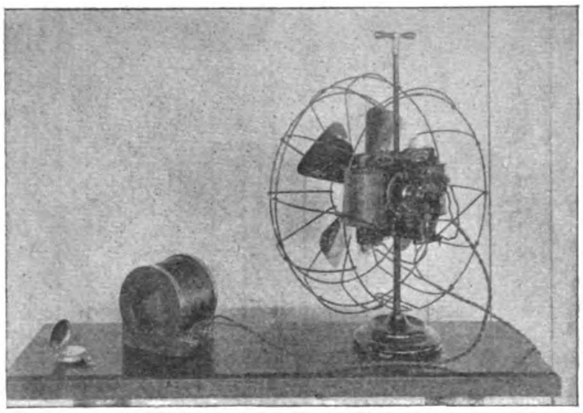
ONE order of three hundred (300) miles of aerial cable! The Day Kerite Wire Company have just secured this prize from the New York Central and Hudson River Railroad. This cable is an eight conductor, and is to be used in the most complete block signaling system ever installed. This cable will be stretched between New York and Buffalo, and will be, when finished, the longest stretch of one cable ever sold by any company in this country.

NEW YORK AGAIN WEDDED TO NEW JERSEY BY KERITE.

ON Saturday, July 16, the Kerite 18 conductor armored submarine cable, recently completed for and accepted by the Metropolitan T. & T. Co., was successfully laid. Its length, from landing to landing is 5,300 feet. Another cable, similar in every particular, is about completed, and will be put in use in about two weeks.

THE "ELECTRO-DYNAMIC" WATCH DEMAGNETIZER.

WE illustrate on this page the new watch demagnetizer brought out by the Electro-Dynamic Co., 224 Chestnut street, Philadelphia. It consists substantially, as shown, of one of the standard Electro-Dynamic one-sixteenth h. p. fan motors and an induction coil. A device is connected to an extension of the commutator nut inside the bearing-stand, so constructed as to admit of its introduction by being curved inward. By means of brushes an alternating current is taken off the device and carried to the coil by a flexible cord. Jewelers and watchmakers generally will find the device a useful adjunct to their equipment, and it should be brought to their notice by local companies, etc. The Electro-Dynamic Co. are placing the device on the market at a low figure, and are furnishing outfits of the entire combination.



THE "ELECTRO-DYNAMIC" WATCH DEMAGNETIZER.

WESTERN NOTES.

ELECTRIC APPLIANCE CO.—The severe and unusually heavy electrical storms of the past two months have proven very disastrous to electrical machinery in a number of instances. They have also served to show the effectiveness or otherwise of the many devices on the market designed to protect electrical machinery. The Electric Appliance Company are getting considerable satisfaction out of the many unsolicited testimonials they have received in regard to the "Swinging Ball" lightning arrester. They have equipped a large number of plants in the West with this device, and have received nothing but the most flattering testimonials from every customer, substantiating every claim that has ever been made for the Swinging Ball lightning arrester.

THE CENTRAL ELECTRIC COMPANY have just gotten in a consignment of Lundell fan motors, and they are making a breeze, which is needed at this particular time of the year. They report the sales of Okonite for the past week as almost equal to the sales of the preceding week, which was the largest in the history of the company. The Central Electric Company also report a very lively demand for arc light carbons. The Washington carbon, for which they are the general Western agents, are giving general satisfaction.

MR. GUSTAVE MONRATH, who has been installing the new plants at Marseilles, Ill., is now back at Chicago, where he will put the Armstrong elevator signals into many of the new skyscrapers.

IMPROVES WITH HARD USAGE.—F. W. Cushing, general Western agent for Day's Kerite wires and cables, has just received from a local lighting company a section of marine cable that has been in use for over four years carrying all this time both night and day a pressure of 2,400 volts without a leak ever having been detected. This cable seems to have actually improved, and looks as perfect as a new piece. Kerite insulation is the reason for this no doubt.

LIGHTNING ARRESTERS.—Referring to the great amount of trouble experienced this season on electric roads from lightning, the Railway Equipment Co., Chicago, state that they are about ready to place on the market a lightning arrester of unusual merit for station, car and line use. Parties who have had trouble during this season from any cause should write them for full information, which will be cheerfully given on application.

MR. G. M. ANGIER, general agent of the Mather Electric Company, has just returned from a business trip South and West. Mr. Angier has established a number of agencies and reports the outlook for business good especially in power transmission and isolated lighting plants of which the Mather Electric Company make a specialty.

MR. J. B. WOOD, who for the past two years has occupied a prominent position with one of the large Chicago supply companies, has resigned and accepted a position with the Knapp Electrical Works. He is receiving the congratulations of his many electrical friends.

MR. CHAS. M. HOWELL, Bessemer, Mich., president of the Illinois Electric Lamp Co., spent some time in Chicago, recently, looking after his interests in the above corporation.

NEW ENGLAND NOTES.

SHAWMUT FUSE WIRE COMPANY, of Boston, are calling special attention at present to their standard railway fuse links, which have given great satisfaction wherever used. The wire used in these links is most accurately drawn, and is of perfectly uniform diameter and composition. The varying conditions of fuse wire are all carefully taken care of by calculation, and always supplemented by testing. The value of this is easily appreciated when it is known that wire will fuse at a very different ampereage, when the length of the wire varies; thus, a wire fusing at 60 amperes in a 5-inch piece, would carry twice the current in a piece 1¼ inch long.

THE WESTINGHOUSE ELECTRIC COMPANY, through their Boston office, have contracted with the Wakefield and Stoneham Street Railway Company, of Wakefield, Mass., for four car equipments, consisting of two 20 h. p. Westinghouse single-reduction motors for each car. The road will be in operation by August 1, and the roadbed is now in process of construction and will be finished in about a week. The Clemmons Construction Company, of Attleboro, Mass., will do the construction work.

MR. ARTHUR J. ARNOT, electrical engineer to the city of Melbourne, Australia, is sojourning in this city for a few weeks, having come over, amongst other business, to witness the tests of a large number of Thomson-Houston dynamos which are intended for use in lighting the city of Melbourne. Mr. Arnot intends visiting Chicago and other cities, and will return to Australia by way of England, where he will spend a few weeks. Mr. Arnot's present address is the Parker House, Boston.

MR. GEORGE CUTTER, of Chicago, is once more amongst his many friends in Boston, and is feeling in excellent spirits over some peculiarly happy business deals which he has just made. Among others he has just secured the Western agency for the new Enamel Resistance, which he expects to become a most important product in a very short time. This resistance is composed of zigzag wire embedded in enamel, so that it is virtually water and fire proof.

THE ENGINEERING EQUIPMENT COMPANY, 143 Liberty street, New York, has secured, by papers just executed, United States rights of manufacture and sale of the Goodell boiler and pipe covering. This is an important addition to the company's business, which is now divided into three special departments, viz.: Belting, boiler and pipe coverings, overhead electric railway materials. In each of these specialties the company purposes to enlarge its facilities and strengthen its position in the trade from time to time.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

THE
Electrical Engineer.

Vol. XIV. JULY 27, 1892. No. 221.

ELECTRIC SEARCH LIGHTS.[1]—I.

BY

E. R. Knowles. C. E.

WHAT is an electric projector or search light? In simple terms it is an apparatus by means of which a powerful beam of light from an electrical source may be projected or thrown forward to illuminate distant objects. From time immemorial man has endeavored, with more or less success, to communicate intelligence of impending danger, warning of the approach of enemies and instruction as to the avoidance of such danger and the repulsion of the enemy, or news of success, of victory, of peace, or other information of importance to his fellow-men, when separated from them by distances too great for the ordinary means of intercourse. The rudest savages practice such inter-communications either by means of bonfires, smoke, drums, or sounds of various kinds, and more civilized communities have and do now make use of such means as semaphores or moving arms, waving or flashing lights, rockets, whistles, bells, guns, balloons and flags for similar purposes; signaling by means of flags of different designs and colors being one of the simplest and most largely used means which is employed where the persons communicating are within sight of one another.

In more modern times, as the messages to be communicated have increased in number and variety, and the places to which such messages have to be sent have become farther apart and more inaccessible, other and better means of communication have been devised from time to time to successfully convey such intelligence easily and rapidly, and finally electricity has been harnessed into service so that at the present time it is the most widely used means of conveying intelligence rapidly between points or persons separated by vast distances where all other means of quickly communicating intelligence fail. Signaling by electricity may be accomplished in various ways, principally by means of the telegraph and telephone, and at night the electric light is used for all distances at which it is visible. Under this latter head may be classed the subject of this lecture.

The electric projector or search light is simply an enormously powerful electric lamp, so arranged that its light may be visible at a considerable distance, when by intermitting its light according to some preconcerted code of signals or flashes any desired message may be conveyed from one point to another. While the electric projector serves its purpose admirably as a means of communicating intelligence to a distance, it has also another and quite as useful application, that of protection at night; for by its means large areas of land or water can be illuminated, the approach of an enemy discovered, aid rendered in time of accident or shipwreck, and the path of the ship over the wastes of the ocean illuminated and rendered safe from danger and disaster. Its various uses are beginning to be more and mode widely appreciated, and its applications in its manifold and varied forms are rapidly and increasingly being found out and put to practical use.

The earliest use of the electric projector or search light is said to have been during the Crimean war, when it was operated by a galvanic battery. That may be considered the ancestral type of the modern mechanism. In 1867 a projector was placed on board the Emperor Napoleon's yacht, the "Reine Hortense," and in 1870 similar ones were installed on the cruisers "Forbin" and "Distree," a magneto-electric machine, the "Alliance," being used as the source of electric energy. In 1873 and 1874 the Russians had the iron-clad "Peter the Great" and the Imperial yacht the "Livadia" fitted with electric projectors, the source of eletric energy being the then newly-invented Gramme dynamo. In 1877 the French made use of such projectors on the iron-clads "Richelieu" and "Suffren,"

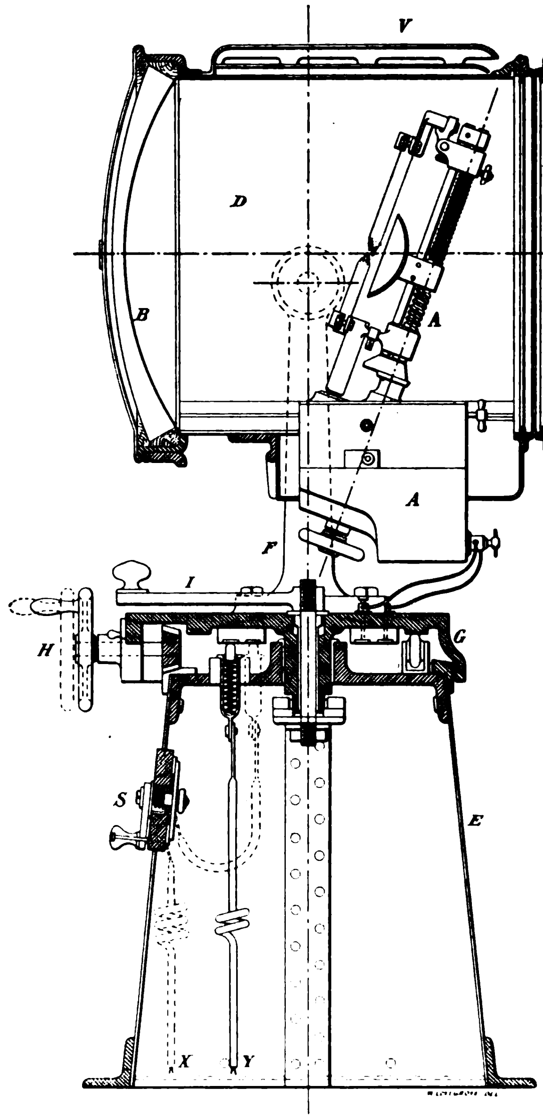


Fig. 1.—A Modern Electric Search Light.

---

[1] Based upon a lecture delivered at Middletown, Conn.

which were also operated by Gramme dynamos. Great improvements now began to be made in projectors, resulting in their use becoming more and more extended, and finally in their becoming part of the regular equipment of our own and foreign men-of-war. In 1887 the use of projectors was begun on the Suez Canal, and has greatly increased its capacity for traffic, vessels provided with the apparatus being allowed to make the passage at night, the receipts of the canal company, by these means, being nearly doubled. The electric projector is also coming into general use in the army, in fortifications and coast defense, and for a great variety of commercial and other purposes; for example, they were used by the Italian expedition to Massowa; also during the recent French Exposition with great success in lighting the Eiffel Tower, and quite recently in Gibraltar Bay when the emigrant ship "Utopia" was lost, at which time the loss of life would undoubtedly have been far greater but for the fact that all the vessels of the British squadron which were provided with electric projectors promptly concentrated their powerful beams of light upon the place where the unfortunate vessel sank, illuminating the spot as by daylight and enabling the rescuers to save the drowning unfortunates who were struggling in the waters. The time is not far distant when every steam vessel of any size and every locomotive will carry some form of this apparatus as a regular part of its equipment, when every fortification will use them as a means of offense or defense, when all important buildings and localities will be furnished with them, and when every lighthouse will use their far-searching beams to warn the mariner of danger or direct him to a haven of safety.

In its simplest form the electric projector consists of an electrical source of light, a mirror or lens for concentrating and reflecting the light and mechanism by means of which the resulting beam of light may be directed to any desired point. A type of such a projector is shown in the illustration, Fig. 1, which represents a vertical cross-section of one of these instruments, so that all its various parts can easily be seen, A being the electric lamp, B the reflecting lens-mirror and C, D, E, F, etc., the various parts of the mechanism for controlling and directing the light. I shall refer to the essential parts of the electric projector in the order stated, and first will describe the electrical source of light.

The voltaic arc is formed between the ends of hard carbon rods or pencils connected to the ends of the conducting wires. The free ends of these carbons are first brought into contact either by hand or by suitable mechanism, and then separated. The heat generated at this point of separation between the carbon rods is so great (about 7,000 F.) that a portion of the carbon is volatilized and acts as a conductor between the separated ends of the carbon rods, and it and the tips of the carbons become white hot and emit a dazzling light. The light so generated is called the electric arc light, and is of all known artificial sources of illumination the most intense.

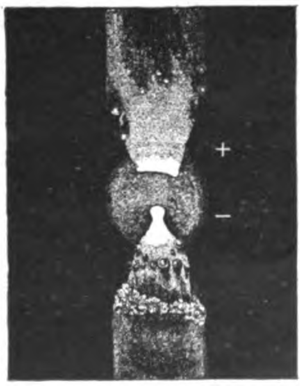

FIG. 2.

Under the action of the electric current the carbons are slowly consumed and assume the appearance shown in the illustration, Fig. 2. If the carbons rods are of the same diameter, one of them, the positive carbon, consumes about twice as fast as the other or negative carbon, and if the electric arc is to be maintained, means must be furnished for gradually bringing the carbons together as they are consumed, so that the distance between their points may remain constant in length and so prevent the extinction of the light. This may be accomplished by pushing the carbons together by hand, in a lamp such as is shown in the illustration, Fig. 3, a rather troublesome and inefficient way of so doing; or, as is the modern practice, they may be so arranged in suitable mechanism, that as they consume and the distance between their ends increases, they will be automatically brought together by the varying action of the electric current which forms the voltaic arc.

It is a well-known law of electric action that the amount of current which will, under a given pressure or difference of potential energy, flow through a given current is inversely proportional to the resistance of that circuit; that is to say, the greater the opposition which the circuit offers to the passage of the current or the greater its resistance the less the amount of current which will flow through it; also, when an electric current is divided, offering more than one path for the passage of the current, that the current will divide itself through all the paths offered and inversely proportional to the resistance of each path. Advantage is taken of these facts in designing a mechanism to automatically separate the carbons and so form the voltaic arc and to bring the carbons together as they consume.

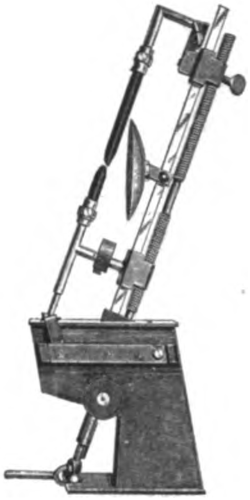

FIG. 3.

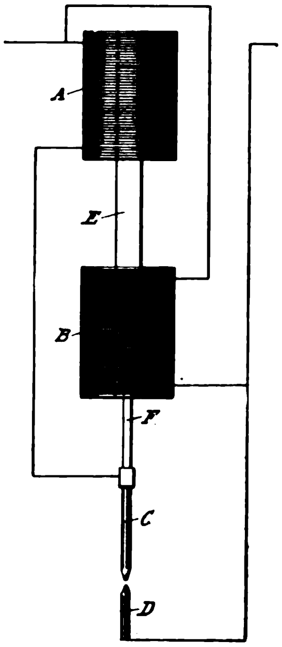

FIG. 3 A.

In its simplest form a mechanism, known as the electric arc lamp, may be represented by the diagram, Fig. 3 A. A is a sucking magnet wound with coarse wire and of low resistance and is connected between the + point of the circuit and the carbon rod C. B is a sucking magnet wound with fine wire and of high resistance and is connected between the + point of the circuit and the — point of the circuit. E is an iron core passing loosely through the magnets A and B and carrying at its lower end by means of the rod F the carbon C. The other carbon is represented by D and is connected to the — point of the circuit. It will be seen that there are two paths offered for the passage of the current, one from the + point of the circuit through magnet A carbons C and D to the — point of the circuit, and the other from the + point of the circuit through magnet B to the — point of the circuit. The first one of these paths is through the carbons and is of low resistance, offering but feeble opposition to the passage of the current, while the second path is around the carbons and is of high resistance, offering considerable opposition to the passage of the current. When there is no current flowing through the lamp the carbons are together, but when the current is applied to the lamp it divides, the major portion going through magnet A and the carbons C and D and the minor portion going through the magnet B. The magnets A and B are so wound and connected that they tend to attract or suck in the iron core E in opposite directions. Now when the current is first applied magnet A is strongly energized and magnet B is feebly energized so that magnet A attracts and sucks in core E against the opposing pull of magnet B, thus drawing the carbon rods apart and striking the voltaic arc between their ends. As the ends of the carbon rods burn away and the distance between them becomes greater, the resistance of the first path for the current increases, due to the increased resistance offered by the increasing distance between the ends of the carbons, and less current flows through it. The magnet A becomes weaker and weaker and offers less and less opposition to the pull of magnet B, which finally balances and then overcomes the pull of magnet A and sucks the core E into itself, thereby bringing the ends of the carbons C and D nearer together and shortening the distance between their points to their original distance apart, thus maintaining the voltaic arc constant in length. When the magnets A and B are just about balanced and B is gradually overcoming A and drawing core E into itself the lamp is in proper working order and the voltaic arc is maintained at a constant length. All the action depends, as stated, upon the varying resistances of the two paths offered for the passage of the current and upon the varying distribution of the current through these paths.

In the design and construction of such a mechanism for use in the electric projector, not only the peculiarities of behavior of the voltaic arc must be considered but certain other conditions which arise must also be taken into account and provision made therefor. In the first place, a mechanism must be provided which will, when the light is required to be produced, automatically bring together the tips of the two carbon pencils and then draw them apart the required distance, thus striking the arc.

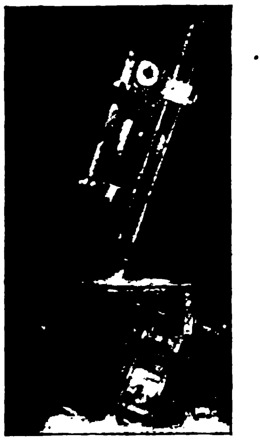

Fig. 4.

Second. As already stated, the carbons slowly consume, and the distance between their ends lengthens, and to prevent this and maintain this distance constant so that the light may not go out, there must be provided a mechanism to automatically feed one or both carbons forward in proportion to their consumption.

Third. In the event of the extinction of the arc, the striking and feeding mechanism must be so arranged as to come into operation and bring the tips of the carbons again into contact and then restrike the arc.

Fourth. As already stated the carbons consume at unequal rates, and if it is desired, as it is in all electric arc lights used in projectors, to maintain the position of the luminous arc at a fixed point, which in the case of the electric projector is at the luminous focus of the reflecting mirror as will be described further on, means must be provided for feeding each carbon forward at a rate of speed proportional to its rate of consumption. In other words, such a lamp must have a striking mechanism, a feeding mechanism and a focusing mechanism, and all of these must be automatic in their action.

The illustration, Fig. 4, shows a type of lamp of this description, such as is used in the electric projector which is being described. If when the current is applied to this lamp the carbons A and B are apart, the shunt magnets C and D operate the clutch E and by it turn the right and left screws F and G until the carbons are brought into contact, when the magnet H is brought into action and strikes the arc by drawing carbon B down and away from carbon A. If the carbons A and B are in contact when the current is applied to the lamp, magnet H draws carbon B down and away from carbon A and so strikes the arc. As the carbons consume and the arc tends to lengthen, shunt magnets C and D, by means of the clutch E, rotate the screws F and G and gradually bring the carbons nearer together, just enough to compensate for the amount of carbon burnt away, thus keeping the length of the arc constant. If the lamp is extinguished it performs the same cycle of operations as above described and relights itself. The arc is maintained at the focal point of the mirror by so proportioning the feed of the screws F and G that they each feed their respective carbons A and B together at a rate proportional to the rate at which they are consumed, thus keeping the luminous arc at a fixed point.

The electric arc lamps used in the electric projector are very powerful, giving with 75 to 100 amperes a luminous intensity of from 20,000 to 30,000 c. p.; that is to say, a light equivalent to that which could be obtained from 20,000 to 30,000 candles all burning at once at one spot, if that were possible. The carbon rods used in these lamps are from ¾ of an inch to 1¼ inches in diameter and the lamps are designed to burn continuously for about six hours. The position of the luminous source of light in the projector is at the luminous focus of the reflecting mirror as shown in the illustration, Fig. 1, and the mechanism of the projector is so arranged that the luminous source may be adjusted exactly to this point.

SENSITIVE WATER JETS.

PROF. W. B. CROFT, in a note to *Nature*, says: "A form of this effect lately presented itself which seemed in some ways new. A thin jet, 5 feet high and arched so as to be 3 feet at the base, was falling in a feathery spray. At 13 feet distance a small Wimshurst machine was set going; not instantly, but after two minutes, the spray gathered itself up almost into one clear line; although the jet was turned up and down and the machine was discharged, the falling water would not resolve itself again into spray for fifteen or twenty minutes. It is difficult to imagine the medium for this action; it is too indefinite, perhaps, to suppose that an indicator is found for the trembling of a disturbed ether while it is dying down. The well-known experiment is not known enough, for it is not often described in books. Take a glass rod, electrified ever so little, to a certain point; at once the jet collects itself; a slight move away brings back the old disorder, while an inch nearer makes things much worse. It is a striking illustration to help one to imagine what the electrical forces of the air may do.

MAGNETIC AND ELECTRICAL PHENOMENA OF TRAINS PASSING AN OBSERVATORY.

A FRENCH journal describes an interesting phenomenon relating to two railways, one the Scaux line and the other the Ceinture, which pass within a comparatively short distance of the Montsouris Observatory, Paris, the former line being about eighty metres distant and the latter sixty. It appears that during the passage of trains on the Ceinture line, which is nearest to the observatory, the bifilar magnet is found to be disturbed, and its oscillations are registered photographically—indeed, the movements are so regular that the curve clearly indicates the exact time of each train passing the observatory. The trains on the Scaux line give rise to a phenomenon not less remarkable; that is, whenever the driver blows off steam the electrometer is partly discharged, the electrical potential of the air falling to about one-half its original value. It appears that these phenomena have been considered of sufficient importance to be brought forward by the Paris Observatory in opposition to the proposed extensions of the railway from Scaux to the Place de Medicis.

MODERN AMERICAN TELEGRAPHIC APPARATUS.—
IV.

BY

F. W. Jones

DYNAMO CURRENTS ON TELEGRAPH WIRES.

THE adoption of dynamos in place of chemical batteries for generating the currents at principal stations to supply the local circuits therein and the main circuits radiating therefrom, marks an important advance in the improvement of the telegraph.

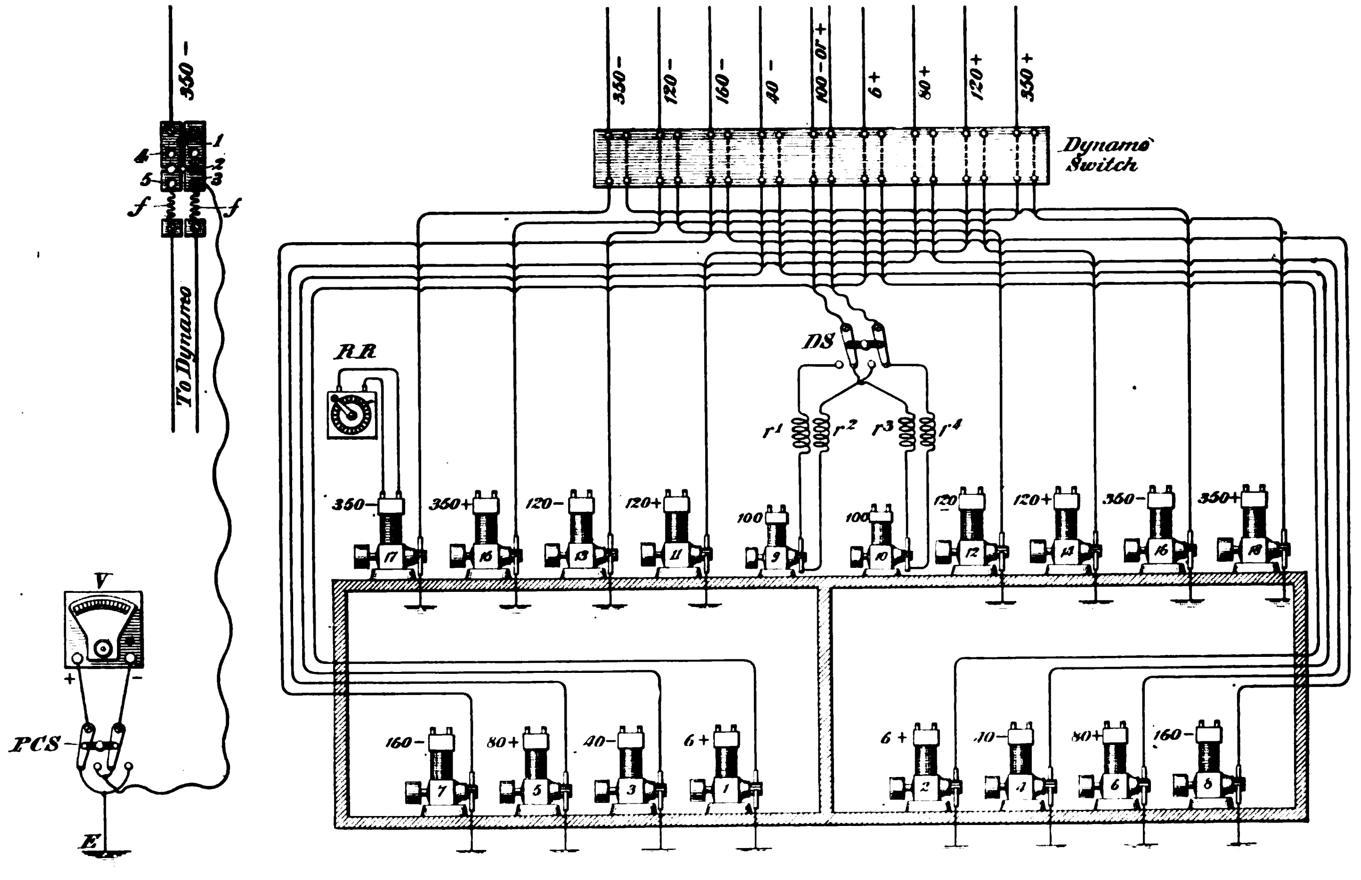

FIG. 2.—"INDEPENDENT" DYNAMO TELEGRAPH SYSTEM IN USE IN POSTAL TELEGRAPH-CABLE CO'S. SERVICE.

From the nature of things dynamos cannot well be employed in such numbers and varying gradations of E. M. F. as batteries; therefore in practice a limited number of dynamos of suitable potential and polarity is employed, and the circuits are grouped and graded to meet the new conditions, necessitating an entire rearrangement of wires and an outfit of novel switches and other apparatus.

Heretofore the Callaud batteries which have been the standard, have had from two to several ohms' internal resistance per cell and the custom has been to connect to one battery several wires (usually four). When such wires were attached to a battery having a high internal resistance, the incoming currents, obeying Ohm's law, made a portion of themselves manifest in each other's circuits. Owing to the low internal resistance of dynamos all circuits attached thereto are brought very nearly to the zero of the earth.

Besides the use of dynamos in telegraphy the adoption of wires of superior conductivity, and the improvement made in some of the electrical and mechanical features of the apparatus employed in signaling, have been the only advances of any importance within recent years towards securing a greater traffic capacity of the wires. An enormous loss of facilities has been sustained by reason of defective insulation and notwithstanding the occasional cleaning of glass in some smoky districts and the addition of petticoats to the insulators, the leakage continues to play a very serious part in restricting the earning power of all interurban circuits which in this country are exceptionally long and subject to locomotive smoke upon railroads, and the frequent contact of ornamental foliage.

There are two distinct telegraph dynamo systems in use, the "series" and the "independent"; the former has been installed by the Western Union Telegraph Co. in the cities of New York, Chicago, Pittsburgh and St. Louis; the latter system is operated by the Postal Telegraph Cable Co. in New York, Chicago, St. Louis, Boston, Philadelphia and Pittsburgh.

The "series" system has already been clearly described by Mr. Alfred S. Brown in THE ELECTRICAL ENGINEER of January 27, 1892. In this system, shown in part in Fig. 1, five dynamos, (two of seventy volts each and three of sixty

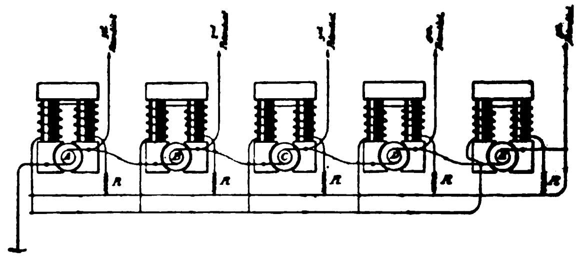

FIG. 1.—SERIES SYSTEM OF DYNAMO TELEGRAPHS.

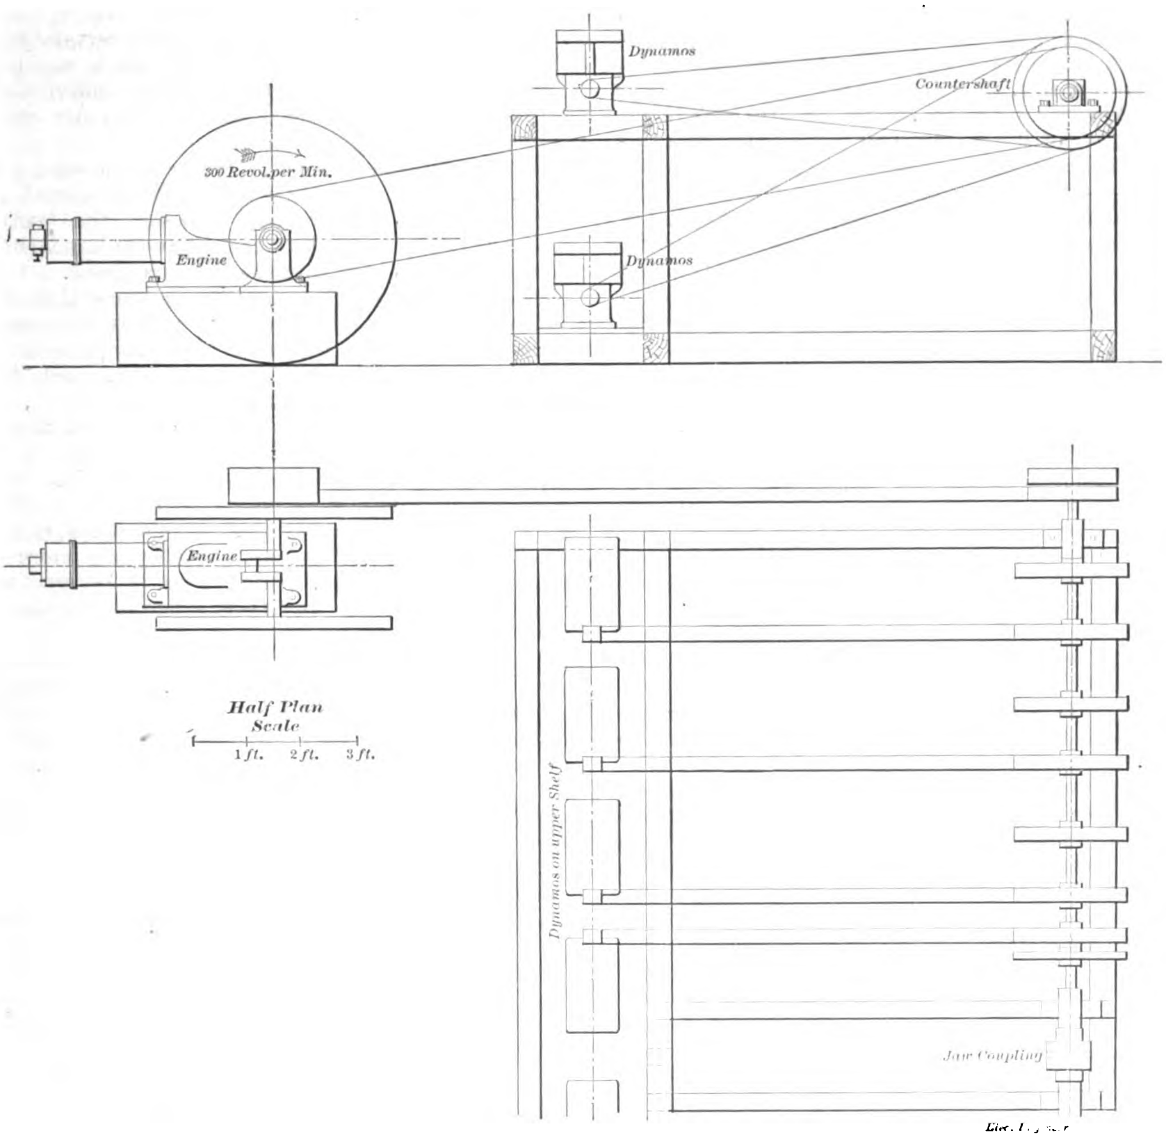
volts each) have their armatures connected up in series with one pole of No. 1 dynamo connected to the earth, and their fields are connected in multiple and are energized by a current from No. 5 dynamo farthest from the earth at an E. M. F. of 60 volts; the machine, however, having a potential of 320 volts at its free terminal. These dynamos are rated as 2½ kilowatts each, or about 41½ amperes and sixty volts each, and in order to develop the full energy of all the dynamos in the series the whole load must be carried by No. 5 machine yielding 40 amperes at a pressure of 320 volts = 12,800 watts. The moment any current is tapped from either of the machines intermediate between No. 5 and earth, that moment the system fails to yield its normal energy. For example, suppose 8 amperes were tapped from each dynamo at their E. M. F. prevailing at the tap wires between them; then the total energy available would be only 7,920 watts, or 62 per cent. of their combined capacity. If 40 amperes were tapped from No. 1 dynamo it is obvious that the energy at 70 volts is 2,800 watts and that no further current could be supplied by the other 4 dynamos as No. 1 is capable of carrying no more than its own current of 40 amperes through its armature. So that each dynamo yielding an average of 8 amperes is only carrying one-fifth of its normal current in its armature, so far as its own output is concerned.

Fig. 2 is a conventional sketch of the independent dynamo system, particularly the one installed in Philadelphia, showing 8 Edison 1½ kilowatt dynamos and 2 Edison ¼ kilowatt dynamos on a top shelf, and 8 Edison 1½ kilowatt dynamos on a bottom shelf of a yellow pine frame which is self-contained, thoroughly braced, with grouted bed, and has no attachments by which any jarring can be communicated to the walls or floors of the building.

Fig. 3 is a half plan of the frame. There are two 7 h. p. Otto gas engines of the latest pattern, belted to driving pulleys respectively on either ends of the two shafts whose inner ends are fitted with a clutch coupling so that they may be run singly or together. At the outer ends of the shafts is a fast and loose pulley with a belt shipper. When starting the engine the belt is on the loose pulley.



FIGS. 3 AND 4.—ARRANGEMENT OF DYNAMO TELEGRAPH PLANT, POSTAL TELEGRAPH-CABLE CO., AT PHILADELPHIA.

The dynamos comprise two groups upon the frame. One group of 9, is on the left, numbered with odd numbers. Eight of these dynamos are connected one pole of each to earth, the other to the left-hand strap of each pair of straps on the dynamo switch. The right-hand group is numbered with even numbers and connected to the right hand switch straps, as shown. From the top of the switch the wires run to the switchboards in the operating-room and furnish the potentials and polarity of currents required to operate the various classes of circuits. No. 9 and No. 10 dynamos on the top shelf of the frame are 250 watts each at 100 volts and are connected to a wedge at the main switch to be used for intermediate or testing purposes the same as 100 cells of Callaud battery, the resistances r^1, r^2,

r^3, r^4 constituting an internal resistance of about three ohms to the volt to prevent sparks and short-circuiting.

Only one group of machines and one gas engine are in operation at one time, the other group being held in reserve. A section of two straps of the dynamo switch over the voltmeter V shows No. 16 dynamo 350 *minus*, of the right group, connected by plugs at 1 and 2 to the wire leading to the operating-room, No. 17 dynamo of the left group being open. The holes 4 and 5 may be used for ammeter plugs and can be inserted and a reading taken without interference by pulling out plug 2. The voltmeter connects at 3 and has a switch P C S to adapt it to dynamos of either polarity. D S is a switch by which either No. 9 or No. 10 dynamo may be put in circuit. Each machine has a regulating rheostat included in the field coils, only one of which R R is shown on No. 17 of the left group.

The dynamos are shunt-wound and are constructed for the amperes and E. M. F. they are respectively expected to yield. Belt slippage, or any accidental imperfection in the operation of either of the dynamos of a group, in no manner affects the currents of the other machines and it is seldom if ever necessary to stop the group on account of the disability of one dynamo. But one set of brushes intervenes between the line wires and the earth, whereas in the series system several sets of brushes may become the path of the line circuits to earth and any default in one machine impairs or destroys the action of every machine beyond and affects all circuits attached thereto.

Just what inductance five series dynamos add to a circuit that is attached to No. 5 machine would be interesting to know, although I do not believe it is very great. An Edison 1 K. W. dynamo 350 volts has about 4 millihenrys with a current of 6½ milliamperes and a similar 40-volt dynamo has about $\frac{1}{1000}$ millihenry. What effect the inductance of these dynamos when running with heavier currents has in adding to the time constant of a telegraph circuit attached to said dynamos, at present, is a matter of conjecture.

Excepting the 6-volt machines used exclusively for local circuits, the dynamos are not only the generators, so to speak, of the currents necessary to actuate the electromagnets in the line circuit at a distance, but they also necessarily constitute the path to earth for all incoming currents from distant stations. It is simply bewildering to try to imagine what takes place in these machines during the operation of several quadruplexed and duplexed circuits. It is to be noted that the energy of distant currents has become nearly exhausted on their arrival at the machines in question. In the "series" system a complete installation consists of three groups of five dynamos each. Two of these groups are kept in constant operation. Local circuits are supplied by other machines run independently. The two running groups have a nominal capacity of 25,000 watts. Of this energy only 14,000 watts can be utilized provided an equal amount of current is taken from each dynamo; but as in practice the lower potentials are in greater demand, it is probable that not 10,000 watts are available. The (8) dynamos forming one group of the Philadelphia plant having a joint capacity of 12,000 watts, each machine being 1½ kilowatt at its normal voltage, are capable of supplying a larger number of circuits than the two groups of 10 2½ K. W. machines arranged in series. Fig. 4 shows the arrangment in end view.

WHAT IS IT?

THE London *Financial News* states that Mr. Augustus de Missoli has applied for permission to erect a telegraph line on the Tesla system between Buenos Ayres and Rosario. The company, which has already the necessary capital is to go under the style of Electrofonia Franco-Argentina. The Department-General of Postal and Telegraphic Service has reported favorably on the proposal.

CONDENSING WITH TRIPLE-EXPANSION ENGINES.

BY

Ernst Egger

I HAVE read with great interest, in THE ELECTRICAL ENGINEER of January 20, 1892, the description of the Van Vleck triple-expansion engine, and I have studied this machine in the Twenty-sixth street station of the New York Edison Co. with care. Everybody will admit that this machine, considering that it is the first of this kind in the country, shows many superiorities, although I am sure that the subsequent engines will certainly be without some defects which are still inherent in this pattern.

I have not in mind to enter into the individualities of the design, but will confine myself to the non-condensing feature of the engine.

At the same time I must refer to the article, published by Mr. Zehme, in THE ELECTRICAL ENGINEER of April 6, which gives pretty clearly the views of the leading German engine builders. Further, I have in mind the answer which Mr. Van Vleck wrote in the same issue.

Mr. Zehme gave expression to the view that by using condensing with triple-expansion engines, one can get an increase of efficiency of from 20 to 25 per cent. I find that this affirmation is quite correct, and Mr. Van Vleck is unable to refute it. He says, merely, that the value of the condenser is not so great, but that he has no time to prove this. That is a queer way of refuting an argument which an adversary can prove at any time. There are running in Germany, Austria and France so many triple-expansion engines, all condensing, that the results obtained with these undoubtedly are more credible than mere conjectures, which one is obliged to make here, because no such engine was running in this country until recently.

It is natural that in one and the same engine the advantages, obtained with the condenser, should vary within certain limits, since they depend on the load at the time, that is, on the length of admission in the high-pressure cylinder, and Mr. Zehme adds, very truly, that, especially in small loads, condensing is not only economical of steam, but very useful for the noiseless working of the engine. That is a fact of importance in engines with long stroke and high-speed piston, especially in upright engines, where the acceleration of the piston is a high one. It may be that Mr. Van Vleck has overlooked this item.

Further on Mr. Van Vleck states that the employment of the condenser is more a question of finance than of engineering. As to this, I believe that it is not quite so. On the other hand, if that should be so, everybody knows that one can save money in this way, and it is very strange to overlook such an opportunity for saving money. There are cases where the erecting of condensers is expensive, for instance, if it is necessary to lay long pipe lines for the incoming and outgoing water, though that does not seem to be the case in New York. Nevertheless, if that is so, it is an outlay once for all which must be recovered in some years, in which I agree with Mr. Zehme. In the central stations of Berlin it was necessary to put in brick-lined canals conducting the warm water to the river Spree, but they did not shirk the expense, because they understood the necessity and subsequent advantages.

Another circumstance has not been mentioned, though it is productive of a great economy in steam, that is, the return of a corresponding amount of warm condensing water to the boilers, which can be done at a temperature of 180 to 200° F. With this, one gets extremely good results, and the firm of Gebr. Sulzer in Winterthur, Switzerland, probably the best steam engine builders in Europe, attained a consumption in this way with triple-expansion engines of less than 1.2 pound of coal per indicated horse power.

A good idea of engine building for electrical purposes was afforded by the late electrical exhibition in Frankfort, where the following upright condensing triple-expansion engine of the well-known firm of G. Kuhn, Stuttgart, was running:

Cylinder diameters, 20 inches, 28 inches, 78 inches; stroke, 24 inches; pressure, 142 pounds per square inch; revolutions, 80 to 100 per minute.

The machine had a capacity of 600 to 1,000 h. p., and worked with a very small consumption of steam.

The Van Vleck engine has the following dimensions: Cylinder diameters, 18 inches, 27 inches, 40 inches; stroke, 30 inches; pressure, 150 pounds per square inch; revolutions, 130 per minute; capacity, 500 to 800 h. p.

Evidently in this machine all the dimensions are the same or larger than the above, except the low-pressure cylinder; yet the maximum capacity is smaller by 200 h. p., that is, 20 per cent. This is due to the condensing.

I have not the space here to say more of Kuhn's very remarkable engine, and can therefore only refer to my treatise on them[1] published in the January number of the Vienna *Zeitschrift für Electrotechnik.* The treatise also contains tables showing at what speeds condensation was employed at Frankfort, and I stated that only once the number of 100 per minute was exceeded in using direct condensers. It is a fact that high-speed is unsuitable for the operation of pumps, although high-speed pumps are now being built. But there are resources enough to draw on, and it seems to me that Mr. Zehme also does not appreciate the value of an independent central condenser.

In all the numerous central stations of Paris central main condensers are used exclusively. The new station of the Compagnie Continentale Edison on the Avenue Trudaine, is a first class plant, and there is working there a main condenser with four steam engines, each of 300 h. p., and running at 130 revolutions per minute. The result obtained is a very good one, and the requisite attendance and inspection is a minimum. That is the modern method, to employ condensation in such stations where high-speed engines are in operation, and I cannot help thinking that this would have been a surer means to save money and produce electricity cheaper, having in view especially the projected enlargement of the Edison stations in New York.

THE ELECTRIC STORM OF JULY 16, 1892.

BY

W. Finn

I.

A MAGNETIC storm of unexampled severity and duration swept over the United States on Saturday, July 16, almost completly paralyzing the entire telegraphic service of the country for several hours. The writer had suspected the presence of abnormal earth currents in the wires on the morning of that date, and was engaged in making observations and taking readings for several hours prior to the advent of the storm.

Between 8 and 10 o'clock more or less difficulty had been experienced in operating many of the eastern and western circuits, and galvanometer tests had shown the existence of strong and variable earth currents in some of the wires. From 10 to 11 a. m. continuous observations were made on a New York-Boston wire in which the current showed incessant variations both in direction and magnitude, the latter averaging upwards of 10 milliamperes. Several tests between 11 and 12 showed similar variations in the polarity of the current though somewhat diminished in strength. Between 12 and 12:15 p. m. upwards of 150 changes in the direction of the current had been noted on a New York-Providence wire, during which time the current averaged 9 or 10 milliamperes.

Suddenly at 12:20 p. m. a tremendous wave struck the wire, which sent the galvanometer needle whirling around the scale and prevented further measurements being taken without the aid of a hundredth shunt. At the same instant every eastern and western circuit, as well as many wires in other directions, became either partially or wholly inoperative. A short while afterwards there was scarcely a wire in any direction, except local ones, that did not feel its effect, though here and there the curious anomaly presented itself of a circuit being operated between two points where other circuits between the same terminals were absolutely unworkable.

At 12:37 p. m. a reading obtained on a No. 6 iron wire to Boston, 213 miles in length and measuring about 3,700 ohms, showed a current strenth of 27 milliamperes, which increased to 32 milliamperes two minutes later, and continued to grow in intensity until it finally attained the unprecedented magnitude of 133 milliamperes at 12:40 p. m., representing a difference of potential between the two grounds of about 492 volts!

This was the highest E. M. F. observed; in subsequent tests many, however, exhibited currents of higher values in the wires than those given above. For instance, the current strengths noted in a wire to Elizabeth, N. J., rose from 55 milliamperes at 1:51 p. m., to 95 milliamperes at 1:55 p. m., and finally to a maximum of upwards of 150 milliamperes at 2:10 p. m., with an estimated E. M. F. at that time of about 210 volts. A wire to Philadelphia, measuring 900 ohms exhibited a current of 140 milliamperes, thus showing a potential difference of 126 volts between the distant grounds.

The writer knows of no record of any previous storm in which the voltage and strength of the earth current ever attained so high a value. The nearest approach in point of intensity is probably the electric storm of January 31, 1881, which developed a current of 41.4 milliamperes in one of the London-Irish wires, the highest E. M. F. observed being 120 volts in another wire between Haverford West and Valentia.

During the prevalence of Saturday's storm it was found possible, as is usual in such cases, to converse, and even send business over the wires without the aid of the ordinary artificially produced signaling currents. By 3 p. m. the disturbing forces had so far subsided as to admit of a resumption of working on most of the southern wires, as well as on several circuits in other directions.

About 4:15 p. m. another, but less powerful, wave struck the western wires but did not appear to further affect other circuits, hardly one of which, however, was entirely free from interruption. The storm continued to disturb the wires at intervals more or less frequent, and with varying degrees of intensity during the whole of the night, and did not finally disappear until the afternoon of the following day.

Sun spots are probably responsible for this latest extraordinary electrical manifestation, as they have been undoubtedly concerned in the production of similar phenomena in the past. The period of maximum sun spots which occurs about every eleven and a half years has always been associated with disturbances of this nature ever since the advent of telegraphy. The present year falls in the midst of a period when sun spots are most numerous, and already eleven electric storms have so far been recorded:

February 13, powerful and variable; March 6, comparatively mild; March 12, mild; April 24, April 25 and April 26, slight and sporadic; May 16, strong; May 17, mild; and May 18, very strong and exhibiting curious anomalies; July 12, strong, but comparatively steady; July 16, very powerful and very variable.

The principal characteristics of these storms are now so well known that it only remains to say that it is generally believed by scientists that the tremendous eruptive forces in the sun during these particular periods disturb the electrostatic lines of force radiating from our electrically charged globe, and thus create the conditions necessary for producing those great differences of potential between various portions of the earth's surface which give rise to abnormal earth currents.

---

[1] Steam Engines at the Frankfort Electrical Exhibition.

II.

The discovery of the great sun spot of Saturday, July 16, at about the time of the abnormal earth current visitation on the same day, was an event that was confidently anticipated by those whose former experience of electric storms had led them to associate the one class of phenomena with the other. The coincidence affords another striking illustration of the close connection that exists between them, and leaves but little room for doubt as to the origin of the interesting though troublesome earth current.

Later advices from various sources confirm the first reports as to the wide extent and serious effect of the storm upon the telegraph service of the country. In addition to the high voltages observed on some of the local circuits, it is also recorded that in one of the wires between Chicago and Omaha, during the height of the disturbance an electromotive force was developed of about 270 volts, or more than double the amount ordinarily used on the circuit for signaling purposes. The intensity of the current was in fact so great in some instances as to raise the lamps in the dynamo leads to bright incandescence.

The disturbances noted were by no means confined to this country, and it will doubtless appear later, that, like all previous perturbations of exceptional violence, the recent storm will be found to have been quite cosmical in character. The cable service across the Atlantic was very greatly affected by it. These cables lie directly in the path of maximum flow, and, being operated by apparatus of great sensibility, are peculiarly liable to derangement and injury from such storms.

The comparatively weak and steady *normal* earth currents which are invariably present in these cables, are prevented from actuating the receiving apparatus—which is placed in the cross-wire of a Wheatstone bridge arrangement—by means of condensers interposed in the bridge wire, but the condensers afford no protection from the strong and violently fluctuating currents of an electric storm. It is usual at such times to cut out the apparatus and ground the cable; so that the latter may more readily discharge its accumulated electricity. The cable apparatus has suffered more or less injury from the effect of previous storms, and the recent occurrence proved to be no exception to the general rule, two coils having been damaged during the progress of the disturbance.

The cable circuits had felt the influence of the disquieting forces between 8 and 12 a. m. on July 16, but they were not of sufficient violence to cause a suspension of working until 12:16 p. m. when all the cables stopped together. The general effect produced by the electric waves upon the suspended coils which actuates the siphon attachment of the recording apparatus, was to gradually twist the coil to a position at right angles to that normally assumed, and to hold it there with the siphon off the recording slip until the wave reversed itself. At times the coil was swung backwards and forwards with sufficient vehemence to break the suspension fibres. One of the waves twisted the coil with a sharp click as though the cable had been struck by lightning. The shock was felt at the same time both at the American and at the European terminal points of the cable.

The time of appearance and departure of the cable currents as well as the characteristics exhibited correspond very closely with the observations made on aerial lines. The cables were, however, subjected to further interruptions from the same cause on Monday and Tuesday July 18 and 19, of which no record seems to have been made on land lines.

A circumstance worthy of note in connection with the disturbance which affected the western aerial wires on the afternoon of July 12, is the fact that the cable apparatus appears to have been indifferent to it. The writer can only account for this discrimination on the supposition that the currents—which on that occasion were singularly uniform in direction though varying in strength—were excluded by the condensers, which only transmit the impulses of *sudden* changes either in the polarity or strength of currents.

Observations during the past six months have shown the most remarkable changes in the appearance and general characteristics of earth current phenomena, and the many strange anomalies presented and curious effects observed make the study of this subject a peculiarly interesting and instructive one.

LORD KELVIN'S AMPERE BALANCES FOR VERY HEAVY CURRENTS.

As a supplement to the already considerable variety of ampere balances, Lord Kelvin has constructed two ampere balances for the measurement of currents up to 10,000 amperes for direct and alternating currents. The serious if not insurmountable difficulty of handling such heavy currents through movable contacts, as is done in the well-known types of ampere balances for currents up to 2,500 amperes necessitated a different construction inasmuch as the main current passes through heavy copper bars or tubular cables (in the ampere balance for alternating current) whilst a known, small current energizes two movable coils connected to the beam of the balance.

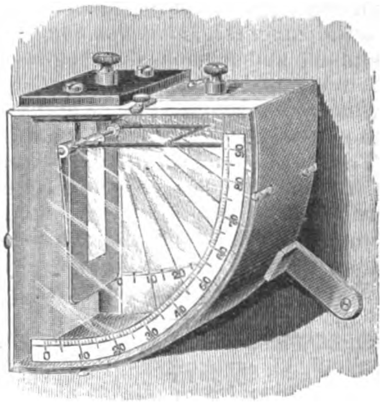


FIG. 3.—LORD KELVIN'S GOLD LEAF ELECTROSCOPE.

Fig. 1 shows the ampere balance for direct currents up to 10,000 amperes. The conductor for the main current consists in this type of heavy copper bars arranged in two rectangles, one above the other. The current entering at the upper right-hand terminal passes through the upper rectangle in the direction of the hands of a watch, thence through a connecting piece into the lower rectangle circulating through this in opposite direction to the hands of a watch and leaving at the lower right-hand terminal. The two movable coils are suspended in the usual way within the space between the two rectangles. The resistance of these two fine wire coils is 10 ohms and the wire is so dimensioned that it may carry currents up to 1 ampere without heating. In series with the fine wire coils a resistance box can be used containing steps of resistances up to 400 ohms.

In connection with this resistance box, the instrument constitutes a wattmeter with a sensibility of 50 to 2,000 watts per division of the scale engraved on the beam of the balance, the sensibility depending upon the respective steps of the resistance box.

To use the instrument as an ammeter for general purposes where the required accuracy is not limited to a small amount it is sufficient to measure the fall of potential at the terminals of the fine wire coil with a good voltmeter and divide the readings in watts by this potential difference. If greater accuracy is required, it is preferable to measure the current passing through the fine wire coil with an auxiliary accurate instrument; for instance, a centi-ampere balance. Since the movable coils can carry currents as high as 1 ampere, the sensibility of the instrument may be varied between very wide limits, so that the constant of the instrument for one degree of the scale may be made anything from 0.1 to 20 amperes, affording a range from 0.1 to 12,000 amperes.

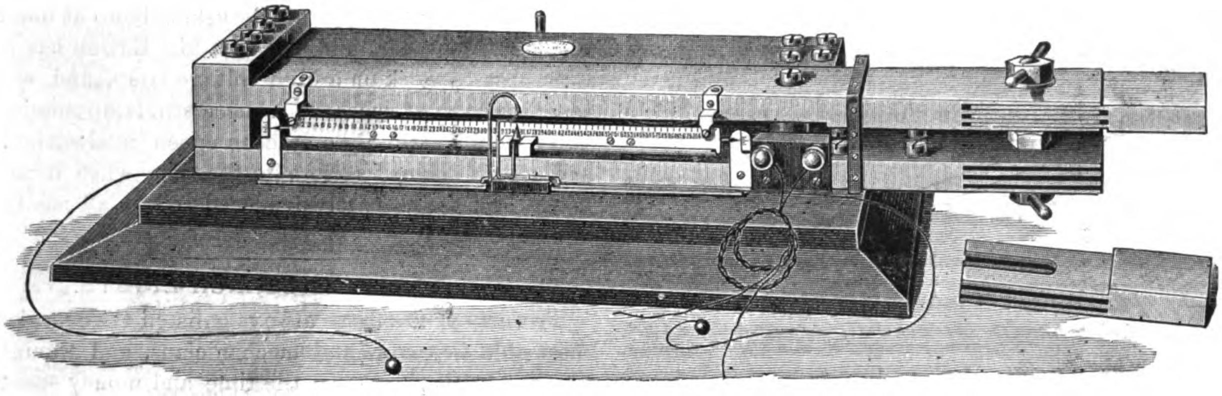

FIG. 1.—THE KELVIN 12,000-AMPERE BALANCE.

In the ampere balance for alternating and direct current, shown in Fig. 2, the main current passes through a U-shaped tubular conductor, made up of a number of insulated wires connected in multiple. In order to prevent the effects of mutual induction of the two parallel parts of this conductor, the insulated wires constituting the conductor are twisted in such a way that those parts which are on the inside in respect to one of the movable coils are on the outside with respect to the other, and *vice versa*. Brass tubes extend through the whole length of the interior of the conductor up to the bend of the U. These brass tubes serve to hold the conductor in position and also afford simple means of ventilating the conductor with a current of air by attaching a pair of bellows to one of the small brass tubes shown on the left-hand side of the conductor.

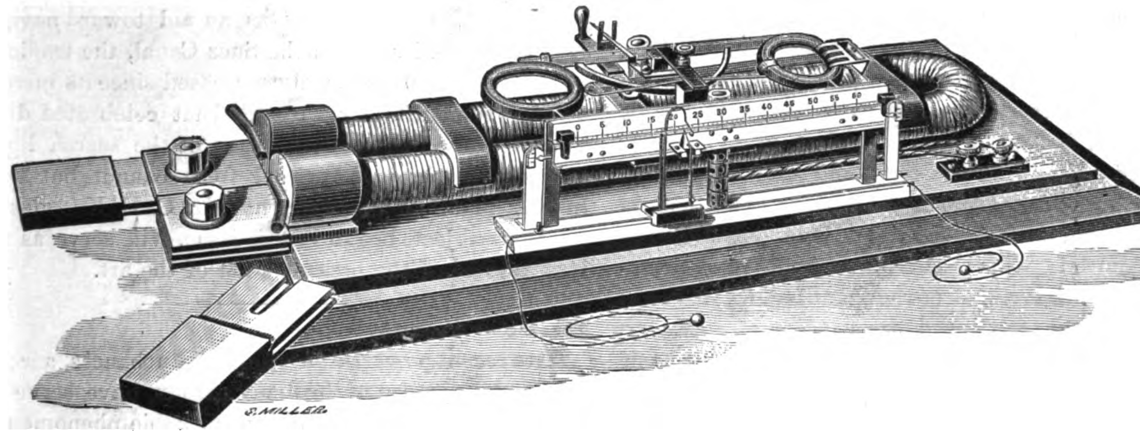

FIG. 2.—KELVIN AMPERE BALANCE FOR DIRECT AND ALTERNATING CURRENT.

In Fig. 3 is shown a simple and improved gold-leaf electroscope of the same distinguished inventor. This instrument is intended for practical purposes and may be used as an electroscope in experimental work, for instance, or may very well be employed as a ground detector by indicating continuously the difference of potential between the ground and one or the other line conductors. Its construction is clearly shown in the illustration. In front of a brass plate connected to the binding post on top of the vase and insulated from the vase, a gold leaf is suspended, which, as in the well-known cruder instruments, will be repelled by the brass plate as soon as both receive a charge. The case consists entirely of metal with the exception of the glass plate in front. A degree scale is engraved on the rear of the inside of the case and another, to similar scale, is fastened against the inside of the glass cover. With this double scale parallax in reading is avoided. One side of the vase is given a cylindrical shape in order to increase the sensibility by a mutual action between the case and gold-leaf by induction. A light frame hinged to the brass plate and shown in a horizontal position in the illustration serves the double purpose of protecting the gold-leaf from injury in transportation, pressing it against the brass plate when the frame is turned down. Otherwise in its horizontal position it acts repellingly upon the gold-leaf, preventing the latter from touching the vase, if too high a difference of potential should be applied. The instrument is of course only a rough and empirical indicator and gives readings from 500 up to 5,000 volts.

LIGHTING THE THAMES EMBANKMENT BY ELECTRICITY.

IT is proposed, says *Engineering*, to light the Thames embankment by electricity. It is suggested that lamps of 1,000 to 2,000 c. p. should be placed on the centre line of the roadway, about 50 yards apart. The capital expenditure is put down at £10,000, and the annual outlay for maintenance, working expenses and depreciation is estimated at £2,000.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can 'entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, JULY 27, 1892. No. 221.

There is a great difference between reading and study; between the indolent reception of knowledge without labor, and that effort of mind which is always necessary in order to secure an important truth and make it fully our own.—Joseph Henry.

A TWO HUNDRED VOLT INCANDESCENT LAMP.

THE indroduction, by Mr. Edison, of 110 volts as a standard of potential on incandescent circuits was one of the numerous details which went to make up the system of electric lighting worked out by him. To many people it might appear that the selection of this potential was an arbitrary one, but such, we may assert, was not the case; indeed it was a subject of much consideration by Mr. Edison at the time, and may be said to have been a compromise between the various conditions as they existed at the moment when incandescent lighting was first introduced. Now that improvements in generating apparatus, insulation, and in the manufacture of lamps themselves have been introduced, the question of operating higher voltage lamps is one which naturally obtrudes itself upon the electrical engineer, for the economy in copper obtainable with a 200-volt lamp over that with a 110-volt lamp is too obvious to need further pointing out. An easy solution of the problem apparently would be the mere lengthening of the filament of the lamp, as ordinarily made, in order to adapt it to the increased potential, and it seems that lamps of this type have been employed with some success abroad, as noted in another column; but we also learn that the life of these lamps is said to be shorter than those of lower potential. We are quite prepared for this statement when we recall the experiments made by Mr. Edison, and others, which went to show that at a potential above 150 volts a brush discharge takes place between one side of the filament and the other, which very soon causes its destruction. The action is in the nature of an electrolytic deposit from one to the other, and is accompanied by a heavy blackening of the bulb, the brush action being especially marked at the points where the leading-in wires are sealed. It is quite possible that much of this difficulty might be overcome by the employment of a perfectly straight filament, with the ends separated as far as possible and resembling the type of Bernstein lamp at one time in vogue. We understand also that Mr. Edison has for some time been at work on a high voltage lamp, and with quite some measure of success. A successful lamp running at 200 volts would certainly create an epoch in electric lighting and would bring us close to the time when incandescent lamps will have entirely displaced gas in all possible cases of competition.

ELECTRIC SEARCH LIGHTS.

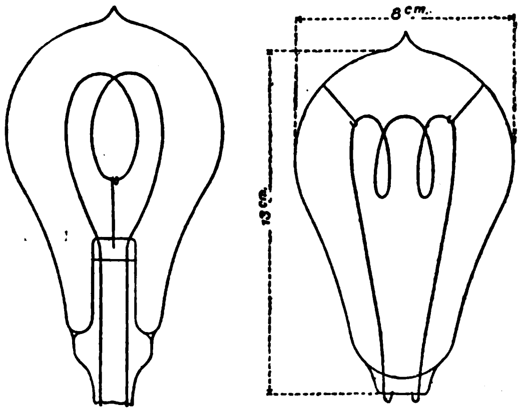
THE arts of war have always enlisted the energies of the most able inventors and mechanicians, and though many perhaps justly deprecate the time and money spent in the production of war material, and the education of men in the arts of killing, the fact cannot be denied that the peaceful arts have gained not a little from the work of the army and navy. We need not go far to find examples of this in the domain of electricity, as in almost every instance the work of the electrical engineer has been taken up by various governments and encouraged. A noticeable instance of this is the perfection which the manufacture of electric search lights has attained under the fostering care of the various naval establishments. From the most crude beginning this apparatus has now reached a stage of perfection which it appears difficult to surpass, not only in the remarkable control of the arc itself and the maneuvering of the light but also in its optical qualities. The search light, however, is gradually, but steadily, coming into use on board vessels of the commercial marine both sea-going and river craft, and its value as an aid toward navigation is well shown in its use on the Suez Canal, the traffic receipts of which have been largely increased since its introduction on the vessels passing through that celebrated ditch. In view of these facts a description of the search light as it exists to-day in its improved form cannot but be of the highest practical interest, and Mr. C. E. Knowles's article on this subject, begun in this issue, will serve as an excellent résumé of the present state of the art.

The Recent Magnetic Storm.

THE recent powerful magnetic disturbances, accompanied by the appearance of brilliant auroræ, have served to call attention once more to these remarkable phenomena and to emphasize the intimate connection between our planet and the sun. The variety of the phenomena observed, both of an electrostatic and an electro-dynamic nature must necessarily make a comprehensive theory as to their cause difficult. The recent auroral displays, however, have exceeded in intensity all previously recorded observations, and the new data, together with past records, gradually accumulated, may eventually serve to throw light upon this still obscure manifestation. We commend Mr. Finn's article to our readers' attention.

200-VOLT INCANDESCENT LAMPS.

A recent note which appeared in our excellent contemporary, *L'Industrie Electrique*, called the attention of electricians to the employment of 200-volt incandescent lamps. It was maintained by the writer that nothing stood in the way of the manufacture of such lamps, for if it be possible to construct a 100-volt 10 c. p. lamp it would be an easy matter to obtain a 20 c. p. lamp by the use of a filament of the same cross-section, but of twice the length. Commenting on this, in the same journal, M. André Larnaude calls attention to the fact that the only difficulty encountered is due to the mechanical qualities of the filaments. The great length which is necessary to employ renders them very flexible and they soon bend over and touch the bulb and break it, if care be not taken to support them at one or more points by platinum hooks. As shown in the accompanying illustrations, Figs. 1 and 2, the supporting hook is carried by the tube carrying the leading-in wires, or fixed in the upper part of the bulb. This extra work, joined to the minute precautions necessary during manufacture on account of the delicate nature of the filaments, increases the cost of the 200-volt lamp, and this fact has been one of the chief causes of their limited employment. It is also to be feared that in operating these lamps a practical difficulty may be encountered resulting from bad insulation in the bases and sockets. However, the trials made with these lamps in installations put up with care allow of the belief that it is not necessary to make use of any special apparatus.



Figs. 1 and 2.—French Edison-Swan 200-Volt Lamps.

We give below the principal dimensions of the three types of such lamps manufactured by the French Edison-Swan Co.:

C. P.	P. D. in volts.	Amperes.	Watts per c. p.	Length of filament in cm.	Resistance in ohms.
16	200	0.31	3.90	27.5	1,200
20	200	0.38	3.80	29.0	1,000
32	250	0.50	3.90	27.5	770

The lamps are mounted and put in service in bayonet sockets. M. Larnaude does not give any definite results as to the life of these lamps, but remarks that their life seems to be shorter than that of the ordinary type. This, he suggests, may be due to lack of homogeneity in the filaments, which are more likely to occur in a long filament, or to increase in the electric dissipation of the filament and deposit of the carbon on the interior of the bulb.

EXHIBITION OF ELECTRICAL APPARATUS.

The committee of arrangements of the annual meeting of the American Electro-Therapeutic Association, to be held October 4, 5 and 6, at the New York Academy of Medicine, 17 West Forty-third street, have decided to have an exhibit of medical electrical apparatus in connection with the meeting, and have arranged to accommodate the manufacturers with suitable space in a room adjoining that where the meeting will be held. The choice of space will be given in the order of application, which should be accompanied by a voluntary subscription of not less than $10, or a promise of compliance on demand. Each subscriber will be furnished with a space 5 x 6 feet, which may be exceeded, if desired, by a proportionate increase in the amount subscribed. Publishers of books upon medical electricity are invited to apply for space upon the same conditions as manufacturers.

An exhibition will be held on Tuesday, Wednesday and Thursday, October 4, 5 and 6, commencing at 9 o'clock each morning. Robert Newman, M. D. and Augustus H. Goelet, M. D., constitute the committee.

CARBONS.[1]

BY H. O. FISK.

It was suggested at one of our committee meetings that I should prepare a paper for this convention on "Carbon Testing," but the time was too short to carry out a series of experiments as at first spoken of, so instead, I have prepared a short description of the process of manufacture of carbon points, as conducted at the factory in Peterborough.

Twenty-five per cent. of gas coke mixed with 75 per cent. of petroleum coke, is said to make a good carbon for low tension work. Another variety of this material is obtained from the oil regions, commonly known as petroleum coke. This is a by-product of the oil stills, and is the only kind used to any great extent in the manufacture of carbon points for the electrical industry. It is of primary importance that the coke, and, in fact, all the ingredients used, be absolutely free from impurities. The other constituent of our carbon is pitch. This is made from coal tar, which is a by-product of the gas retorts. It may also be obtained from blast furnaces, but this kind is more or less contaminated with iron, and therefore is unfit for this class of work. Pitch for this particular purpose is difficult to obtain, as the makers do not care to expose their still to the high temperature necessary to drive out all of the oil and reduce it to the proper specific gravity, and as the men in the factory say, "it is more or less wet."

The first step in the process of manufacture is that of crushing the coke. This is accomplished by means of a machine somewhat in appearance like a mammoth coffee mill. The coke comes from this crushed to about the size of coarse gravel; it is then automatically elevated to a large bin in the upper part of the factory, and from there it is conveyed to a large iron hopper situated directly over the calcining retorts. Into these the granulated coke is conducted by means of spouts with gates arranged to control the flow of material into the several aforementioned retorts. They are then sealed up, thereby preventing combustion, with the exception of a few vents to allow of the escape of gas, arising from the heating of the coke to a state of incandescence, which point is reached in from twenty-four to forty-eight hours after firing. After this if the coke is not pure it will be found to have caked, necessitating in some cases the use of bars to break it up sufficiently to allow of its being drawn from the retorts. If pure it will appear crisp and dry and to have suffered a loss in weight of about 30 per cent. After the retorts have been drawn sufficiently long to allow of cooling, their contents are elevated to the milling department and run through a set of French burr stones incased in iron, very similar to the grist mill chop stones; then through a silk bolter separating the coarse from the fine, the former returning to the milling machine, the latter being conveyed to bins with suitably arranged spouts over scales from which it may be drawn and weighed as required by the mixing department. We will leave the coke here for the present and return to the other ingredient, namely, the pitch. This is dense, hard, solid, very brittle and dry, and in appearance somewhat resembling gutta-percha. This material, when it reaches the factory, is incased in casks, holding about 600 lbs. each. It is then broken up by the men into a convenient size for handling, and subjected to a granulating process similar to that of the coke; finally we find it at a spout close beside the one from which the coke can be drawn.

We have now followed the two principal ingredients through the various processes which were necessary to prepare them for the mixing-room. The other ingredients, if any, we shall not be able to elaborate upon, until we have reached a more confidential relationship with the carbon makers. However, upon the manipulation of the materials at this stage, I am told the success of the future carbon greatly depends, in fact, the great secret lies in the mixing. We can better understand the skill and care required to properly amalgamate the mixture, when we learn that each particle or grain of coke must have its individual coating of pitch, and it may be interesting to learn that this coke is ground so fine that a grain magnified a thousand times would only appear the size of a shot. To obtain these results the materials are carefully proportioned by weight, and placed in a mixing barrel. This is a rotating cast-iron cylinder within which in the same direction revolves an independent shaft, twice as fast as the cylinder, to which are attached arms so arranged that every part of the barrel is covered or swept in each revolution. This is attached to a furnace in such a way that the flues follow the whole circumference of this barrel, maintaining a uniform temperature of about 300° F., which is necessary to bring the pitch to a state sufficiently plastic for amalgamation; thirty minutes is the time required for each batch, which would make about 1,600 carbons. From this machine it is taken to the cooling-room and spread out for ten or twelve hours to cool. Here the mixture solidifies to such an extent that it becomes necessary to pulverize it again, to perfect it for the moulds. This end is attained by means of a mill, the pulverizing feature of which is two discs thirty inches in diameter, with corrugated face plates revolving in opposite directions at the rate of fifteen hundred revolutions per minute (about one one-hundredth of an inch apart). From this it is once more passed through a bolting machine, and then finding its way down gravity tubes to a bin on the floor below (which is the moulding-room) it is carefully weighed out by the workmen on peculiar little scales with clock-like dials, in quantities just sufficient to fill each mould as it comes hot from the oven.

---

[1] Abstract of a paper read before the Canadian Electrical Association, June 15.

The mould having been previously lubricated with some heavy oil, is now ready for its charge, which the operator places in it and works evenly over the whole surface with a spatula, to insure uniformity of density. The cover or top half is placed in position and the mould and its contents pass for a few moments into an oven, the temperature of which is about 300° F. As soon as the mixture has become quite adhesive the mould is placed in the hydraulic press, and subjected to a pressure of several hundred tons. The mould is now removed and opened, and we have a corrugated card containing sixteen or eighteen carbons, each one being joined to its neighbor by a fin which is inevitably formed when subjected to the enormous pressure before mentioned. These cards are placed on plates which are fitted to receive them perfectly. These plates with their contents are piled up and weights placed thereon to prevent warping. When cool they are broken apart, gauged for size, culled, and the fin scraped off. They are then laid in the furnace for baking. This furnace is rectangular in shape 84 x 11, four feet deep and made of fire-brick, and is similar to a large vat set about two-thirds below the surface of the earth. Over this when filled is placed a dome-shaped cover, sufficiently high above the sand and tile which covers the carbon, to allow of a free passage of the flames, and which is continued by flues back through the sides and also underneath, thus completely enveloping the body of the furnace in flames. The carbons are carefully placed in the furnace and separated from each other with washed sand, which is brought from the shores of Lake Ontario. Some days are required to completely load a furnace, as each section will hold about seventy-five thousand carbons.

The cover having been placed in position and sealed with fire clay, the fire is now started, crude oil being the fuel used, as well as in the case of the retorts and moulders' oven. This fire is continued moderately for 48 hours to allow of the gas escaping without blistering the carbon; it is then forced to its utmost for from forty-eight to sixty hours longer, then shut off, and the whole allowed to cool for forty-eight hours before uncovering. The top, which is mounted on wheels, is then rolled off and a few carbons taken from various parts of the furnace and tested by a Wheatstone bridge and galvanometer for resistance, as this at once determines if the baking has been carried sufficiently far. If the measurements of all the samples exceed four-tenths of an ohm, the furnace is re-covered and fired for some hours longer, but this very rarely has to be done. The writer recently tested samples from the north and south ends and centre of a furnace, and they measured 23, 22, and 24 one-hundredths of an ohm respectively. Some difficulty was at first experienced in attaching carbons to the bridge, for the resistance of this substance varies considerably with the pressure of contact, and the same carbon measured at different times would often vary several one-hundredths of an ohm. But an instrument was designed by the writer which obviated to a great extent if not wholly this trouble. The pressure brought to bear, on the sample undergoing test by this instrument is determined by small weights suspended from levers attached to holders so arranged that exactly the same pressure and contact is formed on different samples of the same size. If the resistance of the samples, as before mentioned, shows that the contents of the furnace have been sufficiently baked, it is unloaded, the hot carbon being handled with forks.

When cold they are sorted, the first and seconds being easily determined by rolling on level steel plates. After this inspection they are ready for the plating-room, where they receive their copper coat by being hung in leaden vats containing a saturated solution of sulphate of copper. These vats, of which there are several dozen, are connected in series with a twenty-ampere constant current dynamo. Twenty minutes to half an hour is the time required to complete this plating process. They are then washed in hot and cold water and placed on racks to dry, after which they go to the packing department to be rolled in paper and boxed for shipment.

Letters to the Editor.

THE RELATIVE VALUE OF EXHAUST STEAM.

In a recent article in the London *Electrical Review*, Mr. W. H. Booth attemps to controvert my brief argument in THE ELECTRICAL ENGINEER of June 1, showing the financial advantages of the sale of exhaust steam over the constant use of condensers in connection with central station work. I hardly know which to admire most, Mr. Booth's apparently self-satisfied ignorance and assumption in regard to the subject in hand, or his flippantly "tricky method" of perverting the figures used in my article. Mr. Booth says: "Very many boilers throw away half the heat units, and the steam as it goes to the engine only takes with it the other half." And so he proceeds to debit the engine with only one-half of the total heat units generated in the boiler.

My article did not discuss the economic features involved in the use of different boilers; it did not attempt to compute the possible heat units that could be extracted from the coal bunker by the most approved appliances, and such a calculation would be entirely foreign to the question under discussion. But what we have to deal with is the steam which actually reaches the engine in a given case. Let that be represented by 100. Seven to ten per cent. of the contained heat units only is used by the best plain cylinder engine; the total remaining 90 to 93 per cent. less the radiation from the engine is lost in the exhaust. Compound the engine and save two to three per cent. more; add condensers and three per cent. more can be saved; total 12 to 16 per cent.—provided free water without pumping can be had for condensing. Against this amount saved must be charged the compound and condensing apparatus. All the remaining heat units are in the stream of hot water flowing from the condenser. This is fully 80 per cent. of the units of heat which were in the steam delivered to the engines, and my proposition was to sell this 80 per cent. or more for heating buildings, which has a value as stable as any commodity with which we deal.

I did not propose as he says, to run non-condensing for twelve months for the sake of selling exhaust eight months, but the plan as stated was, where condensers are in use, to disconnect them during the eight months and to run condensers during the remainder of the year. If Mr. Booth had read Mr. Collins' excellent article in the June 1, number of THE ELECTRICAL ENGINEER he could have learned where this plan is in successful operation—fact against theory. And the statement is made that "the profits from this branch of the business are twice what they are from lighting or power."

Mr. Booth raises the question of back pressure upon the engine where the exhaust is forced through long lines of pipe, and is in doubt whether there will be any "go" in the steam at the terminal points. If his attention had been directed to the article before mentioned, he would have learned that with a back pressure of five pounds at the engines, large blocks of buildings were being heated, and still there was plenty of "go" at the terminals, and ready to do still further service. We all know the facility with which gas is distributed through long lines of pipes. Steam under pressure is a quasi gas and invisible, and all who are posted know that the loss of pressure by friction in pipes of medium size, say one-half mile in length, does not exceed five per cent., nor is the percentage of loss by condensation greater, where the best approved methods are followed in protecting the steam pipes.

To circulate exhaust steam then, the station manager simply needs to increase his initial boiler pressure by from five to ten pounds. The additional cost of generating steam at an increase of ten pounds pressure is known to be trifling, while there is no further added cost for energy in effecting the circulation. There is nothing complex about this, and nothing could be more economical in effecting results. Mr. Booth is unfortunate in being compelled, through lack of information, to theorize upon matters which have been already settled by facts based upon experience.

From these doubts, difficulties and dangers in which Mr. Booth has enveloped himself, he escapes by making a marvelous discovery, which is: "To heat water to 130 degrees by the steam and send the water round in the pipes to consumers." The water, he says, "would flow to consumers without any more expense of energy than it is now given to flow to them cold." That means, I suppose, the usual water pressure of 50 to 100 pounds which is required to overcome gravity and friction. He did not tell us how much extra boiler power would be required to simply pump the water; as it certainly would not "flow" to the upper floors of high buildings without pressure behind it. Under the same pressure the rapidity of flow in water is as one to fifty for steam. So that unless very high pressure were carried, say, 300 to 400 pounds, the water pipe would require to be the larger, and the same device being required to take care of the expansion and contraction, Mr. Booth would find his system of water circulation to be enormously expensive. Mr. Booth says that this "method of using and selling heat has not yet been attempted." I regret to destroy his claim to priority of invention. If he had been properly informed in this matter of water circulation he would know that the system was attempted on a large scale in Boston three or four years ago. A very large amount of capital was enlisted and the most elaborate devices employed, but for the reasons I have given, the cost of operation being out of all proportion to possible revenue, the enterprise was a total failure and was abandoned.

Mr. Booth, I judge, enjoys the lacteal fluid supplied by his milkman well charged with water; most people prefer straight plain goods whether milk or steam. He evidently has adopted dilution as a principle, which accounts for his mixture of a small amount of fact with a large supply of fiction, and figures which prove nothing.

I. H. BABCOCK.

LOCKPORT, N. Y., July 18, 1892.

MERCURY *vs.* MECHANICAL PUMPS FOR EXHAUSTING INCANDESCENT LAMPS.

IN an article on "Exhausting Incandescent Lamps by Means of Mercury Pumps," in the July 20 issue of THE ELECTRICAL ENGINEER, just to hand, I note that Mr. Packard quotes a paper by Prof. B. F. Thomas on "A Life and Efficiency Test of Incandescent Lamps," read at Chicago during the recent session of the American Institute of Electrical Engineers to support his belief that a mechanically exhausted lamp will blacken more than a lamp exhausted by mercury. An inspection of Prof. Thomas' paper will show that such a conclusion as is drawn by Mr. Packard from Prof. Thomas' remarks cannot be sustained. Mr. Packard says: "In the recent test by Prof. Thomas * * * lamps which are exhausted by the mercurial process showed considerably less blackening that any of the other makes, among which was the * * *, exhausted by mechanical process." In the paper of Prof. Thomas, as printed in THE ELECTRICAL ENGINEER of July 13 (bottom of page 89, right-hand column), we find in italics the remark by Prof. Thomas: "*The two lots which were least blackened were of the makes which are advertised as exhausted by mechanical pumps.*" This apparent error of Mr. Packard's is very probably due to an oversight.

As a tyro in lamp work I may say that in some experiments made by myself last fall with a view to developing a powerful incandescent lamp for stereopticon work I met with the same results as are indicated in Prof. Thomas' paper. In every case a mercury exhausted lamp blackened far more rapidly than one exhausted by an orthodox mechanical pump. My lack of experience in this sort of work might, of course, be made to account partly for such results, as I may have neglected some precautions exercised by practised makers.

PHILADELPHIA, PA. ELMER G. WILLYOUNG.

(With regard to the above, we may say that just after the forms had gone to press last week, containing Mr. Packard's article, he wrote us, asking that we omit the paragraph referring to the Thomas test on lamps at the Ohio State University. Mr. Packard says: "I had Prof. Thomas' letter as authority for the statement made in this paragraph, but judging from his later publication, there is apparently some mistake about it. The rest of the article is all right." EDS. E. E.)

VACUUM LIGHTNING ARRESTERS.

IN your last edition there appeared a request for information concerning lightning arresters, which consisted of either exhausted or simple glass tubes.

I am able to state that an arrangement of partially exhausted glass tubes has been tried, in that direction, the credit of the idea being due to Mr. R. G. Fessenden.

The arrangement consisted of a sealed glass tube which had been partially exhausted, the arc being formed between two small wires, which were sealed into the tube. Upon the arc forming, the air in the tube expands suddenly, shatters the glass, and the arc is extinguished. The arresters are arranged in banks of half a dozen, so that the line may be struck as many times in succession, the result being merely the destruction of an extremely cheap piece of apparatus.

LOYALL A. OSBORNE.

NEWARK, N. J.

MR. J. H. VAIL, of the General Electric Company, presented recently before the citizens of Westfield, N. J., an able address on the subject of a water supply for that beautiful town. The address has attracted much attention and has now been issued in pamphlet form. Mr. Vail's residence is a fine farm, with modern mansion, in the suburbs of Westfield, and he lights the grounds and premises with incandescent lamps, taking current from the Thomson-Houston plant at Elizabeth nearly eight miles away. He has set an example that will find many imitators among the wealthy inhabitants of Westfield.

Literature.

Die Einrichtung Elektrischer Beleuchtungsanlagen für Gleichstrombetrieb. (The Equipment of Direct Current Installation) By Dr. Carl Heim. *Leipzig*, 1892. Oskar Leiner. 503 pp., 5½ x 8½ inches. Paper. Price, $3.20.

German electrical literature has produced quite a number of excellent treatises on the construction of dynamo-electric machinery, but up to the present, none had appeared which gave the reader a thorough insight into the actual methods employed in the erection and operation of electric lighting plants in Germany, and hence the present work occupies a distinct position. Dr. Heim introduces the subject by an exposé of the fundamental ideas involved in the continuous current in which, of course, the law of Ohm occupies a prominent position, and then leads up to the relation between electrical and mechanical work. Then follow excellent descriptions of the various types of machines built in Germany, with much practical data regarding their construction. The storage of electricity is then taken up and the principal cells described, together with the manner of their employment in isolated and central station work. A number of diagrams are shown in this part, illustrating the method employed in Germany, where, by the way, much more has been accomplished with accumulators than in this country.

The author then takes up the subject of arc lamps, describing the various types, both for series and incandescent circuits. This is followed by an exhaustive treatment of incandescent lamps and their application, both in series and parallel lighting. The author has laid particular stress upon the regulation of incandescent circuits on extended networks, describing and illustrating a variety of apparatus for regulation at the feeder ends. The remainder of the book is largely devoted to auxiliary apparatus employed in electric lighting, such as switches, sockets, accumulators, interior conduits, ammeters, voltmeters, lightning arresters, lamp posts, etc. There is also a short treatise on the management of stations, and to this is added full information regarding the cost of installation of various kinds, so that the book as a whole affords an excellent opportunity for comparing American with German practice. The illustrations throughout, numbering over 300, are very clear, and the work has evidently been prepared with great care in all its details. Our own manufacturers might obtain not a few useful hints from its perusal.

Local Transportation and Underground Conduits. Reports of the Consuls of the United States. No. 139. April, 1892. Bureau of Statistics, Department of State. Government Printing Office, Washington, 1892.

THIS is a compilation of two distinct branches which are nevertheless closely allied in the work which the electrical engineer is now called upon to carry out. With the growth of local transportation in the United States the methods as employed abroad will be of value, for even if the amount of such work, effected by means of electricity abroad, is practically nil, the ways and means of carrying on local transportation in foreign countries nevertheless affords an excellent basis of comparison with our own.

The reports on the underground systems are, for the most part, brief, and, with one or two exceptions, very superficial. An exception to this is that from Deputy Consul Sherman, of Liverpool, who gives a very good account of the work done in that city. Strange to say, the report of the consul at London is confined entirely to the description of the English Postal Telegraph underground system, no mention being made of the considerable underground work of electric lighting companies. We also notice that the consul general acknowledges the courtesies of Mr. William H. Bruce, chief electrician of the British postal telegraphs, for valuable information furnished. Mr. Preece's many friends, however, will have no difficulty in recognizing the printer's bull. The report can be had on application at the Secretary of State, Washington.

Bericht über die Verhandlungen des Internationalen Elektrotechniker-Congresses zu Frankfurt am Main, vom 7. bis 12 September, 1891. Part I. Report of the General Meetings. Frankfort a. M. 1892. Johannes Alt. 143 pp., 7½ x 11 in.

Les Nouvelles Installations de l'Institut Electrotechnique Montefiore. By E. Gerard. *Liége*, 1892. Imprimerie de la Meuse. Pamphlet, 20 pp.

Proceedings of the Naval Institute. Vol. XVIII., No. 2, 1892. Published by the Institute. Annapolis, Md.

MR. CHARLES C. UPHAM, general manager of the Lincoln Street Railway Co., Lincoln, Neb., was a Chicago visitor last week.

THE NEW YORK ELECTRIC EQUIPMENT CO.

One of the most important recent departures in the electrical development of New York City has been the organization of the New York Electric Equipment Co., with Mr. Sigmund Bergmann as president and general manager, Mr. P. H. Klein as secretary and treasurer, and Mr. Augustus Noll as general superintendent. This concern will, it is understood, do all the interior and installation work within the territory of the Edison Electric Illuminating Co., under the Edison patents and privileges, and will carry on an extensive business in the line of supplies, fixtures, apparatus, etc. It has the whole of the large Acme Building on Duane street, adjoining the new Edison station, as offices; storerooms at 431 Fifth avenue and in the Edison Twenty-sixth street station; and the beautiful fixture and electrolier department at 275 Fifth avenue, where all the fashionable styles of fixtures are shown and where orders are received for special designs and electrical decorations. Our engravings on this page illustrate two of the rooms at 275 Fifth avenue, showing how each room is fitted up to exemplify the various styles and finishes. One is a view of the Oriental room, and the other shows a library or office. The whole of the designs and furnishings are in exquisite taste.

The officers of the New York Equipment Co. need no introduction to the electrical public. President Bergmann has been a pioneer manufacturer in a great many branches of the light and power industry, and no name in the fixture and supply line is better known in America, while he also enjoys a wide European reputation. Mr. Klein's association with the electrical field is also of long standing, and he has every qualification for his post. Mr. Augustus Noll, while perhaps the youngest, is one of the most experienced electrical engineers of the day in wiring work, while his familiarity with the various branches of installation dates back to the very beginning of electric lighting. Some idea of the activity of the company may be formed from the fact that they have no fewer than five large gangs of men at work in different parts of the city, all under competent foremen and receiving Mr. Noll's direct personal supervision. The company does not touch outside or underground work, but in inside work takes contracts for everything in a plant, including engines, boilers, dynamos, wiring, fixtures, lamps, and all details, complete. It proposes to do work of one class only—the best. One feature is the filing away of all plans carefully, as architects do, so that if changes are required in any building at a later date, the plan is there for reference. Nothing is left to chance or guesswork. So, too, in fixture work, the company is prepared, with the best designers, to execute original ideas, and to provide special fixtures to correspond with the architecture or fittings of any building.

It will be seen that the work of the new company is very comprehensive, and covers all the many features that now enter into electric light and power consumption in large cities, as well as touching, upon the other side, many of the most important details of supply manufacture. It would seem to be an excellent plan for any large local company to concentrate its energies and ability upon the economical production of current, leaving to a responsible concern like the New York Electric Equipment Company the care of all the multitudinous matters that have no more to do with current generation than the production of gas has to do with gas piping, gas stoves, or gas engines. The new departure has been well and wisely made, and it may fairly be expected that it will do much to hasten the time when every New Yorker will be able to enjoy the incandescent light in his home and sit in the breeze of his own fan motor. A great deal has been done in New York electrically, but the larger part is still awaiting development.

FOURTEENTH ANNUAL CLAMBAKE OF THE AMERICAN ELECTRICAL WORKS, OF PROVIDENCE, R. I.

SIX to four in favor of New York was the score in the great annual base ball game played between New York and Boston at the Haute Rive Club, on the Providence River, on the occasion of the fourteenth annual clambake tendered to the electrical profession by the American Electrical Works, of Providence. The game was hotly contested, (it was 95° in the shade) and Umpire Martin Day of the *Providence Journal*, had a hard time preventing the teams from claiming home runs on each and every occasion. It would be invidious to mention any names. Suffice it to say that both teams developed a knowledge of the sport that would have put professionals to the blush. The batting was of the heavy hitting order, while the fielding was done with rare skill accuracy, although it must be admitted that a large number of shady trees in the vicinity helped the fielders in many instances by making some good stops.

A better day for the clambake could not be imagined, and even though at times most of the boys (we are all boys on such occasions) seemed to be in rather a melting mood, yet that might be attributed to the unwonted exercise in which they indulged, and the feeling of good-fellowship which prevailed.

Mr. Phillips has always something new with which to surprise his guests. This year it took the form of a large straw sun hat about 18 inches in diameter, and it required only a few minutes to equip each and every one with one of these Wild Western sombreros. They certainly were welcome in the hot sun, and made the scene very bright and interesting. The usual games at football, baseball, shooting and all sorts of pranks were indulged in, and thorough justice was also done to the clams and salads, as well as to the punch bowl of generous dimensions, which, like the widow's cruse of oil, never seemed to run down. It may be well to state here that it was the general opinion that the punch had never been excelled.

About 3 o'clock the clam dinner was served, over 200 people seating themselves at the tables under the marquee, and enjoying the hospitality of Mr. Eugene Phillips, who occupied a position near the centre with Governor Brown on his right hand, and Mr. Charles W. Price, of *The Electrical Review*, who acted as toastmaster of the occasion, on his left hand. After the clams had all been devoured, and they never seemed to taste better, Mr. Phillips in a short speech welcomed all present. Governor Brown then made a few remarks, followed by a short and pithy speech from Judge McLeary of San Antonio, Texas. Mr. S. G. Stiness of Pawtucket, then replied to the toast of Rhode Island, and spoke in eloquent terms of the little State where the succulent clam finds its home, being followed by Mr. Martin Day, of the *Providence Journal*, who responded to the toast of the press, Mr. Price announcing that the members of the electrical press present were all "too full for utterance,"—their hearts, it is to be presumed. Mr. C. R. Huntley spoke in fitting terms of the National Electric Light Association, and proved to be an orator of no mean degree. Mr. Charles W. Hagar, of Montreal, followed with a few well-chosen remarks, and the exercises were brought to a close by a speech from General Embler, who presented Mr. Eugene Phillips with a handsome full-size portait of himself, in the name of Mr. George Phillips of Norwich, Conn., who was too modest to make the presentation himself. Mr. Phillips acknowledged the gift in a few words. After singing "Auld Lang Syne," the guests departed well pleased with their day, and all promising to be there again next year. A list of the gentlemen present will be found below:

REVERSAL OF POLARITY IN PLATING DYNAMOS.[1]

BY HARRIS J. RYAN.

SHUNT machines used for copper-plating carbons are frequently found to have their polarity reversed after being stopped. The cause can be ascribed only to voltaic action of the unplated or partially plated carbons, copper anodes, and the plating solution. Any electromotive forces in the bath that would result from the electrolytic action of the dynamo current must be counter to the E. M. F. of the dynamo. Any current that these counter E. M. F.'s might set up through the dynamo when at rest, as is well known, could tend to only maintain the same polarity.

To determine the extent of the voltaic action, Messrs. Thayer and Warner, of the senior class in electrical engineering at Cornell, made a copper plating bath of the density that is found to do best for copper voltameter work. This solution was increased 20 per cent. by the addition of commercial sulphuric acid so as to obtain a solution practically the same as that used by the carbon platers for good tough deposits.

Time.	Volts.	Remarks.
11:20	— .170	Carbon unplated,
11:20½	— .004	Current on 30 seconds. Lower part of carbon plated; plating on the upper part scarcely perceptible.
11:28	— .012	
11:30	— .138	
11:32	+ .085	Current on 1 minute. Well-marked deposit on carbon.
11:34	.000	
11:36	— .002	
11:40	— .064	
11:48	— .130	
11:50	+ .064	Current on 5 seconds.
11:52	— .124	
12:15	+ .138	Current on 13 minutes.
12:20	+ .064	
12:36	+ .053	
12:55	+ .021	
1:45	+ .006	

+ Indicates a counter E. M. F.
— Indicates a voltaic E. M. F.

The table explains itself, and shows that the difference of potential between the unplated carbon and copper is .17 of a volt. After the deposit of a thin film of copper on the carbon this E. M. F., which immediately after stopping the current, was .004 volt, was raised so that at the end of ten minutes it was .138 volt. When a marked deposit was made by the application of the electrolytic current for one minute the cell gave a counter E. M. F. of .085 of a volt immediately on stopping the current. The return of the voltaic E. M. F. was evident, for two minutes later the E. M. F. of the cell was zero, and sixteen minutes from the time of stopping the current the voltaic E. M. F. of the cell was .130 of a volt. At this point the application of the current for but five seconds produced a momentary return of the counter E. M. F. of the cell. Even after the carbons had been well plated by the application of the electrolytic current for fifteen minutes, when the counter E. M. F. of the cell at the moment of breaking the circuit was .138 volt, there was a strong tendency manifested for the return of the voltaic E. M. F.

It is seen, therefore, that with a shunt electroplating machine at work on a bath for plating carbons there is danger of reversing its magnetism whenever it is stopped before the carbons are well coated. It may be avoided by breaking the main circuit before shutting down, and making it again only after the machine has been brought to full speed. This method would generally require the use of a large and expensive knife switch. Breaking and making the field circuit in the same manner would do just as well.

---

[1] A paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, Ill., June 6, 7, and 8.

THE BLOCK SIGNALS OF THE PRESENT, AND WHAT IS REQUIRED FOR THE FUTURE.[1]

BY J. B. STEWART.

A GREAT deal has been written on this subject during the past year. Railroad officers have given more attention to it than ever before, and the American Railway Association (formerly called the General Time Convention) has appointed a committee to consider and recommend a standard block signal system, involving, as it does, the very safeguard to the reputation of any railroad that attempts to meet the demands of the traveling public for high speed and safe transportation.

The English or Sykes system is the one now generally in use. Does it meet the requirements and give the necessary security? To answer this question let us first give briefly the method of protecting trains by this system. Each office is supplied with a semaphore signal; the lever controlling the arm is locked. An operator desiring to give a signal to an approaching train must ask the operator in advance to unlock his lever. The signals between block stations are given by bell code on some roads, and on others, where the locking arrangement is not used, by the regular Morse code. As soon as the train passes into the next block the operator places his signal to indicate danger, the lever being again locked. He then signals the operator in the rear that the train has passed out of the block. On crowded roadways, and especially where trains are "closing up" on approaching the great terminal points, these signals must be given instantly, so as to not detain the following train. Herein lies a very great danger. The high speed of our fast freight trains and the distance covered by such trains after the breaks have been applied for an emergency stop will, I think, convince all of you that we are surely and rapidly advancing to the high limit now set and that our block signals have not kept pace with it.

The author then showed the weak points existing in the signaling methods at present in vogue and continued: If we then conclude that the present systems must be improved to insure absolute safety, what will be the system of the future?

Will it be entirely automatic, by means of the rail circuits?

Will it be electro-pneumatic with an attachment to the last car, or will it be, as a writer in the *Railway Equipment Guide* for April suggests, "A system that will display signals continuously throughout each block, so that the signal to proceed or stop will always be in view of the engineer?" This idea strikes me very favorably. With such a system the operator controls the line of signals for a certain distance in the blocks each side of his station. In any event, it is my opinion that electricity will play an important part in the block signal of the future, and as the superintendent of telegraph, or division operator, is the man to whom electrical matters are entrusted, I venture to bring the matter before the members of this association, that we may keep in advance of the movement, and in the hope that some one of you will be fortunate enough to devise the system that will meet all the conditions.

My own experience and observations have led me to believe that a combination automatic and manual will meet the requirements, and, I would suggest, that the blocks be not less than three-quarters of a mile—the home signal operated by a lever, and signals operated by electricity, and gravity or air pressure placed 1,000 or 1,500 feet apart throughout the block, the circuit connecting these signals to be also connected with the lever at the home station, so that in moving the lever to place the home signal at danger the circuit will be opened and the signals go to danger by gravity, or weight; these signals will give ample notice of the position of the home signal and protect a train stopping just beyond a block station—it also admits of giving notice to the train should the block ahead clear after the train passes the distant signal and schedule speed may be resumed before the train reaches the home station.

To eliminate the chance of an operator unlocking the lever while any part of the train is in the block I would add to the above the connecting and insulating of one line of rails throughout each block, this rail to be free from contact with cinder ballast; stone ballast gives best results, running taps from this rail circuit to one side of the metallic line circuit which is used to unlock the lever at the office in the rear.

A train passing over the block will ground the side of the circuit connected by taps to rail; close the relay and the local of this relay will lock the lever which operates the home signal, open the circuit of the block in rear and will remain so till the last pair of wheels connected by a metal axle passes out of the block. With this arrangement it will not be essential that the operator sees the "markers."

There will, of course, be objections raised by railroad officers to depending upon electricity, and their past experience may justify them in doing so, but I believe that it *can* be depended upon, and in my opinion the day is not far distant when it will be. All failures can, undoubtedly, be traced to defective designs or instruments, failure through inattention to the batteries, or, perhaps, all together. We have track circuits, both open and closed; also electric signal circuits, normally closed, and I require that a closed circuit battery be renewed every fourteenth day, no matter what its conditions may be, new zincs placed in the track battery and using the cleaned zincs in the local circuit.

With this systematic way of handling the batteries and reliable men to do the work, and to watch the circuits, there will be no failures of the electrical parts. We have been experimenting with the Beatty zinc on our track circuits with very good results. The zinc is self-cleaning and always presents a clean surface, and, if the solution be kept at a proper strength a uniform current is given out so that changing the adjustment of relays is unnecessary. We are also trying them on normally open circuits, and expect to use them to replace Leclanché cells with gravity, as they do not run out if short-circuited. The first cost of the Beatty zinc is a little more, but a less number of cells are required and the zinc does its work until nothing is left but the stem. Since we arrived here our attention has been called to a new battery, which, if further tests prove as satisfactory as those already made, the zinc will no longer be needed and a long step taken towards the ideal gravity battery.

With a good and reliable battery I believe that electric signals and highway crossing bells will come more generally into use, and, by requiring strict attention from men in charge, our officers will soon lose their distrust of electrical appliances, and recognize in them very useful and economical adjuncts to the service.

---

[1] Abstract of a paper read at the meeting of the Railway Telegraph Superintendents, Denver, Col., June 16, 1892.

VARIATIONS OF E. M. F. OF SECONDARY BATTERIES.[1]

FOR some years there has been quite an exciting controversy going on as to the cause of the variations of electromotive force at different stages of charge or discharge. Some say that the resistance of the cell varies; others say that this is the case, but that it varies in the wrong way to account for the phenomena. A fully charged cell, for instance, has PbO_2 on one plate and Pb on the other, with strong acid in the pores, and fairly strong acid between the plates, all of which are good conductors. When discharged it has a percentage of $PbSO_4$ in the coatings of both plates, and weak acid in the pores, and these are bad conductors. The resistance must, therefore, be less at full charge, and yet the electromotive force needed to charge a nearly full cell is much higher than that needed when the cell is practically empty. According to Mr. G. H. Robertson, the rise of electromotive force is due to the formation of persulphuric acid and hydrogen peroxide. Mr. Robertson's views were stated very fully in an able lecture before the Society of Arts in December last.

Dr. J. H. Gladstone, F. R. S., and Mr. Walter Hibbert, F. I. C., in their paper on "The Cause of the Changes of Electromotive Force in Secondary Batteries," recently read before the Institution of Electrical Engineers, champion another theory. They maintain that when a cell is freshly charged the coatings are full of strong sulphuric acid, due to the decomposition of the lead sulphate on both plates. It is, of course, well known that a battery gives a higher electromotive force with strong acid. Messrs. Gladstone and Hibbert's paper is really an elaborate argument in favor of this theory, and is fortified strongly with experimental data. No doubt the variation of acid strength will account for some of the variations of pressure, but it hardly seems to explain the whole matter. If the variation of acid alone produced the results, a battery which had stood for a short time after complete discharge—that is to say, after being run down to, say, 1.85 volts—would give the electromotive force due to the strength of acid employed, the acid having diffused till the electrolyte in and outside the coatings had become homogeneous. On charging with a normal current there would be a little extra resistance due to lead sulphate to be overcome, but the resistance would in most cases be so low that the variation of pressure lost over it may be neglected. The back pressure would, however, rise gradually until the points were reached where gas is given off at one or both of the plates. When fully charged the cell would show a high electromotive force, but, after standing some time, this would fall to almost the same value as at starting. On discharging it would fall gradually as the acid in the interstices weakened.

This theory does not explain the very high initial electromotive force of a cell. That may, however, be due to other causes, such as the formation of a layer of gas, which would not interfere with the action of the acid, and thus would not conflict with the theory. Batteries of different makes give very widely different charge and discharge curves; and in studying such a question it is absolutely necessary to avoid considering one cause only. Some cells discharge fairly completely, and then drop suddenly; others fall more gradually. The form of the discharge curve may be largely due to the using up of the available spongy lead and peroxide, as well as to the gradual impoverishment of the electrolyte in the pores of the coatings.

The question is of purely scientific interest, and unless some remedy can be found it does not matter much why a cell needs a high charging pressure, except the knowledge leads to some method of charging at a lower electromotive force.

---

[1] *Industries.*

THE AMERICAN TYPE TELEGRAPH.

Printing telegraphs are almost as old as the electric telegraph itself. House, Hughes, Phelps and others followed quickly in the footsteps of Morse, with devices for supplanting the Morse character with the Roman letter. In some countries they almost succeeded, and, to this day, Continental Europe does a large amount of its telegraphing by means of the Hughes printing telegraph. In England the Hughes machine was extensively employed by the old companies and was only abandoned after the telegraph had been absorbed by the government. In this country there was once a "House" telegraph line using that system exclusively and the Western Union Company has for years transmitted press and other telegrams between Boston, New York, Philadelphia, Baltimore and Washington by means of the Phelps improved "motor printer" with success and at a rate of speed far exceeding that of the Morse.

One of the chief objections to the printing telegraphs in the past has been the "form of delivery." All of them printed their messages on a narrow band of paper or "tape." A press dispatch of a few hundred words would be many feet in length and liable to kinks, breaks and entanglement.

Users of the telegraph have always objected to receiving their dispatches on a ribbon and many have refused to accept them by the yard, asserting that filing with safety was impossible, and that portions of messages were frequently lost. As a result, all dispatches received by printing telegraph in Europe are now torn into short lengths and clumsily pasted on ordinary delivery blanks. The tearing and fouling of the tape in the basket of the ordinary "ticker" is familiar to all, often rendering a backward search for some particular item of news, impossible.

The American type telegraph machine has been designed with a view to overcoming these and many other objections to printing telegraphs as they have heretofore existed. By means of this latest device, the delivery is in the form of a printed page, eight inches wide. All the letters, numerals, fractions and other signs necessary to ordinary typewriting are provided.

The receiving instrument is entirely automatic in its action, requiring no skilled operator to watch or adjust it. The transmitter is similar in form, as far as the arrangement of the keys is concerned, to the typewriter, and can be worked by any person familiar with that instrument. The transmitting operator, by means of his keyboard, has full control of the machine at the distant end of the line, and can vary the length of a printed line or the space between two items of news or two telegrams, at will.

Electrically, this instrument has been designed with the object of relieving the electromagnets, which are operated or connected with the main line, of as much work as possible. This object is accomplished by the use of a suitable motive power (a small electric motor) independent of the magnets, for effecting the mechanical operation of the several parts of the printing and feed mechanisms, and by utilizing the electromagnets merely for releasing, arresting and generally for controlling the action of this motive power.

The type-wheel employed has four rows of characters, and is combined with means for raising or lowering the same for the proper alignment of any one of the rows. An oscillating movement is also given to the type-wheel whereby any desired character is printed on the paper. Mechanism is provided for rotating the type-wheel to present any desired character of a given row to the paper in the printing position; also for moving the type-wheel and its carriage laterally across the face of the paper and for its return to the starting or initial point, and for feeding the paper upward at the end of each printed line.

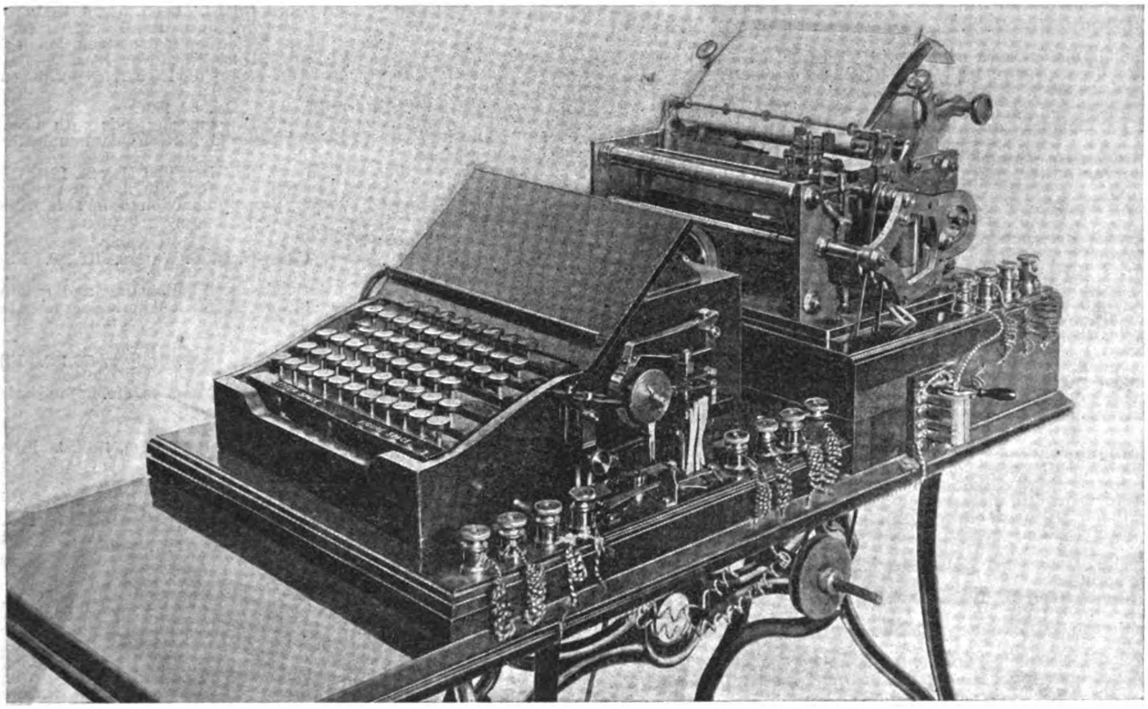
Mechanisms, all actuated by the above-mentioned motor, also set the type-wheel, make the printed impression, control the letter feed and spacing, return the type-wheel carriage and feed the paper. The first, second, third and fourth positions of the type-wheel, presenting the various rows of characters to be printed, are obtained by the action of the motor, as well as the restoration of the wheel from the fourth to its original or first position.

The setting mechanism which governs all of the above movements is a small light shaft actuated frictionally by the motor, and released, step by step, by a sensitive polarized relay in the main line circuit. Here, inertia is small and a consequent high speed of revolution is obtained, four hundred or more revolutions per minute. On this shaft are an escapement wheel, ratchet retaining wheel, unison device and a setting pin and wedge. The moment the pin is placed in the proper position by the action of rapidly reversed currents, other magnets in the circuit, neutral and less sensitive, are affected by the prolongation of the current and release the mechanisms connected with the motor, necessary to perform the various functions already enumerated.

The work done by these magnets, which are in the main line circuit (there are three of them), is of the lightest character possible, and the working of the instrument over long circuits where light currents are necessarily employed, is practically assured. In practice, a speed of over 40 words per minute on a 200-mile circuit, using the ordinary Morse power has been reached, and will probably be exceeded when operators shall have become entirely familiar with the working of the machine.

Typewriting by wire and by ordinary typewriting methods have been the objects sought to be obtained in the American type telegraph. The width of the paper, the form and action of the keyboard, as well as the manipulation of the machine generally, are made to conform, as nearly as possible, to the practice with which an ordinary typewriting operator is familiar.

The accompanying engraving illustrates the machine which has been referred to above. The company are, however, manufacturing another and smaller machine, which also works at a good speed and delivers its matter in the same form, for private line working. In this latter device, the motor is eliminated and the construction is generally simple. A column, or page printing machine, by the same inventor, Mr. J. E. Wright, of New York, has been working successfully in London for the past three years delivering news reports to all the leading newspapers and clubs.



The American Type Telegraph.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JULY 5, 1892.

Accumulators :—

Secondary Battery, J. H. Gerry and C. E. Long, 478,230. Filed Aug. 1, 1891.

Consists of a cell containing shallow compartments separated by insulating partitions and containing active material and lead plates the lower edges of which extend into the active material.

Electric Battery, C. F. Waldron, 478,485. Filed Aug. 22, 1891.

A secondary battery element consisting of a wooden base and a metallic plate presenting a surface of active material in immediate contact with the base; these parts constituting a horizontal tray and remaining in permanent contact without intermediate spacing.

Alarms and Signals :—

Electric Alarm Clock, G. C. Darche, 478,155. Filed June 1, 1891.

Electric Indicator, W. E. Decrow, 478,274. Filed March 8, 1892.

Relates to automatic means for resetting an annunciator after a given lapse of time.

Indicator for Electrical Signaling Systems, C. F. Gillette, 478,324. Filed Aug. 13, 1891.

Provides means whereby the connection between a magneto generator and any desired one of several different points may be readily made.

Conductors, Conduits and Insulators :—

Electric Cable, W. H. Sawyer, 478,367. Filed Feb. 18, 1892.

An electric cable having extremely low electrostatic capacity and great mechanical strength.

Insulator, L. McCarthy, 478,518. Filed April 19, 1892.

An insulator composed of metallic parts separated by interposed compressed sheets of mica.

Distribution :—

System of Electrical Distribution, H. Ward Leonard, 478,844. Filed Nov. 27, 1891.

Consists in maintaining upon each one of three or more conductors a potential different from that in any of the others and connecting the armature terminals of the motor with different pairs of said conductors.

Dynamos and Motors :—

Brush-Holder for Dynamos and Motors, M. H. Hathaway, 478,104. Filed Oct. 8, 1891.

A carbon brush holder of simple construction providing means for compensating for the wear of the brush, and that can be applied to any form of dynamo or motor.

Dynamo-Electric Machine or Motor, E. A. Sperry, 478,142. Filed Nov. 16, 1891.

Relates to special construction of the field magnets, armature cores, windings and insulation for the purpose of cheapening the construction.

Electric Motor, J. B. Secor, 478,475. Filed Jan. 30, 1891.

Employs a base to which all the magnets are magnetically connected and which forms a pole common to all, and a cylindrical field embracing an unwound and non-magnetized armature of magnetic material.

Dynamo-Electric Machine, C. W. Thomas, 478,529. Filed Oct. 21, 1890.

Claim 1 follows:

A duplex commutator of electric currents which consists of a series of long insulated segments alternating with pairs of short segments in two different planes and having dynamometric connection in combination with two pairs of brushes for conversions of a continuous into an alternating current and vice versa.

Lamps and Appurtenances :—

Electric Arc Lamp, E. Thomson, 478,145. Filed March 22, 1890.

Employs an electric motor constantly in operation and a speed-responsive device connecting the carbon with the motor so as to be actuated thereby upon any variation of the speed of the latter.

Incandescent Electric Lamp Socket, H. E. Werline, 478,149. Filed Dec. 22, 1891.

Employs a series of connected resistances composed of carbon filaments and connecting springs.

Electric Lighting System, H. T. Cooke and W. H. Mackay, 478,186. Filed July 17, 1891.

Has for its object to light or extinguish from different points one or more lamps in a circuit.

Suspension Bar for Electric Lamps, T. Dillon. 478,275. Filed April 28, 1892.

Swing Joint for Electric Light Bracket, H. P. Drew, 478,417. Filed May 15, 1892.

Electric Arc Lamp, R. M. Hunter, 478,510. Filed Nov. 12, 1891.

Employs a method of feeding the carbons towards one another at an angle so as to compensate for the inequality in their combustion.

Measurement :—

Electric Measuring Instrument, S. Evershed, 478,097. Filed Dec. 18, 1891.

Has for its object to increase the maximum rotation of the indicator to ninety degrees or more to facilitate the construction of the instrument and to check the oscillations.

Apparatus for the Measurement of Electrical Resistances, S. Evershed, 478,098. Filed Dec. 22. 1891.

An ohmmeter consisting of a current coil surrounding a magnetic needle fixed on an axis supporting a second astatic needle, the coil being supported in a brass frame on which a pressure coil is wound with its magnetic axis at right angles to that of the current coil.

Time-Registering Apparatus for Electricity, H. H. Pattee, 478,237. Filed Dec. 11, 1891.

Relates to means whereby the time during which a current is traversing a given circuit may be accurately and automatically registered.

Metal-Working :—

Electrical Brazing Device, W. Mitchell, 478,201. Filed Aug. 17, 1891.

Consists of a holder for the article to be brazed, forming one electrode of the circuit and a movable pencil forming the other electrode.

Solder for Aluminum, J. W. Richards, 478,238. Filed Oct. 5, 1891.

A solder consisting of an alloy of aluminum, zinc and phosphor tin,

Miscellaneous :—

Prospecting Drill, A. Ball, 478,077. Filed Dec. 31, 1891.

An electric drill for mining purposes.

Electrical Distribution for Cars, S. Young, Morris Moskowitz, L. D. Adler and J. Loewenberg, 478,182, Filed Oct. 15, 1891.

Employs an air compressor driven by one of the car axles and in turn driving an air engine, which latter drives a dynamo generating electricity for light or heating purposes.

Electric Car Lighting System, S. Young and M. Moskowitz, 478,182. Filed Jan. 13, 1892.

Similar to 478,182.

Illuminated Advertising Sign, C. R. McGimsey, 478,204. Filed June 2, 1891.

Operating Submarine Guns, H. Berdan, 478,215. Filed Mar. 22, 1892.

A hydraulic buffer for a torpedo boat, to the rear end of which is connected a contact-making device adapted to discharge the torpedo when the buffer is forced backward by contact with an enemy's ship.

Magnetic Lock, H. V. Smith. 478,245. Filed Dec. 18, 1891.

Rheostat, W. P. Eayrs, 478,276. Filed Aug. 3, 1891.

Employs two resistances having two sets of contacts connected respectively with them, corresponding contacts in each set being connected with their respective resistances at similar points, said resistances being respectively always in contact with the legs of a main circuit, the contacts being movable and adapted to be brought in pairs in contact with the legs of a local circuit.

Voltaic Glove, F. Simpson, 478,293. Filed Mar. 25, 1892.

Employs elements of copper and zinc, which, when brought into contact with the flesh are intended to produce currents of electricity.

Lightning Arrester, C. S. Van Nuis, 478,383. Filed Sept. 16, 1891.

Employs sections of fusible wire in series, the meeting ends being separated by a short space.

Gas Lighting Device, D. J. Quinn and P. W. Hoffmann, 478,522. Filed Nov. 27, 1891.

Railways and Appliances :—

Electric Mine Car, E. A. Sperry, 478,138. Filed Feb. 16, 1891.

Relates to means of transmitting power from the motor to the traction wheels of mine cars while permitting the flection of the trucks from alignment with the frame.

Electric Locomotive, E. A. Sperry. 478,139. Filed April 8. 1891.

Relates to electric supports and driving connections between the motor and the car axle.

Trolley-Wire Splice, E. A. Sperry, 478,140. Filed April 18, 1892.

Claim 1 follows:

A combination of a trolley wire, splice on such trolley wire, tapering clamps each side of splice and a metallic connection between such clamps.

Electric Railway Conduit, M. Shoemaker, 478,175. Filed May 25, 1891.

Employs a metal tube set upon glass insulators and having a blast of hot air constantly forced through it for the purpose of keeping it perfectly dry and preventing the escape of the current from the conductor which is laid upon it.

Electric Locomotive, S. H. Short, 478,242. Filed Nov. 6. 1890.

Relates to the placing of the armature axially with reference to the driving axle and making but one revolution to one revolution of the latter.

Electric Railway, F. Mansfield, 478,846. Filed Nov. 18, 1890.

Relates to improvements in the pickup device carried by the car in a conduit system.

Trolley, J. W. Davis, 478,410. Filed Oct. 22, 1891.

Consists of an elongated body having tapering ends with a central groove and spiral grooves about the papered portions communicating with the central grooves.

Electric Locomotive, S. H. Short, 478,477. Filed May 26, 1891.

Has for its object to combine a motor with axle of the street car and transmit a practically constan propelling action to the axle without the use of the earth.

Switches and Cut-Outs :—

Time Switch for Electric Circuits, B. E. Waters, 478,180. Filed June 11, 1891.

Employs a movable contact maker and supporting and guiding slide bar provided with engaging projections and pivoted spring-actuated levers whose arms co-operate with the projections.

Telegraphs:—

Device for Reproducing Characters, H. C. Bridger, 478,152. Filed Aug. 10, 1891.

A device for reproducing messages, drawings, etc. in fac-simile at distant points.

Telephones and Apparatus :—

Microtelephonic Apparatus for Divers, R. Wreden, 478,493. Filed March 28, 1890.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JULY 12, 1892.

Accumulators :—

Electrode for Storage Batteries, H. Tudor, 378,661. Filed May 30, 1891.

Consists of a core composed of one or more metal bodies having main ribs provided with secondary ribs forming between them grooves and having active substance imbedded in said groove.

Electrode, A. Vanden Kerckhove, 478,661. Filed Feb. 12. 1892.

Consists of a grating and electrodes each secured to the grating by solder on one of its sides and by lugs on the other sides thus leaving a space on three sides for expansion and contraction.

Alarms and Signals :—

Thermal Alarm, H. F. Maxim and J. M. Price, 478,701. Filed Jan. 7, 1891.

Employs a mercury column which closes certain contacts corresponding with varied degrees of heat.

Electrical Thermostat, W. L. Denio, 478,788. Filed Dec. 8, 1891.

Employs a fusible solder having a predetermined melting point.

Electric Signaling Apparatus, W. L. Denio, 478,789. Filed Dec. 8, 1891.

A fire-alarm signal system comprising two main circuits one leading from a central station to the building to be protected and the other to the fire department.

Electric Time Alarm, J. Jacobi, 478,865. Filed Nov. 17, 1891.

Distribution :—

Distribution of Electric Currents, E. Thomson, 478,722. Filed Dec. 6. 1886.

Provides an automatic cut-off in case of accidental short-circuit either in the coils of the generating apparatus or upon the local wires.

Dynamos and Motors:—

Electric Locomotive, J. Gray, 478,591. Filed June 12, 1891.

Has for its object to provide means for increasing the traction between the locomotive and the truck when desired.

Electric Motor, H. F. Ong, 478,968. Filed April 4, 1891.

Employs a field magnet formed of a number of sections corresponding with those of the armature and a multiple switch for sending the current through one or more of the field magnet sections in either direction.

Metal Working :—

Method of Welding Metal Wheels, E. H. Scott, 478,643. Filed Jan. 28, 1889.

A method of securing the spokes of metal wheels to the felloes by welding them together by electricity.

Method of Making Metal Wheels, E. H. Scott, 478,644. Filed Jan. 28, 1889.

Similar to 478,643.

Miscellaneous :—

Magnetic Separator, C. M. Ball, S. Morton, 478,551. Filed Oct. 12, 1891.

Apparatus for Lighting Locomotive Engines, A. R. Cavner, 478,683. Filed August 1, 1891.

An electric head light for locomotives.

Mold for Glass Battery Jars, J. Gayner, 478,792. Filed Nov. 9, 1891.

Electro-Mechanical Apparatus for Starting or Reversing Machinery, A Piat, 478,816. Filed Apr. 2, 1890.

Claim 2 follows:

In machines actuated by an electric motor the combination with the lever for controlling the current and the motor, of a contact arranged on the under side of said lever, fixed contacts on each side of the lever and in the path of the first contact, hinged levers and springs whereby a movement of the lever will cause said contact to move under and raise one of said hinges until the contact shall have been passed and a reverse movement of the lever will cause it to travel above the contact.

Electric Elevator, A. B. See & Walter L. Tyler, 478,821. Filed March 14, 1892.

Relates especially to electrical devices for stopping and starting elevators.

Railways and Appliances :—

Electric Rail Bond, T. J. McTighe, 478,629. Filed Apr. 1, 1892.

A rail bond having shoulders and rivets all in one piece.

Conduit System for Electric Railways. W. H. Ford, 478,956. Filed July 6, 1891.

Employs a main insulated conductor, a sectional bare conductor composed of one long and two short sections alternately, suitable connections between the main and sectional conductors and switches between the same under the control of the moving vehicle.

Switches and Cut-Outs :—

Cut-Out Switch, W. E. Cleveland, 478,689. Filed Sept. 21, 1891.

A combination of cut-out switch and fuse, the latter connected with the contacts and being supported away from the switch lever.

Arc Extinguisher for Electric Switches, S. H. Short, 478,718. Filed Mar. 10, 1891.

Employs a series of supplemental contacts in the path of the switch lever, each being a good conductor of heat and electricity.

Telephones and Apparatus :—

Desk Attachment for Telephones, L. C. Butler, 478,564. Filed Sept. 9, 1891.

Telephone, P. H. D'Unger, 478,692. Filed Mar. 29, 1892.

Claim:

The combination in a telephone of the diaphragm and arm projecting over the diaphragm, a screw in said arm and a buffer actuated by said screw and adapted to bear against the diaphragm.

Telephone Repeater, T. A. Edison, 478,743. Filed Oct. 14, 1885.

Claim 1 follows:

The combination with the telephone line of two or more reciprocal telephone repeaters connected therewith, each repeater comprising a receiving and transmitting telephone.

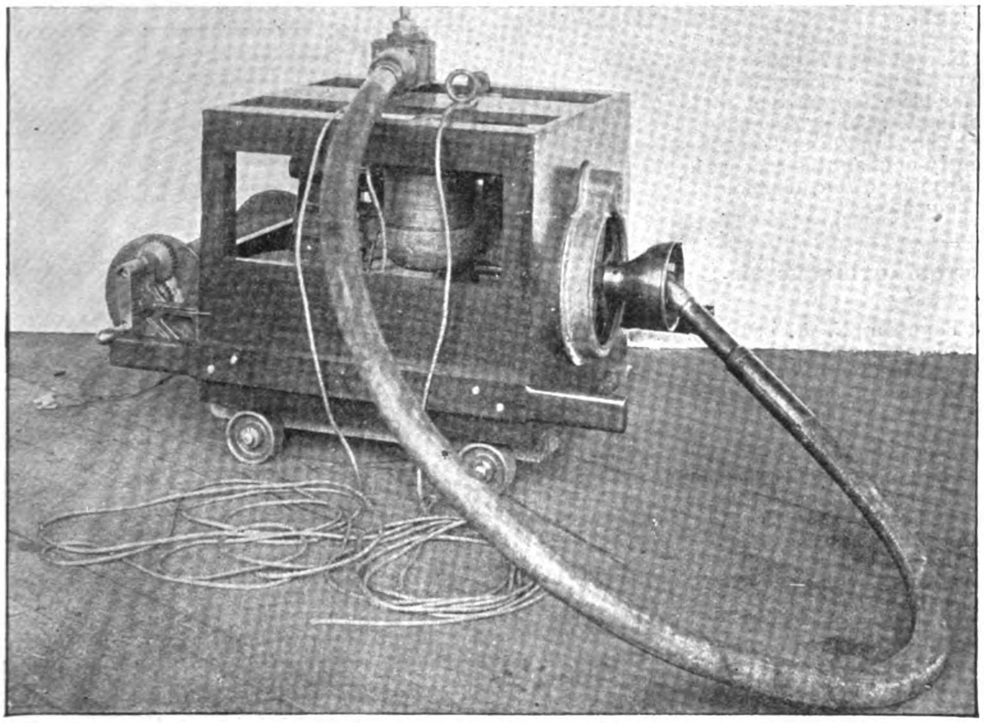


FIG. 2.—BILLBERG PORTABLE MOTOR.

THE GLASGOW UNDERGROUND RAILWAY, the contract price of which was over $5,000,000 is nearly finished. It was begun nearly three years ago and is seven and a quarter miles in length.

BILLBERG PORTABLE MOTORS.

THE accompanying cuts, Figs. 1 and 2, represent a Billberg portable motor for driving drill presses, portable reaming machines, etc., where the power is a long distance from the work. The frame of the motor is of wrought iron, to combine the most power with the least weight. The bearings are all self-oiling, of the sleeve type, and can be easily replaced. The motors are first class in construction and have improved armature commutators and self-feeding brushes.

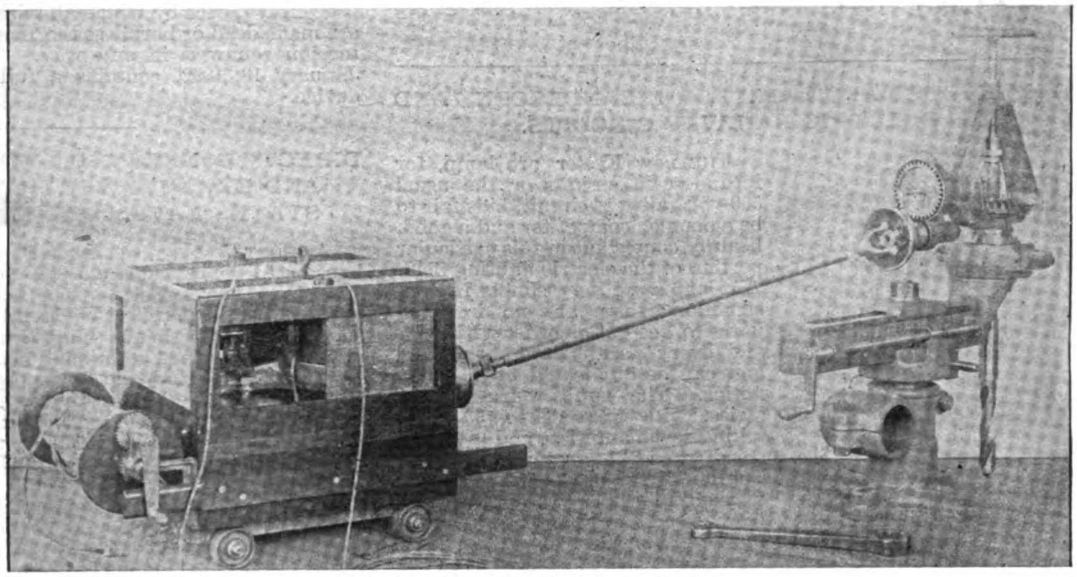

FIG. 1.—BILLBERG PORTABLE MOTOR.

The motor is furnished with a switch and rheostat for changing the speed, and also reducing gearing so that the spindle for attatching the connection shaft can be run at 250 and 500 revolutions and eight intermediate speeds. It is fastened upon the box containing the rheostat and is covered with a wooden top with wire cloth which protects it from injury and at the same time allows a free circulation of air.

To one end of the box is attached a reel containing 100 feet of flexible connection, which will allow of the motor being used anywhere within this distance from the connection box. The motor box is mounted on wheels so that it can be rolled when at work and also has wooden batten handles so that it can be carried. These machines are made of two sizes, at present; the 2 h. p. weighing complete 275 lbs—boxed for shipment 350 lbs; the 3 h. p. size weighs complete 375 lbs.—boxed for shipment 500 lbs. Fig. 1 represents one of the motors coupled by a telescope shaft to a Dallett special portable drill.

Since the Billberg motors were brought out about two years ago they have become very popular and have given entire satisfaction. Among some of the many concerns using these motors are the Franklin Sugar Refinery, William Sellers & Co., Phila.; Sotter Bros. Pottstown; Edgemoor Iron Works, Edgemoor; De La Vergne Refrigerating Co.; New York Central R. R., and Brooklyn Navy Yard, New York; Norfolk Navy Yard, etc. These special motors, as well as a standard line of motors, generators and dynamos are manufactured by Thos. H. Dallett & Co., York street and Sedgeley avenue, Philadelphia, Pa.

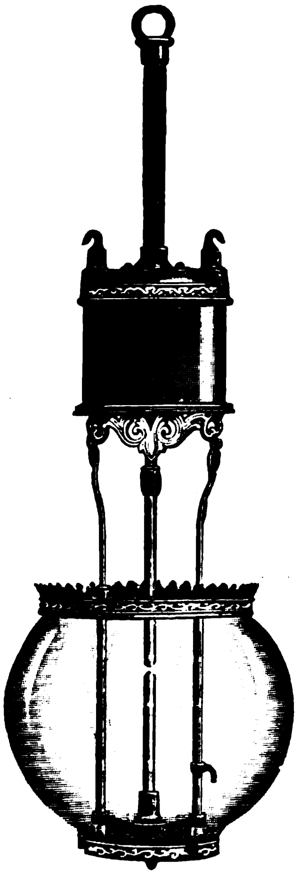
THE PENNSYLVANIA'S electric railway system, extending from Jersey City to the adjacent towns, is under active discussion. With the exception of the usual fossils, New Jersey residents are quick to see the advantages of the proposed system.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

In this wideawake age advertising is absolutely essential.

THE KESTER ARC LAMP FOR INCANDESCENT AND ELECTRIC RAILWAY CIRCUITS.



Kester Arc Lamp.

The new Kester arc lamp, for incandescent circuits or the usual 500-volt railway circuit, bids fair to be a popular competitor and a good, healthy contestant in this particular portion of the electric lighting field. The lamps are very simple in construction; there are no intricate parts to get out of order whatever, and every part is interchangeable and can be duplicated on shortest notice. The lamps burn two in series, with from 100 to 150 volts, taking seven amperes, and giving a steady arc at 3½ amperes per lamp. The lamps for use on electric railway circuits burn four in series on from 220 to 500 volts. There are four especial features in the lamp worthy of particular attention, viz., positive clutch, single armature, clutch-releasing device and lifting spring. These devices are all mounted on one frame and practically make up the entire working parts of the lamp.

The company is not an old one, but although only recently organized, is already in receipt of some desirable orders and is anxious to locate a limited number of desirable agencies. Mr. J. F. Kester, the president and general manager, has had excellent experience in Terre Haute, Ind., where he was the active head and electrician of the Kester Electric Co., whose products are well known. A large factory, with excellent facilities, is located at 173 South Canal street, Chicago, whence lamps are being shipped to all parts of the country in quantities that are highly gratifying to the stockholders of the company.

A SUCCESSFUL TEST OF THE JOHNSTON AUTOMATIC DISCONNECTOR.

A very interesting test was made at Paterson, N. J., on the afternoon of July 18, of the Johnston safe automatic-electric disconnector as applied to trolley wires, under the direction of Mr. Wm. A. Cullen, superintendent of line construction for the Paterson Railway Company, and Mr. F. B. Jacobs, secretary of the Johnston Company, in association with Colonel Rice.

A No. 0 B. & S. gauge trolley wire was strung along East 33d street a little over 500 feet in length. The disconnectors were cut into this line, with about 250 feet of wire between them and a trifle over 125 feet on each end, the wire being drawn up to the usual tautness and so subject to the same strain as usual. Connections were made to the feeder wire which was supplying current to the cars on the Cedar Lawn Division near by, and taps were made at the top or centre of each disconnector.

All then being in readiness Mr. Cullen, to show those assembled that there was current on the wire, made a momentary contact with the track with a light wire; a flash resulted, satisfying every one that the wires were alive. Word was then given to a lineman, who was stationed on top of a tower wagon near the middle of the centre span, to cut the wire, which he did, allowing both ends of the wire to drop to the ground. Though every one watched to see a flash or the wire burn off, they were disappointed, as the wires were perfectly harmless, the current being completely cut off at each disconnector. Not fully satisfied with one trial Mr. Cullen ordered the wires restrung, which being done, they were cut a second time, with the same result as before.

Every one went away perfectly convinced that the disconnectors were just the thing for the work. All that was needed was a little strengthening of a few minor mechanical details to make the apparatus perfect. Those who witnessed the test were Mr. E. J. Lawless, manager of the Paterson Railway Co., Mr. M. Ludwig, superintendent of the Edison Electric Illuminating Co. of Paterson; Mr. Geo. G. Rhoderick, secretary of the Cullen & Rhoderick Engineering Co.; Mr. Jas A. Heagon, of the Paterson Railway Co., and a score of others. The "Disconnector," as its name implies, is a safety device by which all wires in which it may be placed are made dead or harmless the moment they are broken or the tension removed in any way. The Electrical Engineer of January 13, 1892, contains a full description of this valuable device.

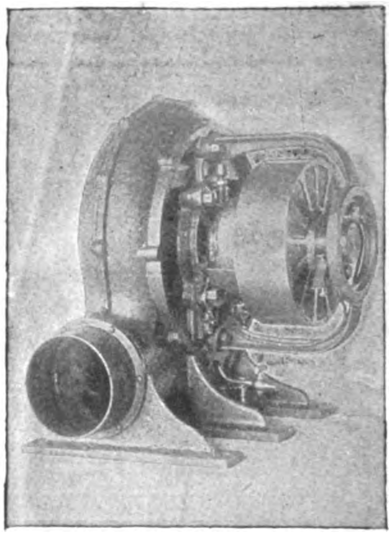
DIRECT CONNECTED WADDELL-ENTZ MOTOR AND EXHAUST VENTILATOR FOR THE UNITED STATES NAVY.

A short time ago the Navy Department called for an air exhauster to be driven by a direct-connected electric motor, which should be so arranged as to be readily detachable. In carrying out the specifications the Waddell-Entz Electric Co., of this city, submitted a design and built a machine which has proved so satisfactory that ten additional motors have been ordered by the Navy Department for the ships now building.

The general design of the combination will be seen in the accompanying engraving. The armature shaft of the motor is prolonged and carries the fan, a single bearing only being employed, which is situated within the core of the hollow field magnet.

The motor is series wound for 80 volts and 3.2 amperes. The resistance of the series field at 15.5 deg. C. is 4.2 ohms and the resistance of the armature 2.5 ohms. During a recent test the motor ran for three hours at 80 volts, taking 1.8 ampere at 1,850 revolutions, with the exhauster wide open, the motor running cool in all its parts. A ¼ h. p. being called for by the Navy Department, the motor was designed for that power, but owing to the high efficiency of the motor, as shown above, the power consumed was very much less. The motor was also tested for about one hour at 110 volts and 3.2 amperes without heating or sparking. The insulation resistance in all tests was 1 megohm on the field and 35,000 ohms on the armature.

The machine is designed so that it may stand on deck independently wherever required. For this purpose the side of the shell is strengthened by a ring, and extra long feet are provided giving a firm base to the combination. In actual service the motor is completely enclosed in a brass shell, so that it can be exposed to the weather at all times without injury. The entire arrangement is most compact, and has called forth high praise from the navy officials.



Direct Connected Waddell-Entz Motor and Exhaust Ventilator.

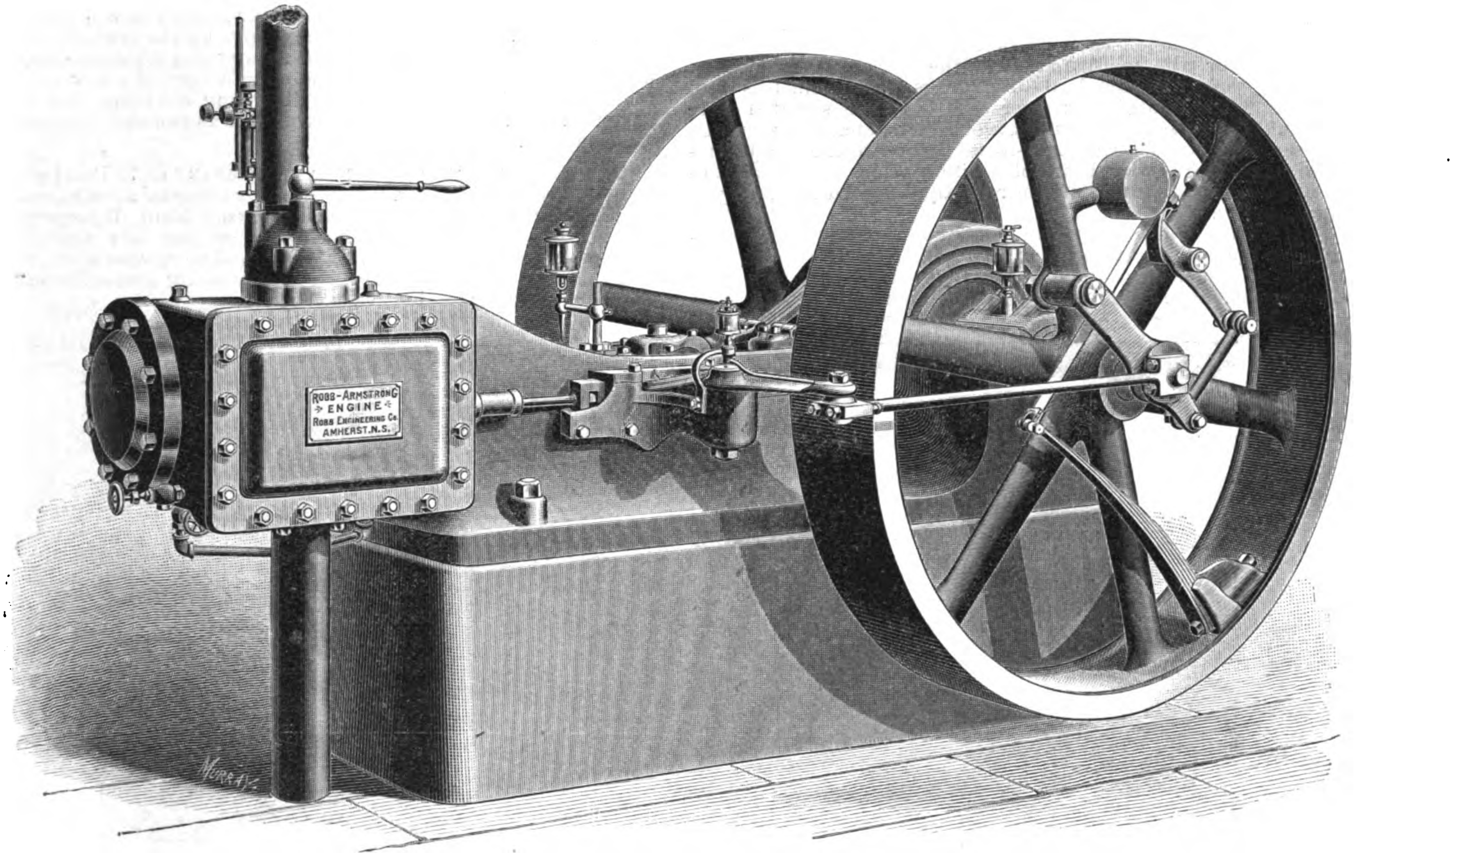
MANUAL OF TELEGRAPHY.

The Western Electric Company publish, in connection with their April catalogue of telegraph instruments, an excellent telegrapher's manual in condensed form, comprising the Morse code, with explanations and directions for sending and receiving, and numerous exercises intended to test the progress and skill of the beginner. There is also a quantity of useful miscellaneous information and advice to young operators.

THE ROBB-ARMSTRONG ENGINE.

THE accompanying illustrations show a new engine of the single-valve automatic type lately introduced by the Robb Engineering Co. of Amherst, Nova Scotia.

The engine weighs about 100 pounds per horse power, so distributed as to give the greatest attainable stiffness, while the foundation furnishes all the weight required. The frame, as will be seen by referring to Fig. 1, is of the "Porter" type with a double-disc crank particularly thick at the top, thus bringing the metal in the direct line of strains between the cylinder and shaft bearings.



ROBB-ARMSTRONG
ENGINE
ROBB ENGINEERING Co.
AMHERST.N.S.

FIG. 1.—ROBB-ARMSTRONG ENGINE.

The crank is built up of cast discs and the fits of the shaft are very long, as seen in Fig. 2. The bearings are ground with great accuracy and both shaft and shells are made to gauge and are interchangeable. The crank is covered by a cast iron case which is hinged, as shown in Fig. 2, so that free access within may be had at all times.

The crank-pin is oiled through two ½ inch holes, extending from either side of the crank to the centre of the pin, and all oil wasting from the outer ends of shaft bearings is caught, and returned by a ring to the bearing, until it finds its way to the crank-pin and escapes to the crank pit, whence it is drawn off and filtered.

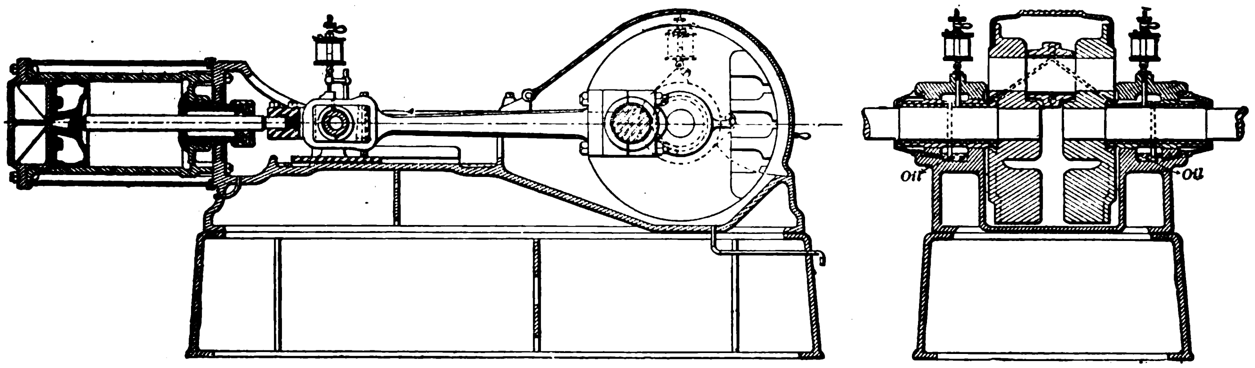


FIG. 2.—ROBB-ARMSTRONG ENGINE.

The fly-wheel governor is a modification of the "Straight Line," and, with the valve and the oiling devices is used by arrangement with the Straight Line Engine Co.

What corresponds to the eccentric rod, although there is no eccentric, has ball-and-socket bearings at each end. The rocker arm is horizontal, and there is no twisting strain on either of its bearings, as a straight line passes through all three of them. An index finger shows the movement of the valve. Oil passes to the eccentric pin through the hollow eccentric rod, and what escapes is caught and held in the flanged fly-wheel.

This engine was designed by Mr. E. J. Armstrong, of the Ames Iron Works, Oswego, N. Y., where it is built in this country.

F. P. LITTLE & CO.

THE above firm of 141 East Seneca Street, Buffalo, N. Y., have just closed a contract for wiring the Lyceum Theatre in Buffalo, for 600 incandescent lights. furnishing all the fixtures, stage regulators, etc., complete. They have also closed a contract for lighting the Woodlawn Beach summer resort, on the south shore of Lake Erie. For this plant they furnish a 30 h. p. locomotive boiler, a 7½ by 12 Rice automatic engine, a 16 kilowatt Thomson-Houston dynamo, 16 Mosher arc lamps and 75 incandescents of 16 c. p., all wired up complete. They furnish all the poles, line wire, etc., put in position, as well as build the foundations for the machines. Both of these jobs have been begun.

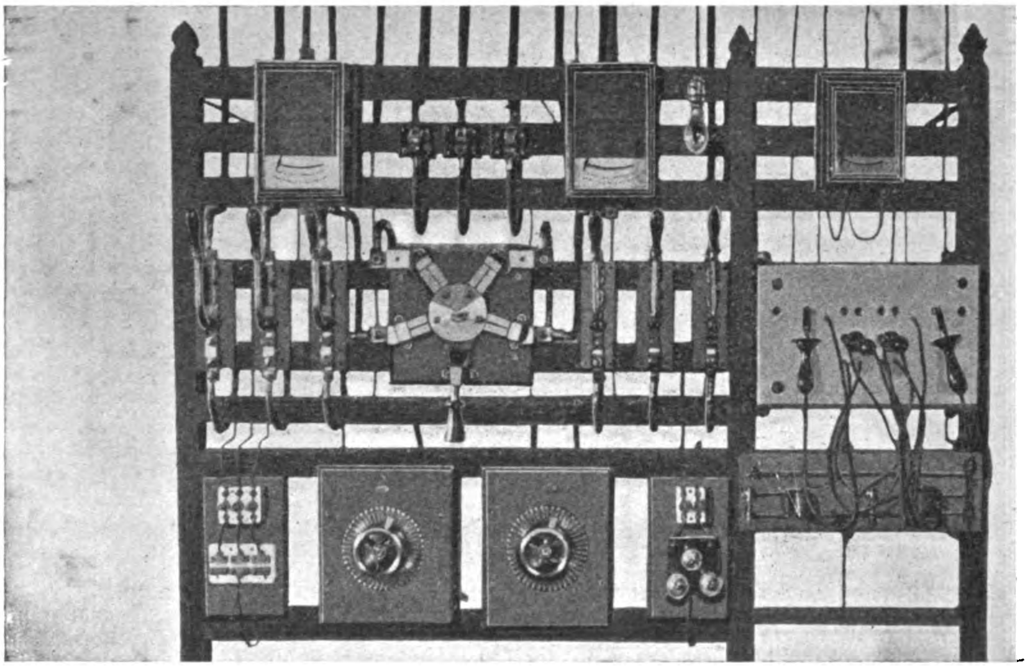
THE GREENVILLE, PA., ELECTRIC LIGHT STATION.

In Greenville, Pa., there has recently been installed by the Edison General Electric Company for the People's Electric Light Company of that town, an electric lighting plant for incandescent and arc lighting. The steam plant consists of two Buckeye compound non-condensing engines each with a capacity of 75 h. p., and an upright Syracuse boiler of 150 h. p.

The electrical equipment comprises two 45 K. W. compound wound Edison standard incandescent dynamos, and one 40-light 2,000 c. p. standard Edison arc dynamo.

The different controlling and measuring instruments are mounted on a skeleton switchboard so constructed that it has only sufficient wood to support the instruments, as seen in the figure. The left-hand portion is devoted to the different appliances for the manipulation of the incandescent system, consisting of the standard regulators, amperemeters and switches. The lightning arrester used is of the serrated plate pattern. The pressure indicators, voltmeters, etc., are mounted on a separate board. The right-hand portion of the board supports an arc light switchboard of white marble, a standard Edison ampere meter andtwo of the recently-designed Edison lightning arresters.

The Edison three-wire system is used, and all customers burning more than six lights are supplied with a three-wire service. Customers burning less than this number of lights have a two-wire service, the lights being carefully arranged against each other so that too much current may not be carried over the neutral wire. The Edison meter system has been adopted, the latest type of electrolytic meter being used. The meter-room is completely equipped in order that this part of the service may be adequately attended to.



Incandescent and Arc Switchboard, Greenville, Pa., Electric Light Station.

The pole line for the incandescent system is about 2,000 feet in length. Where the incandescent and arc systems are common the lines are run on the same poles. In the outlying districts, however, the lighting is done by arc lamps exclusively. The line for the arc system is between four and five miles long.

The dynamos operate so well that they take care of the load with but little adjustment of the field regulators, and the load can be thrown from full to no load without the necessity of altering the resistance in the least.

NEW ENGLAND NOTES.

Swan & Lane, of Boston, have just completed arrangements with the Jenney Electric Motor Company, of Indianapolis, whereby they will act as their agents in this city. The Jenney motor is well and favorably known to the trade, and Swan & Lane will carry a complete line of all sizes in their store at 194 Summer street, for quick shipment. The Jenney Company have recently been making a specialty of installing complete power installations, consisting of generators and motors, for use in factories in connection with lighting plants, and have already installed a number of these plants with complete success.

The Eastern Electrical Supply Company, of Boston.—The controlling interest in this company has just been secured by Messrs. D. A. Andrews, Sr., D. A. Andrews, Jr., and C. B. Price, all of the Pettingell-Andrews Company, of Boston. Mr. Maybin W. Brown will continue as president and Mr. D. A. Andrews, Jr., will hereafter act as treasurer of the company, in addition to his duties with the Pettingell-Andrews Company. The business of the Eastern Company will be conducted for the present from their present quarters, though it is expected that they will remove to 196 Summer street later on in the summer.

The Consolidated Electric Manufacturing Company, of Boston, have given up their Franklin street retail store, and will hereafter do all their business from their factory at 355 Congress street, Boston. They have decided to give up the general electric supply business but will retain the factory and wholesale department, confining themselves to the manufacture of a few specialties, such as the Lyon brake, the Heymann arc lamp, and other novelties. Mr. C. E. Bibber will continue as general manager of the company.

The Boston Incandescent Lamp Company of 70 Pearl street, Boston, has appointed Mr. C. E. Bibber as general sales agent for the United States, of their new incandescent lamp. This company has only been in existence a short time, but has already established a good reputation for its lamps, and is crowded with orders to its utmost capacity. They are now making arrangements to about double their productive capacity.

The Berlin Iron Bridge Co., of East Berlin, Conn., have received the contract for the new tinplate works which Hughes & Patterson are to erect at Philadelphia, Pa. The buildings will be of iron from the designs of the Berlin Co. The main building will be 40 feet wide by 253 feet long with a wing of the same width, 300 feet long, both two stories high. The rolling-mill will be 120 feet wide by 160 feet long, with an annealing room 75 feet wide by 160 feet long. The whole plant will require about 800 tons of iron to be used in its construction.

The Walworth Manufacturing Company, of Boston, have purchased a piece of land in South Boston at 485 Congress street extension, for the purpose of erecting a factory for the manufacture of the steel poles used in electric street railway work. They will also put in this factory a large pipe-bending plant, and other necessary machinery for the manufacture of iron and steel material used in equipping electric railways; in fact these plants will be built expressly in connection with their intention to install, and equip electric railways complete.

The Electric Heat Alarm Company, of Boston, gave an exhibition of their system under the management of Mr. J. P. Robinson, in St. John, N. B., a few days ago which was very successful in every way. The alarm has been perfected in a number of details lately, and the company is now ready to apply their system to factories, hotels and all large buildings, as well as to machine shafting and bearings. It is expected that a local company will be formed in St. John.

CROCKER-WHEELER ELECTRIC CO.

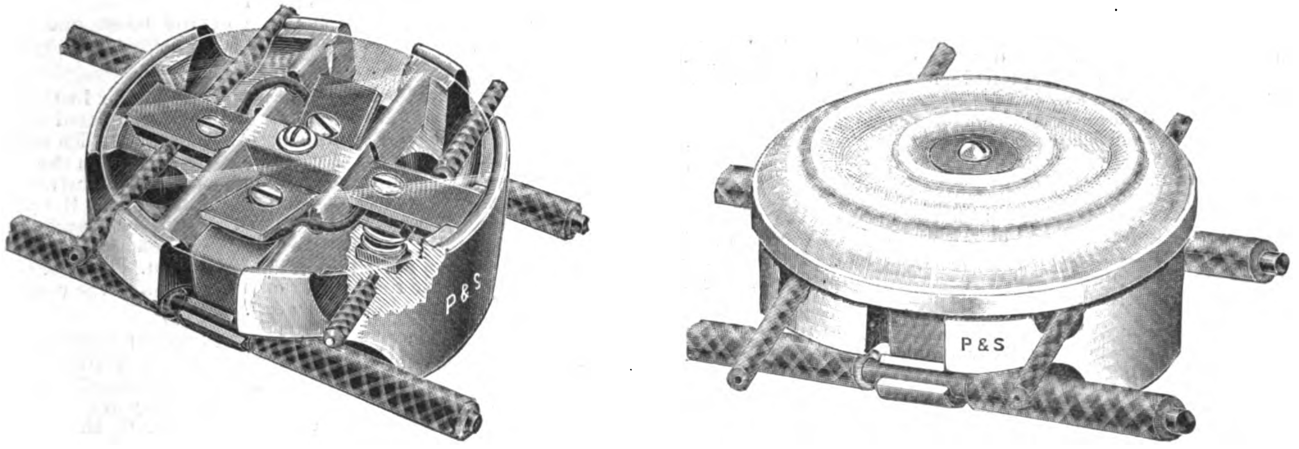
The Crocker-Wheeler Electric Company, New York, have been in operation a little over two years. Last winter they paid a dividend of 5 per cent., and they paid an extra dividend of 3 per cent. July 1, out of the earnings of the company. Their business has increased so rapidly that they were compelled last year to increase their capital stock from $100,000 to $200,000. The new stock was quickly sold for cash at par, all being taken by some of the strongest men in the city. The officers of the company are: President, S. S. Wheeler; vice-president, F. B. Crocker; secretary and treasurer, D. H. Jeffery. The business this year has averaged several times as much as last year, and, notwithstanding their largely increased plant, they have been compelled to run nights to keep up with their orders.

"HONOR TO WHOM HONOR IS DUE."

We are requested by Queen & Co., of Philadelphia, to mention that the cable-testing keys illustrated in our issue of June 29, were suggested to them by E. W. Stevenson, electrician of the Brush Electric Illuminating Co., New York. Mr. Stevenson has had wide experience in such matters, and hence knows well what the actual requirements are. He has used a set of keys similar to those Queen & Co. make, for some time past, with very satisfactory results. In fact, Mr. Stevenson has a number of ingenious ideas in the line of instruments and special measuring apparatus.

THE PASS & SEYMOUR BRANCH BLOCK.

The accompanying illustrations show clearly the construction of the china branch block introduced by Messrs. Pass & Seymour, of Syracuse, N. Y. It is very neat in appearance, and is claimed to entirely overcome any danger of the blowing of fuses from loose connections. It is made in two sizes, with or without a china cover, for 25 and 50 amperes, the former size being but one-fourth inch larger than an ordinary ceiling rosette.



Figs. 1 and 2.—Pass and Seymour Branch Block.

THE AMERICAN GIANT MICA INSULATING JOINT.

The accompanying illustrations show a new insulating joint recently introduced by the Novelty Electric Company of 50 to 54 North Fourth street, Philadelphia.

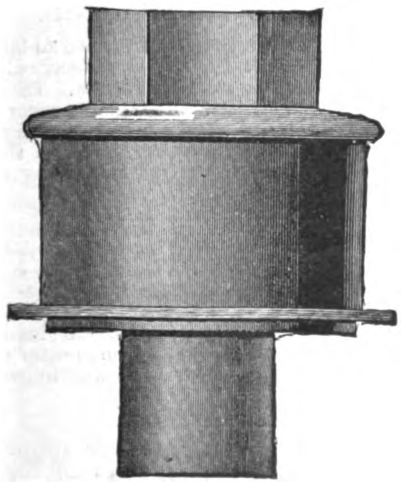


Fig. 1.—American Giant Mica Insulating Joint.

By reference to the sectional illustration, Fig. 2, it will be seen that E E is the main body, D D the upper screw cap, and A A the lower screw cap between which and the body is a heavy mica insulation. B B is a heavy fibre washer, itself a good insulator, upon which rests an iron washer C C into which is firmly screwed the lower cap and stem.

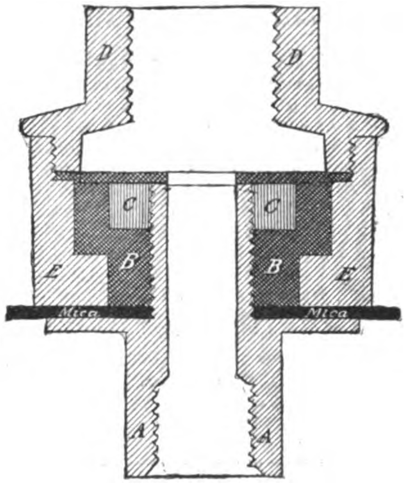

Fig. 2.—American Giant Mica Insulating Joint.

As a further preventive against a possible leakage of gas, the whole body of the joint is filled with cement, poured in hot, covering the head of the iron washer, and filling completely every air space between the washer, B B and body, E E, tightly compressing the mica insulation between the metal parts A A and E E, and forming a perfect gas joint.

An important feature of this joint is the precaution against accident should any defect occur in the insulation. In such a case, if an arc is formed that will burn out the insulation, the heating of the metal softens the cement, which fills in the aperture and effectually closes the leak. This insulating joint has, after repeated tests, been fully endorsed by Mr. William McDevitt, inspector for the Philadelphia Board of Insurance Underwriters.

GROWTH OF THE BALL ENGINE CO.

Less than a year ago, owing to the great expansion of their business, the Ball Engine Co., Erie, Pa., were forced to erect a large and complete machine shop which was filled with the latest and most modern improved tools. No idea was entertained at the time that any further increase would be necessary for several years to come, but the demand for the latest improved Ball engines built by this company has been so great, especially for electric railway work, that already the makers of the engine have been again compelled to make a further extension of the same building. This extension which is now under way will be built on the gallery plan the same as the rest of the building. It will contain, among other valuable features, very complete testing blocks and apparatus, and will be capable of testing engines of the largest capacity. Every engine that leaves the works of the Ball Engine Co. is thoroughly tested and guaranteed to give satisfaction under the most unfavorable circumstances.

Julius Andrae, of Milwaukee, has made arrangements to represent the Central Electric Company in that city.

SALES OF BALL ENGINES.

MR. FRANK R. CHINNOCK, the New York agent of the Ball Engine Co., 15 Cortlandt street, has made the following sales during the past six weeks of the well-known Ball engine, of Erie, Pa.

Prohibition Park Railway Co., Port Richmond, one 150 h. p engine; F. O. Mathiessen, chairman Mfg. Com. Amer. Sugar Refining Co., two 100 h. p. engines for Baltimore; Baltimore Traction Co., Baltimore, Md., two 130 h. p. heavy duty engines; F. H. Leggett & Co., New York City, one 50 h. p. engine; Metropolitan Telephone & Telegraph Co., New York City, one 50 h. p. engine; Brokaw Bros., New York City, two 150 h. p. and one 80 h. p. engine; H. Ward Leonard & Co., New York City, one 150 h. p. engine; Curtis & Dean, New York City, one 50 h. p. engine; Royal Light, Heat and Power Co., Front Royal, one complete steam plant, 100 h. p. engine and 125 h. p. boiler; Hot Springs Electric Co., Hot Springs, Va., one complete steam plant, 100 h. p. engine, and two 80 h. p. boilers; Wm. Kynoch, Guantanamo, Cuba, two 80 h. p. engines; C. S. Furst, Newark Ave., Jersey City, one 50 h. p. engine, one 80 h. p boiler; Navy Yard, Brooklyn, N. Y., two 80 h. p. engines. Mr. Chinnock has also just closed a contract with the Buffalo Board of Trade, Buffalo, N. Y., for one 60 h. p. engine.

NEW YORK NOTES.

THE JOHN A. ROEBLING'S SONS COMPANY have just laid for the United States Port a gutta-percha cable from the Battery to Ellis Island in New York Harbor, the total length of the cable being 9,310 feet. It is composed of four conductors each of three No. 16 B. W. G. copper wires insulated with one-quarter inch gutta-percha. Owing to the constant danger of being fouled by vessels' anchors the cable was armored with eighteen No. 4 galvanized steel wires of very high tensile strength. This gives a strength sufficient to hold any ordinary vessel without damage to the cable. The ten conductor gutta-percha cable laid last year by this company across San Francisco Bay is giving perfect satisfaction. This cable is also very heavily armored with high strength steel wire.

H. DURANT CHEEVER, president and manager of the Okonite Co., Limited, has gone to Europe on a well-earned vacation and generally in the business interests of the company. Mr. Cheever will inspect the European Okonite factories, and besides make a circuit of the continental cities.

PUTNAM, GAY & CO., of Rochester, N. Y., are fitting up the N. Y. State Western House of Refuge for Women at Albion for electric lighting throughout. There are six large separate buildings, and all work is to be done in the tubes of the Interior Conduit Company.

H. WARD LEONARD & CO., of the Electrical Exchange Building, Liberty Street, have closed a contract with Heilner & Strauss, Newark, N. J., owners of the Continental Corset Co., for placing a lighting plant in their new factory.

THE SECURITY INSULATOR is rapidly meeting with the approval of the trade in general, and the Electric Appliance Company of Chicago, who are the general Western agents for this specialty report a very brisk sale.

WESTERN NOTES.

THE ELECTRICAL SUPPLY CO.—The Crocker-Wheeler Electric Company, through their general sales agent, Mr. George W. La Rue, have recently consummated an important arrangement with the Electrical Supply Company, Chicago. By this arrangement the latter firm become sole agents for the Crocker-Wheeler goods in Chicago, and distributing agents for such parts of the Western territory as are covered by their traveling salesmen. Mr. H. C. Hutchison, formerly of the Chicago office of the Edison General Electric Company, is to have charge of the motor department for the Electrical Supply Company, and will be assisted by several well-known motor salesmen and electrical engineers. The popularity of the Crocker-Wheeler goods, and the well-known reputation of the Electrical Supply Company as "pushers" should result in the placing of a large number of these motors and generators on the Western market.

THE CENTRAL ELECTRIC COMPANY are meeting with success with the Acme lead cable manufactured by the Okonite Company. This cable is substantially made, and for underground service, there is none better. It has been on the market now about a year, and no complaints are heard, but rather praises in its favor.

THE ELECTRIC APPLIANCE COMPANY report large success of late with Paranite wire having received very large orders from St. Louis, Milwaukee and St. Paul within the past few weeks in addition to their regular business on Paranite, which has been exceedingly large.

"CUTTER'S RHEOSTATS" are among the coming Western specialties as a nice line of them is now being developed. They will all have the resistance wire buried in enamel, and promise to be safer and much more compact than the resistance boxes now in general use.

CAPTAIN JOHN MCKINLOCK, treasurer of the Western Electrical Supply Company, the Omaha branch of the Central Electric Company, is in the city for a few days.

MR. GEORGE CUTTER is putting out a new version of his magnetic cut-out for protecting stationary motors, and already has several dozen in service.

NEW ENGLAND NOTES.

INSPECTOR OF WIRES B. S. FLANDERS, has, with his usual progressiveness, advanced and recommended the idea of using dynamos for furnishing the current necessary for the operation of the fire alarm system of Boston, in place of the battery, which, in common with other cities, is the present method of supply. The advantages in the use of dynamos in place of batteries are many. One advantage which will be obvious to all who have had experience in such matters, is the small amount of room and little attention which the dynamos will require in comparison with what is necessary for batteries. Inspector Flanders has at the present time a small motor and dynamo set up in his office, which has for several weeks been furnishing current for some of the fire-alarm circuits with perfect success. If the use of dynamos for the fire-alarm system of Boston be adopted, it will be the first installation of the kind in any city for this purpose. It is the intention of Inspector Flanders that in the new fire-alarm station which is to be in the fire department quarters now in process of construction on Bristol street, everything shall be of the latest and most approved pattern, and that Boston shall have a fire-alarm system second to none in the country.

THE SPECIFICATIONS for a 600-light plant for the City Institution on Long Island, Boston Harbor, have just been completed by the Massachusetts Electrical Engineering Company, and bids will be requested from the different electric companies, within the next few days. Such a large number of bids have been received for the 6,000-light plant for the Massachusetts State House, the plans and specifications of which were prepared by the Massachusetts Electrical Engineering Company that it will take considerably more time than was expected to make a decision. The matter is however, being considered by the commission and the contract award will probably be made this week.

THE MASSACHUSETTS ELECTRICAL ENGINEERING COMPANY, of Boston, are at present making the plans and specifications for a 200-light incandescent plant in the mills of the George H. Wheelwright Paper Company, of Hardwick, Mass. They are also making plans and specifications for a 1,200-light plant for the Ipswich Mills, Ipswich, Mass., the specifications for which will be ready in a short time for the bids of the electric companies.

PHILADELPHIA NOTES.

THE AMERICAN GIANT MICA INSULATION of the Novelty Electric Co., 50, 52 and 54 North Fourth street, Philadelphia, is deservedly attracting considerable attention in electrical circles, and their new insulating joint, illustrated in the reading pages of the ENGINEER, is meeting a yearnful necessity. Mr. W. McDevitt, the exacting insurance inspector of Philadelphia, endorses it fully as to strength and its prevention of electric or gas leakage. It is not only good but cheap, and is extremely durable.

THE BLISS ENGINEERING CO. has been formed to take over the business of Congdon, Bliss & Daniels, the electrical engineers, who have their headquarters in Washington. The deal was carried through by Mr. L. D. Bliss, who will be general manager of the new concern, with Mr. W. B. Lewis as secretary and treasurer. With increased facilities for doing business, the company will push for all the electrical work in the territory to which it devotes its attention.

MR. T. W. NESS, of Montreal, has issued a card announcing his removal to larger premises, No. 749 Craig street, owing to his old quarters having become too small for his increased business. In the new place he will have ample room and the best facilities for carrying on his electrical supply business. Mr. Ness is making a specialty of the manufacture of Bell telephones for export, and any one interested in this business would do well to communicate with him.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

ELECTRIC SEARCH LIGHTS.—II.

BY

E. R. Knowles. C. E.

(*Concluded.*)

REFERRING again for a moment to the illustration of the tips of the carbon pencils, Fig. 2, it will be seen that one of them, the lower, or negative, as it is burnt away, is formed into a point or cone, and that the upper or positive carbon is consumed to the form of a cone with its point cut away, and that this point or tip is hollowed out into a concave form called the crater.

The larger portion, about $\frac{9}{10}$ of all the light generated by the luminous arc, is given out by this crater, which acts somewhat as the concave reflector which is frequently placed behind an oil lamp, and reflects the light there generated in an outward and downward direction. If an electric lamp with its carbons placed vertically one over the other as shown in the illustration, Fig. 6, were placed at the focus of a reflecting mirror, only a small proportion of its luminous rays would reach the mirror and be reflected therefrom. In order to overcome this difficulty, it is the practice to place the tip of the upper carbon a short distance behind the tip of the lower carbon as shown in Fig. 5, and to incline the axis of the carbons at an angle away from the vertical face of the reflecting mirror. By this arrangement the carbons will burn away, as shown in the illustration, Fig. 5, and the crater formed at the point of the upper carbon will be on one side and face almost directly towards the reflecting mirror, and in this way practically all the luminous rays therein generated will strike the surface of the mirror and be reflected therefrom.

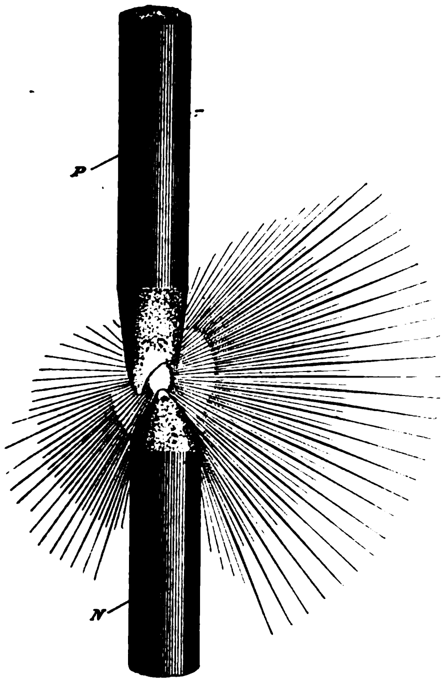

FIG. 5.

The rays of light emanating from a luminous source are not sent out parallel with one another, but are radiated in all directions from a common centre, and in like manner the rays of light emanating from the luminous crater of the electric arc are divergent and form a cone of light whose apex is the centre of the luminous crater, and whose angle of divergence is dependent on the form and size of the luminous crater. Now in order to collect all these divergent rays of light and render them parallel so as to concentrate the light and give it greater penetrating power, advantage is taken of the properties of reflecting mirrors of certain peculiar curved forms, which have the property of receiving upon their surfaces the divergent rays of light from a luminous source, and of concentrating and reflecting them parallel one with the other. A type of such a reflector or mirror is shown in the illustration, Fig. 7, page 98.

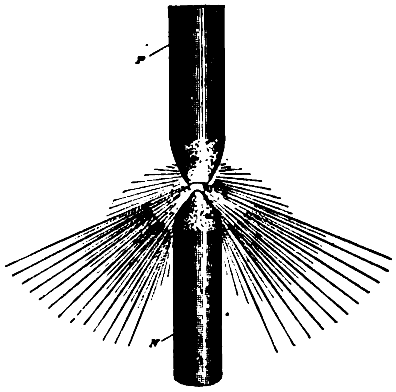

FIG. 6.

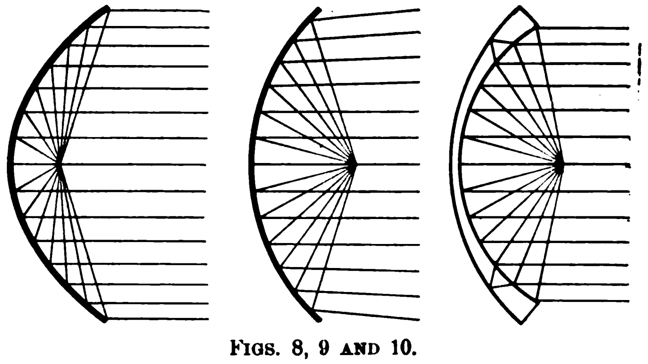
There are two general types of these mirrors, those whose curvature is parabolic, Fig. 8, and those whose curvature is spherical, Fig. 9. They are made either of metal or glass. At first they were made parabolic in form, this being a curve which is theoretically the best for the purposes of reflecting in a parallel beam divergent rays of light received upon its surface from a luminous source situated at its focus. But it is a difficult curve to make correctly in metal and still more difficult to make in glass. Metal mirrors made in this form give unsatisfactory results, the metal absorbing about 50 per cent. of the light, so that the



FIGS. 8, 9 AND 10.

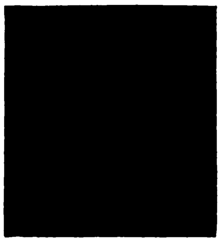


FIG. 7.

reflected beam of light is quite weak and only useful over short ranges of say, a few hundred yards; as a result their use for long-distance projection has been very generally abandoned, their principal use being for locomotive headlights and small reflectors; and mirrors made of glass have taken their place. These were first made of glass silvered on the back, concave in form, of spherical curvature and of uniform thickness throughout. These gave better results, and were less difficult and costly to construct, but spherical aberration limited the amount of surface of the mirror which could be used to advantage, so that a great deal of light was wasted.

By spherical aberration is meant that property of lenses or reflecting mirrors whereby rays of light passing through or reflected by their margins, are more powerfully refracted, that is, brought to a focus nearer the surface of the lens or mirror than those rays which pass through or are reflected nearer to or at the centre of the lens or mirror. When a parallel beam of light strikes upon the surface of a spherical mirror, such as is shown in the illustration, the rays of light composing it are reflected and converged to points upon the axis of the mirror, called focal points or focii.

As the form of curvature of the mirror is part of the surface of a sphere, or one which is generated by the revolution of a circle round its diameter, all the rays of light received upon its surface are not converged to exactly the same point, the rays of light farthest away from the axis of the mirror being refracted or brought to a focus at a point on the axis of the mirror nearer the surface of the mirror than those which are nearer to, or at the centre of, the mirror; so that the rays of light when refracted by the mirror are not all focussed at exactly the same point but lie inside a certain small space upon the axis of the mirror called the principal focus; and conversely, the rays of light emanating from a luminous source, situated at the principal focus of the mirror, are not reflected from the surface of the mirror, parallel one with another, those at the centre of the mirror being sensibly parallel while those at the outer edge of the mirror are more or less divergent from those at the centre.

The problem, then, was to make a glass mirror which should be free from spherical aberration and yet easily constructed and of comparatively low cost. This problem was solved in 1876 by Colonel Mangin of the English Engineers. A cross-section of one of his mirrors is shown in the illustration, Fig. 10, and the mirror Fig. 7, already referred to, is an example of this type.

By combining two spherical surfaces of different radii or curvature, one concave and the other convex, the thickness of the glass between these two surfaces being dependent upon the character or quality of the glass used, and quite small at the centre of the mirror and gradually increasing until it is quite large at the outer edge, Col. Mangin succeeded in producing a lens-mirror, called an aplanatic reflector, which was practically free from spherical aberration. This type of reflector is the one most generally, I may say, almost universally, used in electric projectors.

They are made from carefully selected glass, known as optical glass, especially manufactured for making lenses, mirrors and all optical apparatus. No glass is of such importance in the arts as that of which lenses, mirrors and prisms for optical instruments are made. Both flint and crown glass are applied to these uses, but each of them has its defects. The flint glass, from the great difference in the densities of its ingredients, is with much difficulty obtained of a homogeneous structure, an essential requisite in all glass used for optical purposes. The crown glass is difficult to obtain of uniform composition and texture, due to the high temperature required for its fusion and the resulting tendency to devitrify in cooling; or if this is obviated by an increased proportion of alkali in its composition, this excess causes attraction of moisture from the air and gives a damp surface to the lens. The best flint glass is subject to various defects, chief among which is a wavy appearance called striæ, resulting from a want of uniform density in the glass and a tendency to refract and disperse in different directions the rays of light passing through it; such defects are of great importance when the glass is used for optical purposes.

To stimulate research and the discovery of some means of obviating these difficulties, the French and English scientific bodies offered prizes for a process for making a glass which should be free from these defects. The problem was finally solved by Guinard, a native of Switzerland. By a method which he kept secret, and which was finally communicated to Messrs. Chance & Co. in England, very large plates of flint and crown glass, of pure color, and of such homogeneous structure that light is transmitted through them without polarization, were and are now successfully made. These plates were very costly; a flint glass disc was exhibited at the London exposition in 1888 which was 29 inches in diameter and weighed two hundred weight, and was afterwards sold to the French government for £1,000. Since that time, however, the processes of manufacturing such plates of glass have been greatly improved, and the cost correspondingly reduced, so that now it is possible to obtain at a comparatively low cost optical glass plates of almost any desired size and quality.

The glass used in making the mirrors for the electric projector is very pure and white, of uniform density, and free from all streaks, spots and bubbles. It comes in flat slabs or plates of the required dimensions for making a single mirror. The curves of the back and front of the mirror and the thickness of the mirror are mathematically calculated so as to conform with great exactness to the optical qualities of the glass plate from which it is to be made, each plate being carefully tested for this purpose. A curved form of metal is then made approximating to the desired shape of the mirror, and the glass plate, by careful heating, is made to bend into and conform to this metal form, thus roughly shaping the glass to the desired form of the finished mirror. The outer and inner surfaces of the glass plate so bent are then ground by appropriate mechanism to the required curves and then polished, after which the back or convex surface of the mirror is silvered so as to make it a reflecting surface and is then covered with a coating of protecting varnish to prevent damage to the silvered surface, by scratching or abrasion. A small spot in the centre of the mirror is left unsilvered to serve as a peep sight, by means of which the condition of the electric arc may be seen and examined when the electric lamp is in operation.

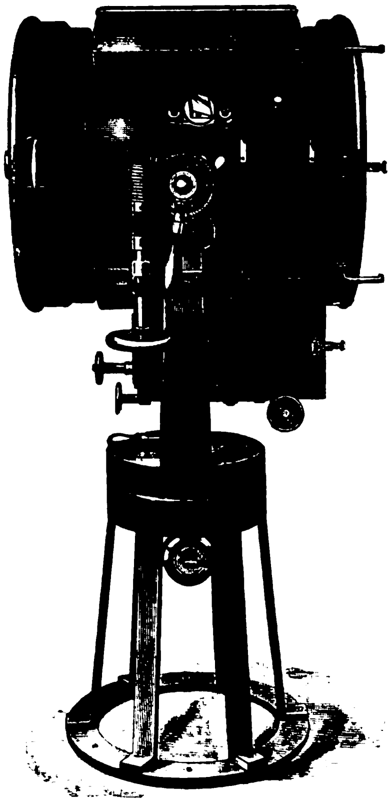

FIG. 11.

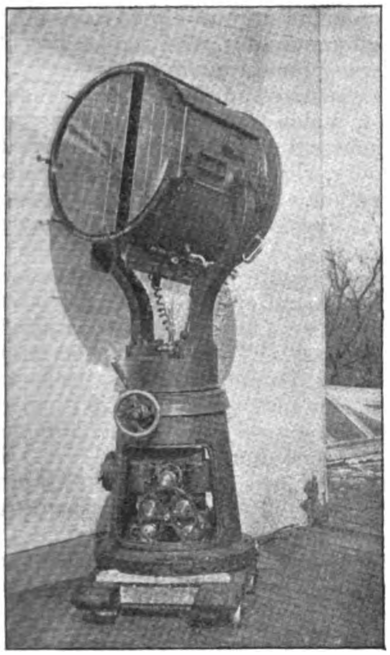

FIG. 13.

The mirror illustrated is 24 inches in diameter, and when an electric arc lamp of 25,000 c. p. is placed at its focal point it will reflect a sensibly parallel beam of light which can be seen for many miles, and is powerful enough to illuminate and render visible a light object such as the white sail of a vessel at a distance of three miles.

Strictly speaking, the mirror does not throw an absolutely parallel beam of light owing to the fact that the source of light is not a point but has a greater or less area which is luminous; nor is it desirable that it should. If the diameter of the beam of light, which, in a 24-inch projector is 24 inches at the orifice of the drum, was maintained constant, it would only illuminate an area 24 inches in diameter at the farthest distance at which it was used. This would appear to the eye as a mere spot of light, and would be of very little value. As a matter of fact, the beam of light is slightly divergent, about two degrees of arc, so that at a distance of, say, 5,000 yards, the beam of light will have spread out and cover an area of about 500 feet in diameter, thus illuminating quite a large area and one, which to the eye, will appear of a size which can easily be perceived and examined.

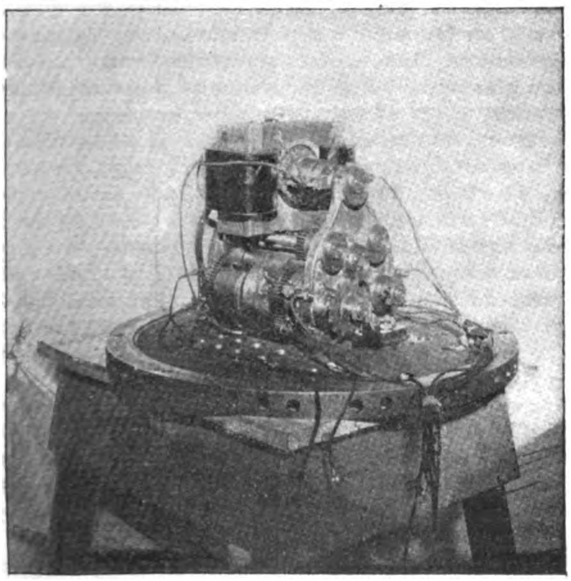

FIG. 14.

Coming now to the mechanism which contains these two essential features of an electric projector, namely, the luminous source of light and the reflecting and projecting device, we have a piece of apparatus, which in its complete form, is shown in the illustration, Fig. 11, and which in detail is represented in Fig. 1. It consists generally of a fixed pedestal, E, upon which is supported a revolvable top, G, to which are attached two vertical arms, F F, forming together what is called a fork; upon the upper ends of these arms is supported in bearings the drum or cylinder D, capable of swinging up and down in a vertical direction. The mirror or reflector, B, is fixed in one end of this drum, and the electric arc light, A, slides in upon suitable guides through an opening in its bottom. At the end opposite the mirror the drum is provided with a door and diverging lenses, L. These diverging lenses and their use will be described further on. I is a lever for locking the horizontally revolving part G in any desired position, and H is a hand-wheel for rotating the part G, and with it the drum D in a horizontal plane. A hand-wheel (not shown) also controls the vertical movements of the drum D. S is a switch for controlling the admission of the electric current to the lamp A.

The tips of the carbons in the lamp and consequently the electric arc are located at the focus of the lens E and the luminous rays from the lamp A are caught by the mirror B and reflected in parallel beam out through the door and lenses L shown in the illustration.

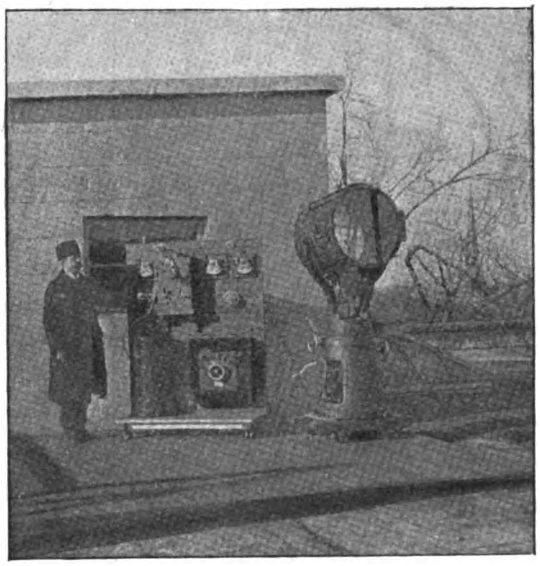

FIG. 15.

The lenses L are for the purpose of rendering the parallel beam of light as it emerges from the drum D more or less divergent, as it is sometimes desirable to spread out the beam of light so as to cover a larger area than it would if the beam of light remained parallel; for instance, it would be used in this way when the projector is in use on a man-of-war and its beams are thrown upon the water close by the vessel in an effort to discover the approach of a torpedo boat. This is accomplished by having two sets of lenses placed one in front of the other, as shown in the illustration, Fig. 12, the one fixed and the other movable. These lenses are strips of glass of alternate plano-convex and plano-concave sections, as shown. When both sets of lenses are directly in front of one another so that a plano-convex strip is exactly opposite a plano-concave strip they act just the same as a flat plate of glass would do, and the beam of light passes through them remains parallel, but if the outer or movable set be displaced sidewise, so that a plano-convex strip is opposite a similar strip, and a plano-concave strip is opposite a similar strip, the lenses act together as a double-concave and double-convex lens would, and the beam of light is dispersed at a greater or less angle according to the amount of motion of the lenses, the maximum angle of dispersion taking place when the movable lenses have been moved a distance equal to their width. By rotating the horizontal part G the beam of light may be directed to any point in a horizontal plane, and by rotating the drum D up or down in its bearings, the beam of light may be directed to any point in a vertical plane, and by combining both motions the beam of light may be directed to any desired point and shifted from one point to another. This general description will give a fair idea of the essential features of the electric projector in its simpler form.

The lamps all operate at about 50-volts pressure, and with currents varying from 25 amperes to 90 amperes, according to size, the list being 25 amperes, 45 amperes, 75 amperes and 90 amperes for the four sizes.

In its most improved form the electric projector is arranged so that all its movements can be controlled and manipulated from a distance. Not only is the lamp automatic in its action, but an electric motor is placed in the base of the projector which trains the projector both horizontally and vertically. From the motor in the pedestal a multiple conductor cable runs to the controlling board, which carries the necessary switches for operating the projector and its lamp. The movement of training horizontally can either be continuous with a divergent beam when the surface of the land or water near by is to be illuminated and the approach of a torpedo boat or an enemy is to be detected, or by small angles at a time with a concentrated beam for long range illumination.

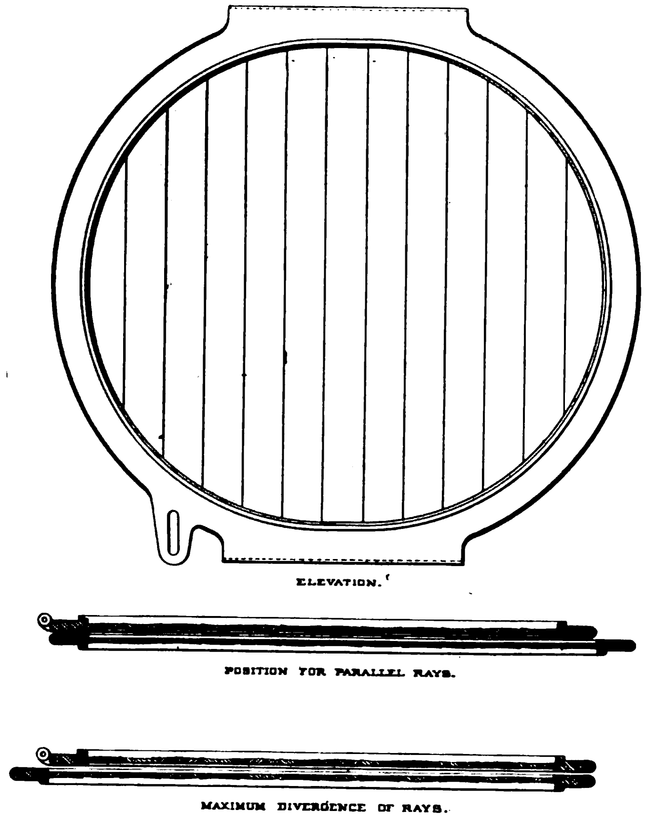

FIG. 12.

Under all of these circumstances the complete maneuvering of the projector together with the starting and stopping of the lamp is regulated by the switches on the controlling or switchboard. In this way, one or more projectors can be electrically controlled, one man only being required who may be stationed in the conning tower of the vessel, or in any other protected position, thus insuring the continuous action of the projectors.

The illustration, Fig. 13, shows a view of the electric projector as it is actually built, the view shown being that of the 24-inch projector made by the Schuyler Electric Company. In this projector everything is made as automatic in its action as possible, and it can be operated as easily by a person distant a thousand feet from it, as by one close at its side. The lamp is similar to the one already described and is automatic in its action, starting itself and feeding its carbons together and running for six hours continuously.

In the base or pedestal is situated an electric motor shown in the illustration, Fig. 14, which by means of gearing and suitable electric connections and switches, can be made to rotate the drum horizontally, right or left, and vertically, up or down, singly or together, at any desired rate of speed, and can be made to stop at any desired point in these movements.

All of these movements are controlled by a combination of switches, shown in the illustration, Fig. 15, which are connected with the projector by a flexible cable containing the necessary conducting wires. These control switches may be located at any desired distance from the projector, so that the operator will be entirely out of the range of the light of the projector and entirely protected from any chance shot directed at the projector in time of war. In actual practice in the navy, the projector is mounted on the deck of the vessel, or on the bridge, or even on the crosstrees on the mast, and the control switch is located in the pilot house or conning tower from which the movements of the ship are directed.

LONG-DISTANCE ELECTRIC POWER TRANSMISSION IN CALIFORNIA.

THE most important electric power transmission plant yet undertaken in this country is one now in course of construction for the San Antonio Electric Light and Power Co. in Southern California. The power plant is located in the San Antonio Canyon where there is a minimum flow of 1,300 cubic feet of water per minute, affording a head of about 400 feet.

The water is brought to the power station through 1,900 feet of 30-inch, and 600 feet of 24-inch, double-riveted sheet iron pipe, which involves a loss of head by friction of 12 feet, leaving 390 feet effective head or running pressure. The laying of the pipe line necessitated a rock tunnel 1,300 feet in length, as well as several heavy open cuts. The power station is provided with four double-nozzle Pelton wheels, 34 inches in diameter, coupled direct to the armature shafts of as many Westinghouse alternating current generators of 200 h. p. each. The wheels will run under above conditions 600 revolutions per minute, giving the same speed to the generators. Two exciters are provided which are also run by Pelton wheels coupled to the shafts in the same manner, of 20 h. p. each.

The current thus generated will be carried on two No. 7 bare copper wires seven miles down the canyon to a point where they diverge, one running to Pomona 15 miles, and the other to San Bernardino 28 miles, covering by the return circuit in the latter case a distance of 56 miles. By means of transformers the potentials will be raised at the generating station to 10,000 volts and the current carried at this pressure to sub-stations located just outside the cities named, where by means of step-down transformers it will be reduced to about 1,000 volts and then distributed for both light and power purposes.

The motors used will be of the Westinghouse synchronous type. The sub-stations will be provided with regulators, by which means the attendant can regulate the voltage of the distributing circuit independently of the generating plant. The necessity of pressure wires upon the voltage system will be obviated by the use of a compensator.

This installation is attracting much attention, as it is by far the highest tension and longest distributing system ever attempted in this country or abroad on so extensive a scale for commercial purposes. There is, however, no misgiving as to results, though it be a long step in advance of anything heretofore accomplished in this direction. The reputation of the firms supplying this equipment, the Westinghouse Electric Co. and the Pelton Water Wheel Co., is a guarantee of the success of any enterprise they may undertake.

MODERN AMERICAN TELEGRAPHIC APPARATUS.—V.

BY

F. W. Jones

There are two distinct methods of applying dynamo currents to the quadruplex system; one is the method adopted by the Postal Telegraph-Cable Company described on page 618 of The Electrical Engineer of June 22, 1892; the other method is the standard of the Western Union Telegraph Company shown substantially in Fig. 5 and exhaustively described in Maver & Davis' book on the quadruplex.

Referring to Fig. 5, P C is the No. 1 or pole-changing transmitter, S T, the No. 2 or heavy current transmitter. Starting at point x, the resistance of the line wire and artificial circuit including the relays is 4,000 ohms, respectively.

Calling the line wire	A =	4,000 ohms,
Artificial circuit	B =	4,000 "
Shunt or leak	C =	900 "
Resistance added to dynamo	D =	600 "
Increase and decrease	R =	1,200 "
Joint resistance of	A and B =	2,000 "

Then the following currents are sent to line:

With No 2 key o	Amperes.	Energy expended. Watts.
Total current....................	.132	42.24
Current in A and B....................	.041	3.36

" " D....................	.12	14.4

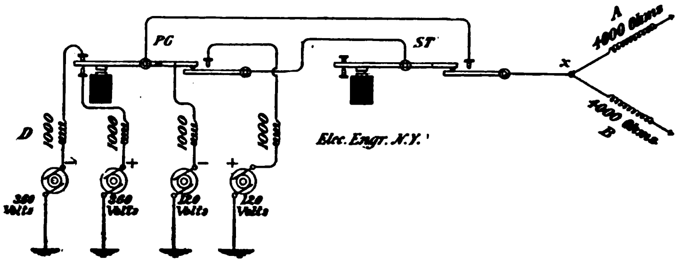

FIG. 6.

Allowing that in each method the No. 2 transmitter maintains a closed contact half of the time that the circuits connected thereto are being operated, the average expenditure of energy per circuit for the Western Union method is at the rate of 40.8 watts, and for the Postal method 24 watts, the former will consume 1,836 watts to supply 45 circuits, whereas the latter supplies the same number at an expenditure of 1,080 watts or at a saving of over one electrical horse power.

On page 455 of The Electrical Engineer of May 4, 1892, Mr. William Finn describes an improvement in the Western Union No. 1 transmitter (P. C. Fig. 5) by which sparking at its points is suppressed. My observation has demonstrated that detrimental sparking occurs between the dynamo contact point and the line at the moment the No. 2 transmitter sends an *agreeing* current to the one being sent by the No. 2 transmitter of the distant station. At this moment over 640 volts are urging a large quantity through the circuit and this causes an arc at the points of No. 1 transmitter. Particularly is this true where the resistance of the line wire and the internal resistance of the leading wires to the generators is low.

In the Postal system where 350 volts are employed on No. 2 transmitter, it will be seen (Fig. 6) that 1,000 ohms of inductanceless resistance of No. 24 or 20 mils diameter german silver well-covered wire, wound upon a tin tube 2 inches in diameter, Fig. 7, is included in each lead between the dynamo and the transmitters. The sparking caused by the operation of No. 1 transmitter when the line wire is detached is not observable, and much less than 1,000 ohms would suffice to afford immunity from sparking under these conditions, but it requires about 3 ohms per volt to restrict the combined incoming and outgoing currents to a harmless degree.

In four years use of these coils, not one has broken down nor required any attention, and they are even better now than when new. The Postal Co. made an extensive trial of incandescent lamps as resistances in connection with the application of dynamo currents, and found their filaments of such a variable nature and the lamps so fragile that their use was discontinued in favor of the tin tube inductanceless coils. It was found that the resistance the lamps interposed in a quadruplex circuit was very different for dots from what it was for dashes, and that much more resistance was needed in the lamp (cold) than in a coil of wire, inasmuch as the lamp would get hot when the No. 2 transmitters of the two stations were closed and the currents were of opposite polarity ; so that any attempt to use the No. 1 transmitter resulted in sparking at its points. The resistance of a hot incandescent lamp is about one-half its cold resistance, and I found that a $3\frac{1}{10}$ watt Edison 16 c. p. lamp, measured :

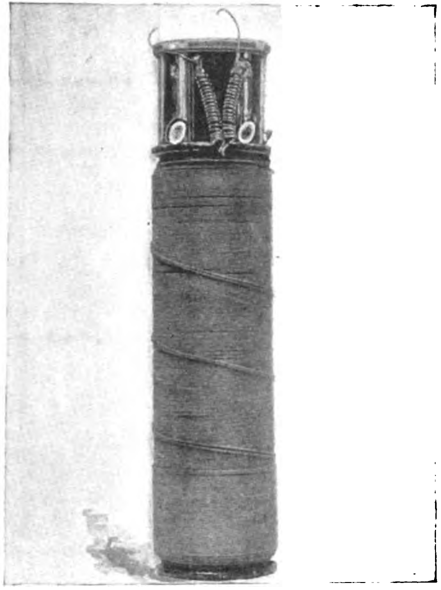

FIG. 7.

330	ohms,	with	.043	ampere.
297	"	"	.100	"
258	"	"	.200	"
239	"	"	.300	"
223	"	"	.400	"
205	"	"	.500	"
187	"	"	.600	"
175	"	"	.700	"
167	"	"	.800	"
159	"	"	.900	"

The value of lamps in indicating by their glow the advent of trouble upon working circuits is probably much larger in theory than in practice, as the troubles that cause a glow are but a small percentage of those that do not, and chief operators would not habitually keep watch for such desultory indications. These tin tube resistance coils are very compact, will stand much hard usage, and their coefficient of variation due to temperature is 0.00044, or nine times less than for copper. They are made up in different sizes to suit the various potentials of the dynamos and applied in the circuits so that at no time shall there be less than $2\frac{1}{10}$ ohms per volt. This prevents all undue sparking on the switches and renders the currents perfectly safe both inside and out.

NEW ELECTRIC ROAD TO CONEY ISLAND.

A NEW electric railroad, to be known as the New York, Mapleton and Van Pelt Manor Railway, is to be operated between Brooklyn and Coney Island, and the company has filed its articles of incorporation at Albany. The route is to be from the Thirty-ninth street ferry, up Thirty-eighth street to the old New Utrecht and Flatbush road to Twentieth avenue, and thence to Bensonhurst and Coney Island. Among the incorporators are Col. Andrew D. Baird, Joseph P. Puels, William P. Rae, Cornelius Fergueson, Jr., and Duncan D. Chaplin.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY—X.[1]

BY

A. E. Kennelly

STRESS DISTRIBUTIONS—(*Continued.*)

AT every point of a magnetic circuit, there exists as we have seen, a tension of $\frac{B^2}{8\pi}$ dynes per square centimetre, normal to the equipotential surfaces, and also a lateral pressure of $\frac{B^2}{8\pi}$ dynes per square centimetre acting uniformly in all directions over the tangent plane, the plane with which the equipotential surface at the point locally coincides. Also at every point not occupied by a source of M. M. F., that is, at every point not within the substance of a magnet or active conductor, this distribution of stress is in statical equilibrium, and it would seem that this distribution (or some numerical multiple of the same) is the only one capable of maintaining equilibrium consistent with the condition of pull along the observed paths of flux. Only within the substance of magnetomotive sources—active conductors, and temporary or permanent magnets—is this equilibrium destroyed and resultant moving force brought to bear upon the space and substance occupied by the magnetomotive source.

If the medium composing the circuit, (wood, copper, air, etc.) were divided into any number of volume elements—individual cells of any shape, each element treated as a rigid body would be in equilibrium under the magnetic stress, and would not experience any resultant force urging it against its neighbors. As an example, let us consider the simple and familiar case of a long straight wire carrying a current C. Fig. 21 represents a section of this wire and the space surrounding it in a plane perpendicular to its length. Suppose another and similar section made through the wire one centimetre further on, so that attention may be confined to the lamina of space one centimetre thick between these planes, surrounding and including the wire. Let A B C D be a small element of this space between the radii O C and O D (including an angle $d\theta$) and the circles A E E and C D G whose radii are numerically r and $r + dr$, respectively. The faces A C and B D are equipo-

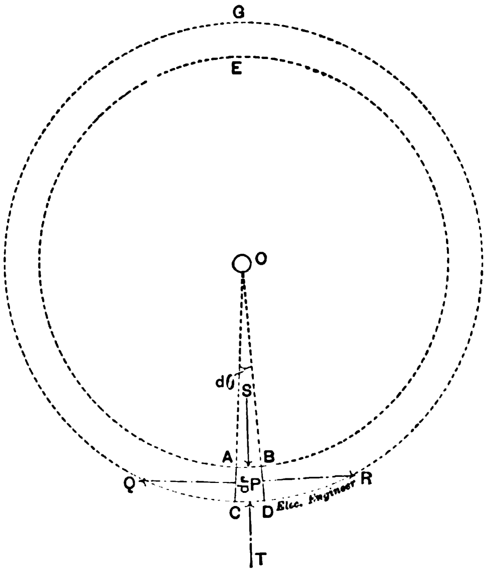

FIG. 21.

---

[1] *Copyrighted, 1892, by A. E. Kennelly.*

tential surfaces. Their area is 1 (cm.) × dr, and the intensity by the results of Part II, $B = \frac{2C}{r}$, is perpendicular to them. Considering the element as a rigid body, it will be subjected to pressures on the faces A B and C D, together with tensions across A C and B D. These four stresses may be considered as exerted at the centres of the respective faces and are indicated by the arrows. They may be reckoned as follows :

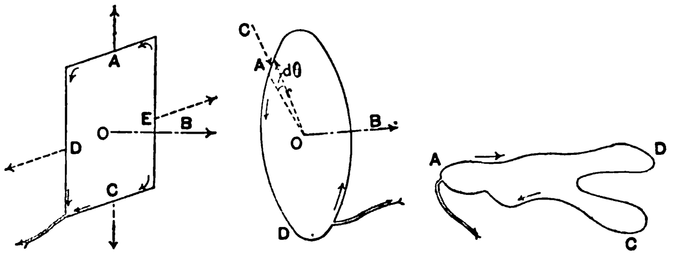
Face.	Force.	Direction.	Theoretical value per sq. cm. dynes.	Local value of B.	Local value of $\frac{B^2}{8\pi}$	Area of face.	Total force acting on face.
A B	Pressure	S P	$\frac{B^2}{8\pi}$	$\frac{2C}{r}$	$\frac{4C^2}{8\pi r^2}$	$r\,d\theta$	$\frac{C^2\,d\theta}{2\pi r}$
C D	"	T P	"	$\frac{2C}{r+dr}$	$\frac{4C^2}{8\pi(r+dr)^2}$	$d\theta(r+dr)$	$\frac{C^2\,d\theta}{2\pi(r+dr)}$
A C	Tension	P Q	"	$\frac{2C}{r+\frac{dr}{2}}$	$\frac{4C^2}{8\pi\left(r+\frac{dr}{2}\right)^2}$	dr	$\frac{C^2\,dr}{2\pi\left(r+\frac{dr}{2}\right)^2}$
B D	"	R	"	$\frac{2C}{r+\frac{dr}{2}}$	$\frac{4C^2}{8\pi\left(r+\frac{dr}{2}\right)^2}$	dr	$\frac{C^2}{2\pi\left(r+\frac{dr}{2}\right)^2}$

The table shows that there will be a difference of pressure on the inner and outer faces of $\frac{C^2\,d\theta\,dr}{2\pi r(r+dr)}$, or ultimately $\frac{C^2\,d\theta\,dr}{2\pi r^2}$ dynes in the direction S P, because the flux is stronger on the inner side, and the stress varying as its square, more than compensates for the difference in area. On the other hand, the tensions are seen to be numerically equal, but they are not exactly opposed, being inclined to each other at an angle $2\pi - d\theta$. The effect of this inclination will be a resultant pull of $\frac{C^2\,d\theta\,dr}{2\pi\left(r+\frac{dr}{2}\right)^2}$ or ultimately $\frac{C^2\,d\theta\,dr}{2\pi r^2}$ dynes inwards in the direction T P, just counterbalancing the resultant side thrust. The element is therefore in stable equilibrium, and since the same could be proved for any similar small cylindrical element outside the wire, it must follow that any larger portion of the space, which could certainly be built up of such adjacent elements, would be in similar equilibrium regarded as a whole.

The proposition arrived at in the foregoing simple case is of general application no matter how complex or irregular the flux distribution may be, and may be stated in the following terms. The resultant side thrust that may be exerted upon any element of the magnetic circuit (not included in the substance of a magnetomotive source) due to the variation of the intensity B in or round it, is balanced by the resultant tension in the opposite direction owing to the local curvature in the flux. In fact uniform flux is straight, while variable intensity always bends so as to keep convex on the weaker side. In other words, the divergence of equipotential surfaces implies not only weakening but also bending in the flux channels, the two effects everywhere maintaining statical equilibrium.

We observe therefore, that when an inactive conducting wire is situated in a prime flux density B, the stress distribution is in equilibrium throughout the field, in the substance of this wire as well as all round it. As soon as a current C is established in this conductor, the flux distribution from the current will have been superposed upon the prime system. The resultant system of stress distribution will again be in equilibrium at all points outside the wire, but there will no longer be equilibrium in the space occupied by the wire.

Regarding the wire as a mere filament without sensible cross-section we have seen that the resultant vector force acting upon it will be $P = V.\ C\,B$, and this force must be applied to the wire to restore equilibrium between its substance and its environment. When the cross-section of the wire cannot be fairly considered negligible, it may be divided into filaments, each carrying its appropriate share of C. The consequence of applying the rule $P = V.\ C\,B$ to each filament in succession, will be that B the prime intensity for any one filament, will be modified by the flux from all the remaining filaments. The vector force on the wire as a whole will still by summation be $P = V.\ C\,B$ as before, where B is the prime intensity for $C = 0$; but there will now be a system of mutual forces between the filaments in addition. These filaments in fact attract each other, and the resultant forces of the mutual system will depend upon the curvature of the wire, as well as upon the dimensions of its cross-section. For a long straight wire of circular section, with a current density of σ units (C. G. S.) per square centimetres, the force on any element of the conductor at radius vector R will be $P = 2\pi R\sigma^2$ dynes per cubic centimetre, agreeing with the force at the surface noticed in Part IX. Practically, the external resultant $V.\ C$B is simple and important, while the internal system of forces through the substance of the wire is more complex, and rarely needed.

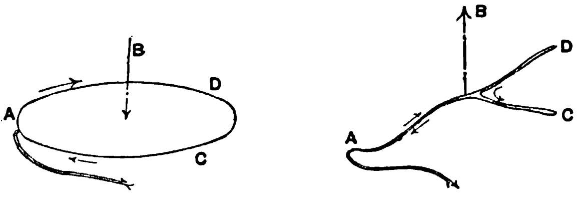


FIGS. 22, 23 AND 24.

It may be advantageous to analyze a few simple systems of electromagnetic force distribution. Fig. 22 represents a wire A D C E bent into a square, the length of one side being, say, S centimetres. The square is supplied by two wires held very close together, with a current C; and its plane is perpendicular to a uniform prime intensity B represented by the arrow O B. Viewed on this side, the current circulates counter-clock-wise. The electromagnetic force acting on each side of the square due to B and C will be $S\ C\ B$ dynes, represented by the arrows at A D C and E, in the same plane.

These will not be the only forces acting on the wire, for should the prime flux B be withdrawn, there would still be a magnetic circuit having its M. M. F. in the turn of current and its flux threading the loop in the same direction as the prime flux O B. Although the distribution of this local flux would not be uniform over the square, the resultant effect will be to establish forces on the sides in the direction of the arrows. The complete system of forces will then be triple. First a compression of the wire towards the axis due to filamentary attractions; second, a set of forces acting outwards and perpendicular to each side, the action varying in intensity from point to point since the flux distribution is not uniform; and third, a force $S\ C\ B$ acting on the establishment of B the external M. M. F., which force s perfectly uniform, namely : $C\ B$ dynes per unit of length along any side. Of these three systems, the first two are evidently not reversible in direction when the current in the square is reversed, because the two factors, local flux and local current reverse together. The third system is however reversed by a change in the direction of current, or external flux B.

In Fig. 23, a circle A D B is substituted for the square of Fig. 22. Here the force on any small arc $r\,d\,\theta$ due to the action of B and C is $r\,d\,\theta\ C\ B$, and according to the direction of current shown it will in this instance be directed towards the centre. Summing all such elements, the total resolved force across any diameter will be $2\,r\ C\ B$ and half this, or $r\ C\ B$ will be the pressure that the wire must at every point longitudinally support. The triple system of forces will again be : A compression of the wire ; a radial thrust of all the parts of the circle outwards due to the application of the rule $V.\ C\ B$ for its own flux local flux, (in this case a symmetrical stress system), and third, a thrust radially outwards, or inwards, bringing a longitudinal stress of $r\ C\ B$ dynes on the wire according to the direction of the external flux B. In this case it will be possible for the second and third systems to oppose and exactly neutralize each other.



FIGS. 25 AND 26.

As a more general case, suppose a loop of perfectly flexible wire A B C, Fig. 24, to lie in a horizontal plane and to be capable of moving only in this plane. This condition eliminates any disturbance due to gravitation. On passing a current in either direction through the loop, the forces set up will expand this, until equilibrium is found in a circular form, and further expansion is resisted by longitudinal tension. This expansive tendency will be further assisted by an external flux vertically downwards, as shown in Fig. 25. If, on the contrary, a prime flux had been established upwards through the loop before the current passed in the direction of the arrows, the loop would have tended to collapse and assume some such form as that in Fig. 26. Total collapse will be resisted by the local magnetic circuit and its outward stress system. The equilibrium would in any event be unstable, and if free to move, the sides of the loop could cross each other until the wire opened out into a circle like that in Fig. 25, but with a cross at A, and with the direction of current opposite to that indicated.

This triple system of forces forms perhaps the simplest analysis in these instances, but it would, of course, be possible to arrive at the same results by determining the resultant system of flux in and outside the loop due to its own M. M. F., and that of the external source, followed by a calculation of stresses on the conductor from point to point by the fundamental laws of tension and side thrust.

MR. R. G. BROWN is leaving per "Gallia" for London and Paris, and expects to be home September 17.

INSULATED ELECTRIC CONDUCTORS[1]—VI.

BY

James Bowstead Williams M.D.

Gutta-Percha.—This substance, when pure, is obtained by evaporating the fresh milky juice of the isonandra gutta, and of over 30 different varieties of trees which grow in Sumatra, Malacca and adjacent islands.[2] Although the general properties of these various guttas are similar, yet, as would naturally be expected, there is a marked difference in their physical and insulating properties, especially when subjected to heat. Thus we find that some guttas will insulate fairly well when subjected to 150° F.; others will insulate at a higher temperature, but if the temperature to which even the best qualities are subjected exceeds about 200° F. their insulating properties are almost if not entirely lost. In this respect gutta-percha differs from india-rubber, for the best qualities of the latter will possess insulating properties when heated considerably above 200° F.

Gutta-percha is sold in the form of blocks, irregular lumps, and in masses resembling chips of wood. When pure, and in thin layers, it resembles, to a great extent, the membrane found on the inside of the shell of a hard-boiled egg, both in color and tenacity. The color of the imported masses, however, varies from light grey to brown. This variation in color is caused by the presence of bits of wood, dirt, foreign juices, etc., which have become intermingled with the milk of the trees during the processes of collecting and preparing the gutta-percha for exportation, and also by portions of the coagulated juice which have become oxidized.

When exposed to the air, pure gutta-percha changes to a brown color, gets full of cracks and is transformed into a brittle, resinous mass. This degeneration is caused by oxidation, and is increased by the presence of light and heat, and especially by alternate dryness and humidity. But if the gutta be kept under water there is practically no change, even after years of immersion. Owing to the changes above mentioned, it is not suitable for insulating aerial conductors, and should only be used for insulating submarine cables—for which purpose it is the best-known insulating material—and conductors which are to be kept continually under water or other liquid which does not attack it.

This substance can be obtained in a pure state by dissolving the best raw gum in benzole, allowing the impurities to settle from the solution, and then evaporating the solvent. When thus purified and free from moisture, its insulation resistance is nearly equal to that of india-rubber. Other hydrocarbons can be used as solvents for it. Paraffine wax is sometimes used as a solvent, but the high temperature necessary to effect a solution is injurious to the paraffine.

It can be incorporated with india-rubber and rubber compounds, both vulcanizable and unvulcanizable. When thus used, it imparts toughness and solidity to the mixtures.

As imported, it often contains adulterations which are introduced, either by accident or design, by the natives who gather and prepare it for shipment. Prominent amongst these adulterants are the coagulated foreign juices before mentioned, which resemble the true gutta in appearance. Some of them ferment easily and are not only of themselves changed to resinous bodies, but impair the durability and insulating properties of the mass. Other impurities are removed by the cleansing processes to which all kinds of gutta-percha are subjected before being used for insulating purposes.

---

[1] *Copyrighted 1892 by James B. Williams, M. D. All rights reserved.*

[2] The word "percha" is derived from "poulo pertja," the native name for the island of Sumatra.

On account of the toughness and inelasticity of this substance, it requires more care and trouble to prepare it for use than rubber. While rubber may be cleansed when in comparatively large masses by the simple process of soaking in a warm alkaline solution and then passing the soaked lumps through a washing machine, the gutta must first be cut into small pieces, then soaked in water, next torn into small shreds and the shredded pieces well washed and dried. The dried pieces are then kneaded in a kneading machine in order to unite the pieces into a homogeneous and compact mass. The gutta, being porous, is almost certain to retain moisture in its pores. If this moisture be not removed before the material is used to form the dielectrics of cables, and the moisture evaporates during the manufacture of the cables, air will take its place; those portions of the gutta in immediate contact with the air oxidize, and the imprisoned air becomes a fruitful source of trouble when the cables are laid in deep water.

Gutta, like rubber, may be combined with "preservative material;" but as preservative material—wood tar, for example—always tends to lower the melting point of combinations of itself with both gutta and rubber, it should be used, if used at all, in very small proportionate quantities, unless the gutta is to constitute the basis of a vulcanized composition, or is to be used in cold climates.

If gutta could be thoroughly protected from air and moisture it could be used to insulate aerial lines. But as its specific resistance is lower than rubber, and its electrostatic capacity and cost greater, there would be no advantage attending its use unless it would be to obtain a firmer and stronger dielectric than one formed of rubber. Besides, every one who has given the matter much attention knows how extremely difficult it is to produce air and moisture proof envelopes—metallic sheaths excepted—for insulated aerial conductors.

Gutta-percha can be used either vulcanized or unvulcanized and in combination with resins, tars and mineral substances, such as oxide of zinc, silica, chalk, etc. Since its first introduction into England it has been made the subject of hundreds of experiments which have been conducted with a view to increasing its utility and durability, and of effecting useful combinations of itself with other insulating materials. To give even an outline of the scope of these experiments would require too much space; but if the reader wishes to acquire a general knowledge of the manufacture, uses and applications of gutta and its compounds —and also of india-rubber—he can do so by consulting the abstracts of British patents on gutta-percha and india-rubber, copies of which should be in every public library.

Gutta-percha can be used to insulate conductors which are inclosed in subterranean pipes or conduits, provided such conduits are kept filled with water by means of reservoirs placed at greater elevations than the conduits, and the temperature of the water is not sufficient to cause softening of the gutta. The insulated conductors thus placed practically become subaqueous cables, and if the proper conditions are maintained there is no reason why such cables should not be as durable as the submarine cables. Furthermore, these cables would not be subjected to the destructive agencies which are continually at work upon the submarine cables.

The best qualities of gutta are known in commerce under the names of gutta merah, gutta taban, and gutta derrian, and these contain the least amount of resinous matters. They are mostly obtained from Java and Macassar. The poorest qualities come from Borneo—some of the best qualities are obtained from Borneo—and contain the largest quantities of the foreign juices and resins.

Mr. W. S. Kelly will hereafter be connected with the General Electric Co. and will have his headquarters in Boston. He will be engaged upon power transmission, especially in connection with mill work and isolated plants.

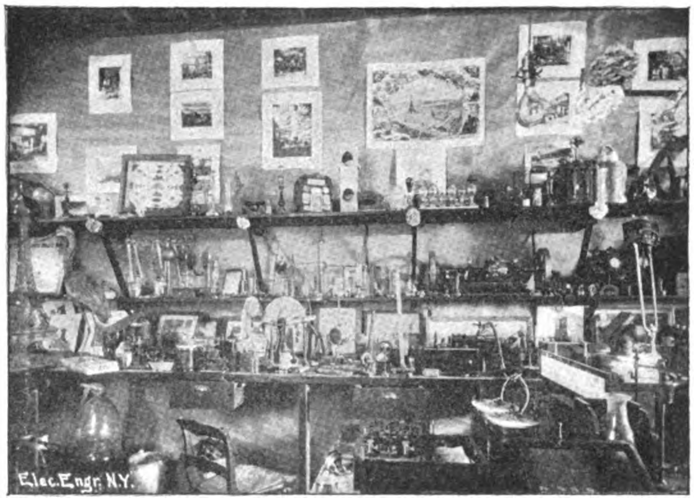
THE FRANKLIN EXPERIMENTAL CLUB.

BY

Wm. J. Hammer

The Franklin Experimental Club, of Newark, N. J., was organized Jan. 31, 1890. The object of the club, as stated in its constitution, was the advancement of its members in scientific knowledge by study and experimental research through the helpful influence of united effort. It was a modest little organization, composed of a small but earnest band of workers, and during the past two and a half years it has accomplished much of the work which its enterprising members had laid out for themselves.

So little has been known of the Franklin Club that it may, perhaps, be appropriate at this time to refer briefly to its aims and its accomplishments, particularly as the rooms occupied by the club were destroyed by fire on the night of the Fourth of July last. The fire originated in an adjoining saloon, and soon spread to the Franklin Club, which its facetious members frequently referred to as the "Chinese Laboratory," by reason of its occupying the premises over Mr. Sing Lee's laundry. The club and Mr. Lee were soon upon speaking terms, owing to the "high periodicity" of the upset battery jars and chemicals in the club rooms. The bare beams and walls of the club the members covered with heavy paper, hung with many photographs, pictures and diagrams. At the time of the fire a dozen or more flags from various parts of the world brightened the room. The members despised not the day of small things and looked forward to an early removal to more elaborate quarters and a broadening out of its sphere of usefulness. The accompanying illustrations give a fair idea of the electrical and other apparatus belonging to the club, and they possessed, also, quite an outfit of chemicals and a library of books. All the electrical and other scientific papers were on file, and the club-rooms were supplied with electric light, both arc and incandescent, and with heat and water. The fire is a serious blow to the club as there was but a small amount of insurance, one member alone losing several thousand dollars in books and apparatus.



Franklin Experimental Club, Newark, N. J.

The dues for active membership were $1 per month and the initiation fee $5. There were active, associate and honorary members; a portion of the receipts went towards an apparatus fund, and the balance was used for the working expenses of the club. Each member was supplied with keys to the rooms, to which he had access at all times. All apparatus, books, etc., whether the property of the club or of individual members, were at the disposal of all the members and were kept in order by the club's curator. Lectures and informal talks were given by the members and invited guests, and special encouragement was given to original experiments and the construction of original apparatus.

Prior to the incipiency of the Franklin Club the writer had broached to a number of influential men a scheme for the establishment in New York of a scientific laboratory and museum, where popular scientific lectures, á la Faraday and Tyndall, should be given, and where youths possessing scientific tendencies could spend their spare time in study and experimenting under the guidance of able instructors and without being put to any expense, care being taken that such privileges were extended only to such as were properly fitted and really desirous to avail themselves of such opportunities. In connection with this lyceum would be a scientific museum where valuable historical relics, those "scientific footprints in the sands of time" would find a home and proper care. Here, also, would be shown working models demonstrating the first principles in sound, light, heat, electricity, magnetism, etc., so arranged that the signs could read "please handle" instead of the usual "please do not handle," and each with a few terse words on an accompanying card explaining the principle enunciated. The scheme would, of course, embrace a workshop supplied with electric power, and an important feature would be a scientific library and reading-room where all the scientific papers would be on file. The writer did not succeed in arousing much interest at that time, but that was long ago, and in 1889 he visited the "Urania" Museum in Berlin, which has been fostered by the authorities and many eminent men, with Dr. Werner Siemens at the head. Here is shown, on a small scale, just such a scheme as the writer had proposed, and upon his return to America he made another effort in that direction and eventually took the initiative in the starting of the Franklin Experimental Club. Is not the time now ripe for some such scheme to be taken up by the public-spirited citizens of New York? Will this not be the means of popularizing science in a way that the growing taste of our enlightened people demands? Would not the co-operation of the electro technical press, the electrical societies and the electrical financiers secure it? It would seem so. Is there a question as to the inestimable value to our people of our art galleries, our museums of natural history, etc., our conservatories of music and our public libraries? And yet these would all be subordinated in the public esteem to such an institution as above referred to properly endowed and equipped and run upon the broadest humanitarian principles.

Franklin Experimental Club, Newark, N. J.

ELECTRICAL ENGINEERING AT TULANE UNIVERSITY, NEW ORLEANS.

Among the numerous evidences of progress which the South is now affording none is more significant than the opportunities offered students for obtaining instruction in the higher branches and especially in the mechanic and electric arts. Where thorough, scientific training precedes or follows practical work in any branch it must of necessity be done with more intelligence and hence with better results than where the rule-of-thumb method alone is employed, and this is especially the case in electrical work. It was with the object of affording both theoretical and practical training in electrical work that the course of electrical engineering was organized at Tulane University, of New Orleans. This institution as now organized was started in 1884, and was the result of the turning over by the State to the Tulane administrators of the old and poor University of Louisiana. In reality it is a new school, and considering the comparatively short time it has been in operation the progress has been remarkable.

This has been particularly the case in the Department of Physics which is in charge of Prof. Brown Ayres, who has also organized the Department of Electrical Engineering, which has been considerably developed during the session of 1891-92.

The student is given a thorough course of theoretical instruction in electricity and magnetism, accompanied by lectures and practical demonstrations and exercises on the applications of electricity to lighting, and the distribution of power, and to telegraphy and telephony.

But it is in the electrical laboratory that the student requires much of that practical knowledge which he is called upon to employ in the practice of his profession, and hence Prof. Ayres has taken special pains to make the electrical engineering laboratory as complete as possible.

The accompanying engraving shows this laboratory, which contains a variety of apparatus probably not excelled by any similar institution in the country. Thus we find here the following apparatus:

A complete plant of the Slattery induction system, including dynamo of 300 lights capacity, exciter, all necessary station instruments, converters, ranging from 5 to 50 lights capacity, alternating meter, and a large cabinet switchboard of slate of the best finish. A Wood arc lighting dynamo of a capacity of 15 lights, with all necessary station instruments and arc lamps. An arc lighting dynamo of the Edison General Electric Company of 8 arcs capacity, with all necessary station instruments and a full complement of lamps. Four smaller Edison incandescent machines, for use as motors and in laboratory practice in the study of the principles of dynamo machines and the various investigations connected with the distribution of potential, the law of the electromagnet in dynamos, magnetic leakage, etc.

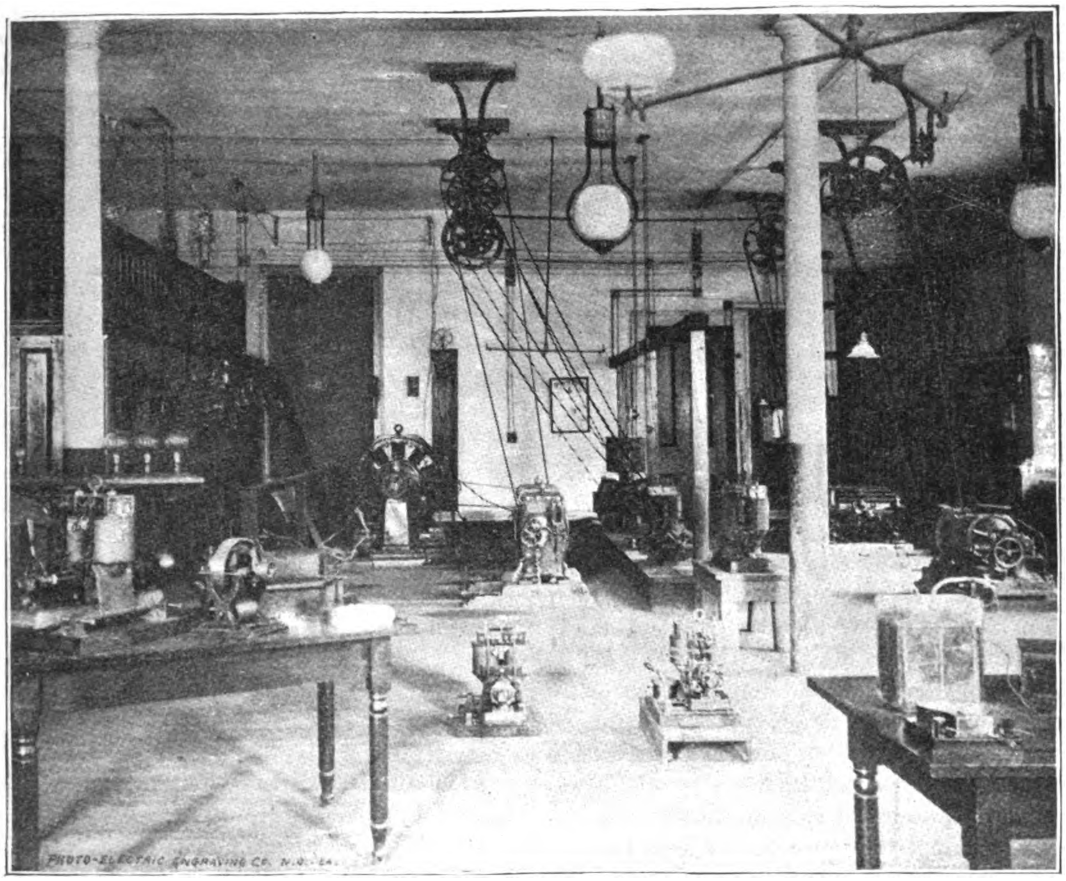
Besides this there are several other arc machines and motors of various makes, and a full equipment of measuring instruments by the best-known makers.

The practical work in the laboratory includes the testing of the machines for conductor and insulation resistance, the study of the law of the electromagnet in dynamo machines, the determination of the strength of field in absolute measure, the mapping of the characteristics of shunt, series, and compound machines, the determination of the electrical and commercial efficiencies of dynamos and motors, the determination of the candle powers of arc and incandescent lights, and the study of the influence on them of varying conditions of potential, etc. Some practice is also had in laying out installations and in designing machines and appliances to fulfill definite conditions.

For advanced students there will be a course during the next session based on Emtage, Mascart and Joubert, and Maxwell. To follow this course a good working knowledge of the calculus will be esential. Every encouragement and facility is extended to post-graduate and other advanced students, both in the laboratory and in their theoretical studies, as it is the desire of the university to build up this side of their work as rapidly as possible.

Ten post-graduate scholarships, entitling the holder to free tuition and one hundred and fifty dollars, are awarded annually to graduates of Tulane College.

Tulane University, we may add, has the largest endowment of any college in the South, with the exception of the Johns Hopkins University, and the largest number of students in all departments, there being no less than 951 students on its rolls, not including 333 who attend the free drawing classes.



Electrical Engineering Laboratory, Tulane University, New Orleans, La.

THE TROLLEY DOG.

Sitting out in the open air a few evenings ago at the house of a friend in umbrageous Greenwich, Conn., a New York electrical engineer remarked as his face took on suddenly an intent look of surprise:

"I didn't know you had any trolley cars here."

"Well, we haven't," was the reply.

"Funny, any how. I didn't see any as I passed through the town, but I'll swear that nothing but a trolley car could make that noise. Listen!"

Everybody listened, and sure enough through the still night air came that curious rolling, whirring, buzzing, rushing sound that accompanies the passage of an electric car as its trolley pole follows the overhanging wire and its "pick-up" wheel makes flying contact.

The host smiled. "That isn't a trolley car," he said, "it's a trolley dog."

Greenwich is celebrated as containing the residence of a noted electrician, who has long been connected with Edison, and who has filled his beautiful house with all kinds of his own electrical contraptions for use and comfort; and it flashed across the mind of the New Yorker that this must be one of the latest productions of his fertile brain. He supposed, he said, that it was an imitation dog, with a motor in his little inside, running around a track; but he didn't see where the utility of the invention came in.

"No," replied the host, "we havent got anything of that kind yet from Electric Hill, but I guess this real piece of flesh and blood machinery deserves a patent. One of our parsons here has a dog of extremely peripatetic tendencies, and so he has put up a big fence right around the grounds. On a rod on top of that fence runs your trolley, to which is attached a long chain. The other end of the chain is attached to the dog. When the dog starts on a tour of the grounds you hear his trolley. He can't get out, and like a trolley car he must follow the circuit, but as long as he does that, he can go on and on like Tennyson's brook. It is a great scheme. Just hear him now!"

And the noise came again, and again, for all the world like a trolley car running fifteen miles an hour.

Mr. W. J. Hammer, of the Temple Court Annex, Nassau street, this city, has just returned from England, where he has been spending several months as the special representative at the Crystal Palace Electrical Exhibition of a number of American electrical firms and inventors. His exhibit attracted a great deal of attention, while Mr. Hammer found his time fully occupied in negotiations and in social duties, his acquaintance in England being quite extensive.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

VOL. XIV. NEW YORK, AUGUST 3, 1892. No. 222.

Without a knowledge of science the practice of art is mere empiricism, often involving operations which are not only unnecessary to the production of the desired result, but frequently detrimental.—Joseph Henry.

A LABORATORY FOR BEGINNERS.

THE interesting article in our present issue, by Mr. W. J. Hammer, on the work of the Franklin Club at Newark, contains more than one valuable suggestion. It will be seen that the Club was, on one side of its work, a practical laboratory, where the members could try their prentice hands in testing the truth of principles or the value of any presumably new ideas that had occurred to them. In this way they were enabled to get an acquaintance with electricity, at close range, which they could hardly get otherwise, and could supplement lectures and reading by the instruction derived from seeing and handling. Mr. Hammer is quite right in emphasizing the importance of such teaching, and we can only hope that his suggestion looking to the establishment of a similar laboratory in New York could be carried out. Probably the New York Electrical Society is the best body to attempt anything of the kind, and it is noteworthy that for some time past, thanks to the enlightened policy prevailing at Columbia College, the Society has had a liberal use of the appliances of the Electrical Engineering Department there. But it would be well, of course, if the Society had an equipment of its own, available by members only. We do not mean a place where all the members, at their own sweet will, could make a wasteful use of material in bangs, stinks and short-circuits, but where, under judicious guidance, they who were anxious to increase their knowledge and train their hands could be assisted over the rough places and could feel themselves advancing in the art. Even then, it might be difficult to help the embryo inventor, as that kind of person is nearly always more or less suspicious and prefers to work in the dark, only to discover, often, when he does unfold his project, that his pet invention was made by somebody else ten years before Christ. But there is no doubt that some young men would gladly avail themselves of the chance to make a few tests of the ideas that are haunting them day and night.

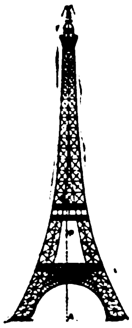
A PROPOSED CHANGE IN UNITS.

HARDLY has the system of absolute units, as employed at present, gained firm ground when there are already attempts made to substitute others designed to still further simplify our methods of calculation and our conception of the interrelation between the units of length, time and mass. Among those who propose such a change is Prof. Ostwald, upon whose system a writer in *L'Indûstrie Electrique* looks with considerable favor. Starting with the idea that the general system of absolute units has for its final object to give an expression for energy in all its forms, Prof. Ostwald proposes to consider the latter as the fundamental value; length and time would be retained, whereas mass would be abandoned. In this way the formulæ of dimension in mechanics become more simple and more easily comprehensible. In each particular branch one value added to the three first would give the complete definition of all values. For example, in the case of heat, one would define temperature, and specific would follow as a derived value; in the case of electricity one would define arbitrarily the unit of E. M. F. or of quantity, or any other constant that one wished to represent by a standard. We would thus avoid the introduction of mass in an artificial way in a domain which would appear to be foreign to to its nature. With a well-known electrician in England vehemently protesting against the loading down of the science of electricity with units which, he claims, as often hamper the student as aid him, the proposition embodied in Prof. Ostwald's system may be looked upon with more favor than a change of this nature ordinarily would be.

DYNAMO TELEGRAPH WORK.

IN continuing his valuable series of articles on modern telegraph apparatus Mr. Francis W. Jones has taken up the subject of the substitution of dynamos for galvanic batteries in the operation of telegraph circuits. Although we were slow to adopt this system in the United States, the number of plants now in operation in this country exceeds those of any other country, and with the experience gained improvements are being introduced. Mr. Jones calls special attention to the departure taken in the arrangement of the machines of the Postal Telegraph Co. as distinguished from that in vogue in the Western Union service. While the latter company place all their dynamos in series, those of the Postal Telegraph Co., as arranged by Mr. Jones, are independent units which can be coupled to the desired potential as the service demands. Mr. Jones shows that by this arrangement considerable economy in power is obtained, and that the machines work to the best advantage. He also touches upon a subject which would bear further investigation, namely, the amount of retardation introduced into the circuit by the employment of the dynamo, owing to its dynamic inductive action, an effect which evidently is not present when batteries are employed.

THE FALL OF BODIES AND THE RESISTANCE OF THE AIR.



AN exceedingly interesting series of experiments is now being carried on in Paris, by MM. Cailletet and Colardeau, in which they are seeking to verify the law of falling bodies and at the same time those of the resistance of the air to the passage of bodies. Now that high speed electric railway work is seriously contemplated, the results of these experiments cannot fail to be of the highest interest. In order to carry out their work, the investigators have installed their laboratory on the second landing of the Eiffel Tower which gives them a free fall of 120 meters, or about 370 feet.

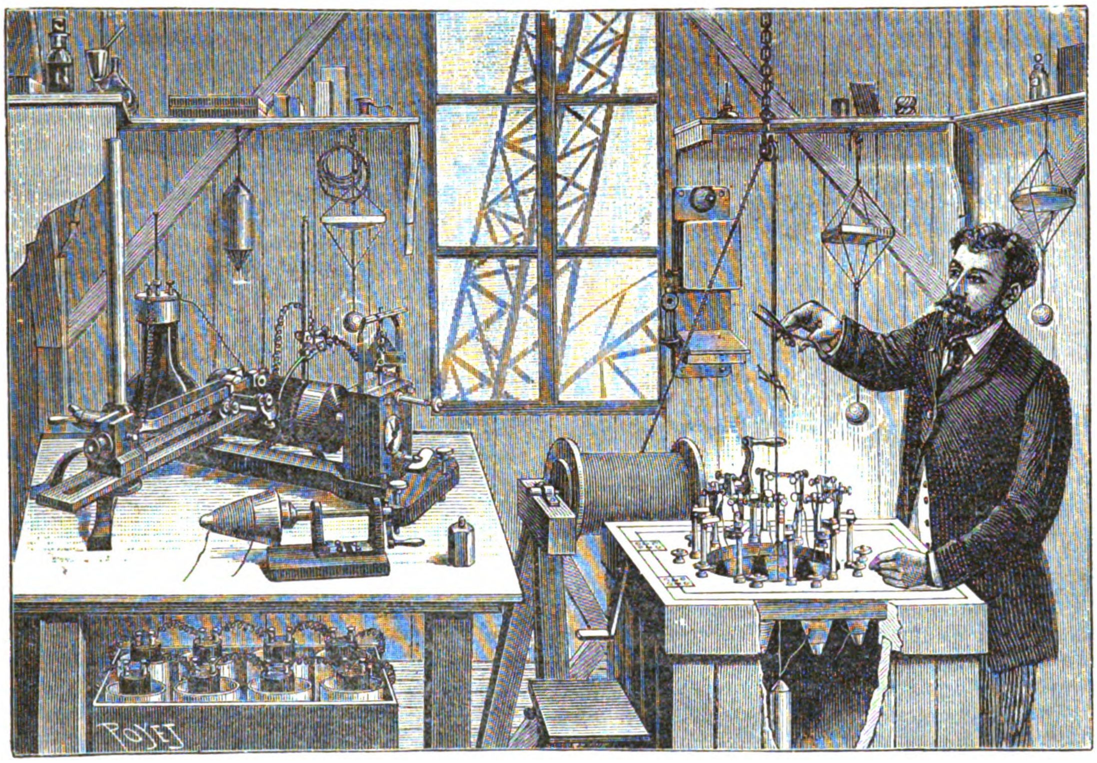


Fig. 1.—Laboratory in the Eiffel Tower, Paris.

In carrying out their experiments MM. Cailletet and Colardeau have employed a very ingenious electrical method of timing the fall of the variously shaped objects experimented with, and particularly with the view of knowing at every instant the position of the falling body. The laboratory itself is shown in the accompanying engraving, Fig. 1, taken from *La Nature*. Fig. 2 shows an enlarged view of the principal apparatus. The falling body is attached to a very fine light thread which is divided into sections of 20 metres each; each one of these sections is wound on a wooden cone, c^1, c^2, c^3, etc., all fixed vertically with their points facing downward so that the thread is very easily unwound. When each of the sections of 20 metres is unrolled, an electric contact actuates a registering pen upon which an electric tuning-fork chronograph indicates the instant with a precision of $\frac{1}{100}$ of a second. Thus at the end of every 20, 40, and 60 metres, etc., a time record is automatically made.

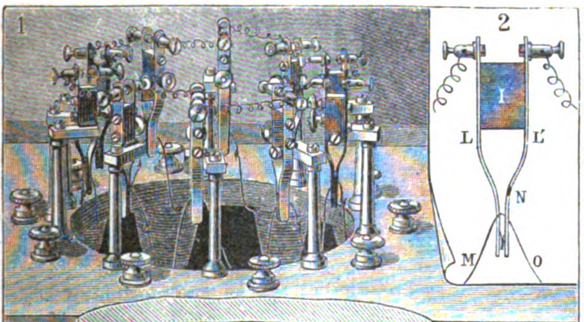

Fig. 2.—Apparatus for Experiments with Falling Bodies and Air Resistance.

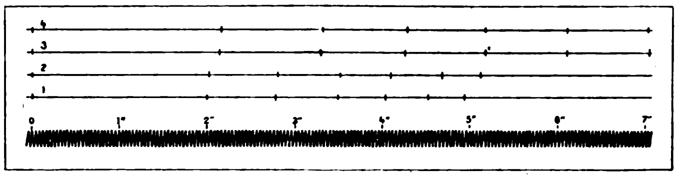

Fig. 3.—Record of Falling Bodies.

The electric contact is accomplished as follows: In passing from one cone c^1 to the following c^2 the thread is looped around a contact M N O, Fig. 2, the contacts being separated by an insulating block I and supported by two springs L L', which press the contacts together very lightly. The falling body pulls the thread through the contacts and thus for an instant breaks the circuits and allows the pen to register. Experiments have shown that the retardation to the fall of a body weighing 1 kilogram through 20 metres caused by the separation of the spring contacts is less than 0.2 millimetre per second; that is, less than 1 one-hundred-thousandth. The retardation due to the resistance offered to the unrolling of the thread on the cone has been shown be about 1 per cent.

Up to the present the experimenters have confined themselves to investigation to ascertain if the resistance opposed by the air to plane surfaces of equal area, moving in a direction normal to these surfaces was dependent upon their form; thus they have employed circular, square, triangular, etc., surfaces. They have found that the time of fall differs only by insignificant amounts, as indicated in the record reproduced in Fig. 3. This figure is a production of the chart obtained by means of the apparatus above described. No. 1 is the theoretical record of a body falling freely in vacuum. No. 2 is an experimental record obtained of the fall of a long wooden arrow, weighted by a metallic mass at its point. No. 3 is the record of the fall of a square surface (0.0225 cm. sq.) pulled by a weight of 800 grams. No. 4 is the record of a triangular surface of the same area as the preceding, pulled by the same weight. The lowest curve in Fig. 3 is the record of the tuning-fork.

Messrs. Cailletet and Colardeau have also investigated whether the resistance encountered by a flat surface moving through the air is proportional to this area. For that purpose they employed two square surfaces the areas of which were in the ratio of 1 to 2, and pulled by weights of like proportion. The corrected time of fall was respectively 6.92 and 6.96 seconds, these figures being practically identical confirm the strict proportionality.

LAMP AND WIRE CALCULATIONS WITHOUT TABLES OR CURVES.

BY

E. P. Roberts

1. To determine the resistance of the lamps when candle power (c. p.) and voltage are known.

2. Given the percentage of loss to be allowed in the line, to ascertain the line resistance (*R*).

3. Given the line resistance *R*, to determine the size of wire, weight, etc.

1. Evidently, if the total c. p. and watts per c. p. be known, the total watts is their product. The current equals the total watts divided by the voltage. The resistance of the lamp equals the p. d. (*at lamp*) divided by the current. All that is needed is to apply Ohm's law.

$$\left.\begin{array}{l}\text{Total c. p.} = a.\\ \text{Watts per c. p.} = b.\end{array}\right\}\text{Total watts} = ab.$$

$$\text{p. d. at lamp} = V;\ \text{therefore current } (C) = \frac{ab}{V}.$$

$$\text{Lamp } R = \frac{V}{C} = \frac{C \times V}{ab}.$$

Example.—Given 200, 16 c. p., 3.4 watts per c. p., 100 volt lamps: To find the *C.* and *R.*

$$\textit{Ans.}—C = \frac{200 \times 16 \times 3.4}{100} = 108.8 \text{ amperes};$$

$$R = \frac{100}{108.8} = .92 \text{ ohms.}$$

2. This is evidently a matter of percentage. In the example above, if 10 per cent. of the *total* energy given to the line is to be allowed for line loss, and the loss is to be calculated on the basis of 200 in use, (probably 250 to 300 connected), then the line resistance will be

$$\frac{.92 \times 100}{90} \times .1 = .102 \text{ ohm.}$$

If the line considered be 800 feet total length then the *R* per 1,000 feet is *R* of 800 feet + *R* of $\frac{1}{4}$ of 800 feet = .102 + .025 = .127. Or, taken as an example in percentage, $\frac{.102}{80} \times 100 = .127$ ohm.

3. The next point is to determine the size of wire, its weight, etc. The writer would recall the following facts:

a.—The B. and S. gauge is based upon the law of geometrical progression.

b.—No. 10 B. and S. gauge wire is .1 inch in diameter and measures one ohm per 1,000 feet.

The factor connecting the area of cross-section, and consequently the resistance and weight, of one size of wire with the size next on the scale is $\frac{4}{5}$ or $1\frac{1}{4}$, according to whether ascending or descending. Therefore the *R* of any wire smaller than No. 10 is $1\frac{1}{4}$ (1.25) raised to a power equal to the difference between No. 10 and the size desired; and the *R* of any size smaller is $\frac{4}{5}$ (.8) treated in the same way.

For example: No. 14 wire = $1\frac{1}{4}$ to the fourth power = 2.44 ohms per 1,000 feet. According to the table the *R* of No. 14 = 2.59. Greater accuracy could be obtained by using 1.26, or, if larger than No. 10 wire, .79.

To take an application to a larger size, consider No. 6. The difference between 10 and 6 = 4; therefore .8 to the fourth power = .409; the tabulated *R* = .395, evidently practically accurate. Whatever allowance is deemed advisable can be made for conductivity; usually it will be a matter of nearest size without considering 2 or 3 per cent. loss due to 97 or 98 per cent. conductivity. If it so happen that a table of logarithms be accessible, then calculations are assisted by noting that as the *R* of No. 10 wire is one ohm per 1,000 feet, its logarithm = 0 and that the logarithm increases by .1 for each number higher than 10 and decreases by .1 for each number smaller. If, therefore, the *R* of No. 5 wire be desired, the logarithm of the *R* will be 0 less .5 = 1.5, *R* = .317 ohm per 1,000 feet. If the wire be No. 18 the logarithm will be 0 + 8, giving 6.31 ohms.

Evidently an order could now be sent to "Express at once — feet No. — wire," but possibly the investigation involves a question of weight. The weight of No. 10 wire is 31.37 lbs. per 1,000 feet, (approx. 33$\frac{1}{3}$ per cent. or $\frac{1}{3}$); it is perhaps easier to remember that No. 5 weighs 100 lbs. per 1,000 feet. If preferred, an effort can be made to remember that one cubic foot of copper weighs 555 lbs. or that one mil. foot weighs .003 lb. As the diamter of No. 10 wire is .1 inch and as the resistance is inversely proportional to area, or weight, it is evident that the weight can be readily calculated. For most sizes of wire used in aerial work the insulation weighs approximately 20 per cent. of the total and therefore 25 per cent. must be added to the weight calculated for bare wire. Then by adding 3 to 5 per cent. for slack and error in measurements and an additional percentage if the size be not No. 10 or near thereto (see table at end of article) the investigator is in a condition to telegraph for the pounds required, or to make an estimate of cost of wire. That is, provided he can remember:

1. Ohm's law, and can use it.
2. That lamps are made of from 3 to 4 watts per c. p.—safe average 3.5.
3. That No. 10 wire measures 1 ohm per 1,000 feet, and is .1 inch in diam. and weighs about 33 lbs. per 1,000 feet.
4. The $\frac{4}{5}$ or $1\frac{1}{4}$ ratio law of B. & S. gauge.

B. & S. G.	*R.* of pure copper. Ohms per 1,000 feet	*R.* obtained by raising 1.26 or .79 to power.	per cent. of error,	*R.* by log. tables.
2	.156	.152	7	.158
4	.249	.242	5	.251
6	.395	.389	3.5	.398
8	.629	.624	1.7	.631
10	1.	1.	...	1.
12	1.590	1.59	1.9	1.585
14	2.591	2.52	5.8	2.512
16	4.019	4.13	6	3.982

The question of carrying capacity seldom enters lamp wiring calculations, as wire large enough for the drop is usually safe to use. No. 10 will carry safely 20 amperes and other sizes, between the limits used for aerial lines, about in proportion to cross-section; small sizes will carry more in proportion than large ones but it is well not to approach the limit in any case especially for interior work, because of safety in fusing.

Of course any man who neglects to use tables, curves, slide-rules and other conveniences of a like nature when they are accessible, is foolish, but sometimes it will happen that a calculation is desirable and the usual conveniences are not obtainable. In such cases a knowledge of *principle* is essential, and if to the same be added the remembrance of a few fundamental constants there will almost surely come a time when the trouble taken to add to one's stock of permanent and personal information will be far more than repaid.

APPARATUS FOR DEMONSTRATING CURVES OF ELECTRIC CURRENT FLOW IN CONDUCTORS UNDER DIFFERENT CONDITIONS.[1]

THIS apparatus, due to Dr. Frolich, of Messrs. Siemens & Halske, of Berlin, was exhibited at the Frankfort Exhibition and excited so much interest at the time, that Messrs. Siemens Bros. obtained the loan of it for the late Crystal Palace Exhibition, where it was shown in the Pompeian House.

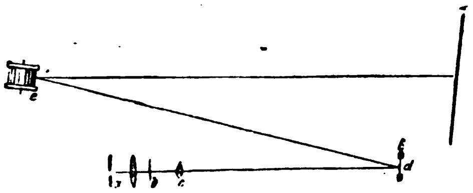

FIG. 2.

It is well known that the flow of an electric current along a circuit, or the value which the current has at any instant, is varied according to the nature of that circuit, and it is to demonstrate this curve of flow under different conditions that the apparatus to be described was constructed.

To this end the light from an arc lamp *a*, Fig. 2, is passed through a lens and a small opening in the screen *b* and is concentrated by the lens *c* upon a small mirror *d* fixed between the centre and the periphery of a telephone membrane *t*. It is therefrom reflected on to a series of revolving mirrors *e*, and is finally thrown upon a transparent screen *f*, where its vagaries can be carefully analyzed and photographed if desired.

Fig. 1 is an elevation of the small Siemens alternator used in these experiments for producing alternate currents, and for giving intermittent currents. The mirrors *e*, of which there are twelve, are arranged on a vertical axis which carries above the mirrors a worm-wheel gearing with the worm *w* on the alternator shaft. Each mirror is provided with three screws, so that it can be adjusted with great exactness in order to bring it parallel with the axis, and to insure that the mirrors make equal angles with one another. The ratio of gear between mirrors and alternator is 1.24. The alternator has twelve poles; so that it gives six complete periods per revolution, or 144 complete periods per revolution of the mirrors. For alternate currents the usual collector rings are supplied, but for intermittent currents a small 12-part air commutator *c* is provided, and by means of a small switch *s* on the end of the spindle the alternator can be conveniently made to give either intermittent or alternate currents. The combination is driven from the Siemens motor by means of a strap passing over the pulley *p*. Many interesting acoustic experiments can be performed with this apparatus but we must confine ourselves to the electrical.

Electrical Experiments.—These are divided into two groups, namely, those obtained by the use of intermittent currents and alternate currents.

(*a*) *Intermittent Currents.*—The following experiments were so arranged that one end of the telephone circuit was alternately connected to the one pole of the battery and to the other pole, which was connected to earth. In this manner the telephone circuit was alternately short-circuited on itself.

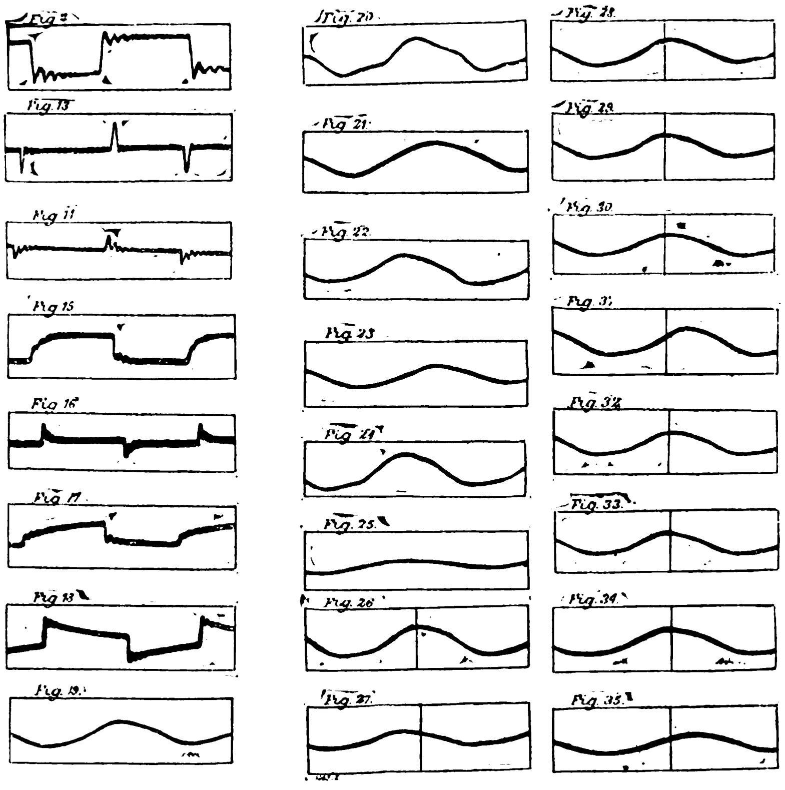
Experiments with ordinary resistance coils wound bifilarly, gave curves as shown in Fig. 4. This curve shows distinctly a slight rounding off at the corners, thereby indicating the presence to a slight degree of self-induction.

Fig. 13 shows the curve of current when a condenser is placed in the external circuit, the charge and discharge being clearly shown. Fig. 14 is very interesting, representing as it does the flow of current when a resistance of 470 ohms was placed in series with the condenser. One sees how strongly the current curve is modified by the introduction of resistance. With an ordinary reflecting galvanometer this difference would be unnoticed.

Experiments with an induction coil so arranged that the core, which consisted of a bundle of iron wires, could be removed at will, are full of interest. The two windings are precisely similar and consisted of 4,900 turns of wire, the resistance of each being 200 ohms.

Fig. 15 shows the curve of current in the primary winding with core removed, whilst the secondary current is shown in Fig. 16. In this case the primary current attains its maximum quickly whilst the induced secondary changes as quickly as did the current in the case of the condenser without resistance, Fig. 13.

Figs. 17 and 18 represent the primary and secondary respectively, with iron core in position. The effect of the core is very marked. The primary current gradually attains its maximum on making the battery current. By breaking the battery current and short-circuiting the primary coil on itself the current gradually falls to zero. The secondary current does not, as in the case without core, suddenly fall away, but as one would expect, it gradually falls to zero. In these experiments the time of a complete impulse was from $\frac{1}{10}$ to $\frac{1}{30}$ second.



CURVES OF ELECTRIC CURRENT FLOW IN CONDUCTORS UNDER DIFFERENT CONDITIONS.

(*b*) *Alternate Currents.*—If the external circuit is free from self-induction the resulting curve is the true curve of the machine, and in this case is substantially a sine curve. Fig. 19 is the curve of the small alternator, Fig. 1, without iron in the armature; Fig. 20 shows the effect of introducing iron into the armature, whilst Fig. 21 is a curve obtained from a small alternator built on the principle of Gramme. The presence of iron in the small Siemens armature is very marked, and the similarity between the curve of the first machine without iron, and the Gramme pattern with iron, is very striking.

In the following experiments the small Siemens alternator was used without iron in the armature.

Figs. 22 and 23 represent an alternate current before entering an artificial cable, and after leaving the same. The amplitude is decreased one-third, thereby partly showing how it is that one is limited to distance in the case of telephony.

The effect of self-induction is very well shown in Figs. 24 and 25. Fig. 24 was taken with an external circuit of 423 ohms, and without self-induction. Fig. 25 represents the same when three electromagnets with vibrating armatures, and having the same ohmic resistance, 423 ohms, were placed in circuit. The diminution in amplitude is worthy of consideration, the same effect in the case of steady currents being only brought about by an increase in the ohmic resistance. The amplitude increases with the speed of the machine, and from this experiment the effect of electromagnets in telephone lines is easily foreseen.

---

[1] Abstract from *Engineering*.

We now come to perhaps the most interesting part of this article—namely, phase difference, which plays such an important part in alternate currents. In order that this effect can be clearly shown a vertical wire was stretched before the screen and was placed at the point where the maximum ordinate occurred. Any phase difference was at once noticed on making the required change in the circuit.

The first experiment consisted in connecting up the primary of the induction coil, already mentioned, to the alternator, and so arranging matters that the telephone could be quickly changed from the primary to the secondary circuit, taking care that the vertical wire was placed on the maximum ordinate of the primary curve.

Fig. 26 shows the primary current with the vertical wire alluded to, when the core was removed. Fig 27 is the resulting secondary current. The phase difference is very marked, and roughly amounts to 53 deg.

Fig. 28 and 29 show the primary and secondary currents with iron core in position. Here the phase difference is very much reduced, and with these curves is scarcely measurable.

Phase difference is shown very strongly in the case of alternate currents in two parallel circuits—the one being free from self-induction and the other containing self-induction. In the first mentioned circuit ordinary inductionless resistances were employed, whilst parallel with it was placed the primary winding of the induction coil.

Fig. 30 gives the current in the inductionless circuit. Fig. 31 the current in the primary of the induction coil without core, and with secondary open.

Figs. 32 and 33 show the corresponding curves with iron core in position, the secondary being closed. In the first case the phase difference amounts to about 35 deg., whilst in the last it is very small indeed.

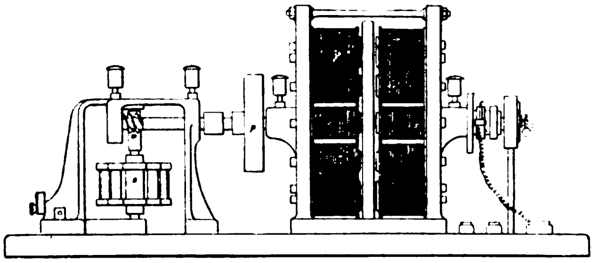


FIG. 1.

In the same manner one can find the phase difference at different points in a cable. Figs. 34 and 35 show the current before entering and after leaving the artificial cable already alluded to. Here the phase difference is about 64 deg., and the amplitude of the second curve is about .68 that of the first. With curves which are taken from circuits containing no capacity the self-induction can be calculated, and the effects of hysteresis studied.

THE GOVERNMENT TIME SYSTEM IN ITS RELATIONS, PRACTICALLY, TO RAILROAD MATTERS.[1]

BY PROF. W. A. GARDNER.

THE first great step toward the possibility of providing for exact similarity and uniformity from a single central source was taken when the railroads of the country adopted what is now known as "Standard Time," that compromise based upon the time of a few meridans, and now universally in vogue.

The people are fast concluding that about as much of their safety, and as many of their interests depend upon an accurate and uniform standard of *time*, as upon standards of area, volume or weight, and also depends on some standard which shall be *universal.*

The Government Observatory at Washington was primarily intended for this very matter, namely, to provide a time service and from its inception its work has been largely devoted to that purpose. Among the instruments of precision of which it had the custody none were of more importance than those of the chronometer class belonging to the navy. From 1844 continuously to this date, all United States vessels on going to sea have been furnished by the Observatory with their chronometers and charts.

For upwards of a half century, the Government Observatory has provided the shipping interest with the exact time. Thus the influence of that Observatory in respect to standard time is more widely established than that of any other. When the writer became connected with the Government Observatory some thirty years ago, its time work was as yet restricted to navy instruments. But shortly after the commencement of that connection he became impressed with the importance of extending this service of a standard time to make it available to transportation on land as well as to navigation. Through many years he tested all the known systems, but was compelled to devise and adapt special instruments. And his ultimate purpose was continually the assisting of railroads in having a uniform standard of time if possible.

Those sufficiently curious can follow the successive stages by reading the bureau's annual reports.

Among the roads which have for a number of years been continuously using the time standard of the Government are the following:

Richmond & Danville; Norfolk and Western; Atlantic Coast Line; Cape Fear & Yadkin Valley; Lehigh Valley; Richmond, Fredericksburg & Potomac; Georgia Central; Chicago, Burlington & Quincy; Norfolk & Southern; Chesapeake & Ohio; Charleston & South Carolina; New York, Chicago & St. Louis; Lake Erie & Western; Baltimore & Ohio; West Point & Atlanta; Illinois Central.

With this brief review of the Observatory and its work in establishing a standard time service, I pass for a moment to that part of its equipment devoted to this work. There is much confusion of idea, even lack of information on this point. Such inquiries are common, as, Where do the Government time signals come from? and, How are they sent?

There are two officers to keep the clocks correct. Observations of the stars are taken by them every night, weather permitting. As you know, all of the "time" stars have been observed so many hundreds of times that one can now know beforehand exactly the instant when any one of them should pass the line of his transit telescope to the hundreth part of a second. The accuracy of your standard time, after all, depends upon the movements of these heavenly bodies, and upon the accuracy of the observations made upon them. They are the ultimate, and the most nearly absolutely accurate standard. All human contrivances are merely compromises, and subject every instant to variations from the fixed standard of the stars.

These two observers make special observations, each upon, we will say, a single star, and with these before them they derive the exact instant of the transit relative to a sidereal clock. Next they compare the reading of this clock with that of a mean-time clock, and by the comparison ascertain exactly the error of the latter, that is, ascertain its variation from the star standard which has occurred since the last comparison. This variation they are able to measure by the chronograph and other instruments (which we cannot stop now to discuss) to hundredths of a second.

The time signals are sent out from the Government Observatory at noon, the observations having been made the night before, and the comparisons having been made in the morning as late as is practicable in order to eliminate the chance of variation between the time of closing the comparison and the time of transmitting the signals. At a few moments of twelve o'clock everything is ready for the transmission over the telegraph wires of the signals, first those signals of a preliminary or attention-calling nature, and, finally, that one which is to indicate the predetermined instant, as, for example, the instant of noon.

Now, how shall these preliminary and the final signals be transmitted?

In order to eliminate all errors due to "personal equation," the writer many years ago set about devising and perfecting some plan for obviating the intervention of the human hand at any point. These efforts culminated finally in the automatic system of transmission which is now, and has been for a long time, continuously employed with entire satisfaction. This automatic plan depends upon the introducing of a third clock in the series, namely, the transmitting clock.

The transmitting clock is caused for a few minutes in the day to indicate correct time as nearly absolutely accurately as is possible with human instruments. And during these few moments it is utilized to open and close the electrical circuits which transmit, first, the preliminary, and, ultimately, the final time signal.

The simple instrumentality which finally accomplishes the signal transmitting is a toothed wheel secured to the seconds arbor of this transmitting clock. Teeth are removed so as to cause those characteristic gaps or intervals now recognized by telegraphers universally over the United States. For three minutes prior to exact noon the impulses are transmitted at each second, with the exception of the well-known gaps or interims. From the Naval Observatory telegraphic loops extend to the main Washington office of the Western Union Telegraph Co. At the latter the signals are transferred by numerous multiple repeaters to a large number of main lines which distribute them over 300,000 miles of main and local wires throughout the United States.

From this point on it becomes merely a matter of accurate telegraphic work in order to get (at the most distant point and through the most circuitous electric routes) an entirely automatic transmission of the signals from the little wheel in that Observatory clock to receiving instruments of any sort.

---

[1] Abstract of a paper read before the Association of Railway Telegraph Superintendents, Denver, Col. June 16, 1892.

So extended has the system been that it is safe to say that at noon to-day that small wheel automatically affected the armatures of 20,000 receiving instruments.

It is not our purpose to discuss at any length the various receiving instruments which have been experimented with and of which two or three sorts have been largely introduced. The two that are possibly the most widely used are known as the "Gardner" clock and the "self-winding clock." So far as concerns the reception of the synchronizing or controlling impulses, these are or may be, essentially similar. The difference lies in the motive power for the clock trains, that in the Gardner system being the one which the experience of horologists has maintained for hundreds of years, to wit, gravity, acting entirely independently of the electric current, and in the other being a battery and a motor. Each of these also has its numerous advocates. But that is a matter of interest rather to the horologist than to the one aiming to systematize the ultimate standards of comparison in obtaining correct time. Of these clocks, many hundreds are now in use upon the various lines of road, and if properly applied and cared for they furnish the most accurate of all contrivances for manifesting visually the accurate time at all periods.

The artificial compromise embodied in "standard time" renders it possible to automatically regulate each and all of many thousands of duplicate clocks scattered over vast territory. For each clock, by a slight adjustment, can be used in any section; to indicate any one of the few times belonging respectively to the geographic divisions, and duplicates can be adjusted to indicate simultaneously all of the several times.

I take the liberty of offering two or three suggestions which may provoke attention even if erroneous:

First. So far as possible all hand work should be avoided, and automatic receiving and distributing should be employed even at the most distant points. Careful tests over comparatively long periods of time have shown it practicable to transmit the signals over thousands of miles with a variation never exceeding a few tenths of a second.

Second. I suggest that after selecting the Observatory which is to be your authority you receive its signals direct throughout your whole system at least once daily instead of receiving the Observatory signals only at some central station and at another hour retransmitting them from there. After its reception each system may, for one reason or another, utilize some other hour for its special time work.

Third. I suggest that, so far as possible, use be made of automatic recorders, specially adjusted and exclusively used for recording the signals. If it be only a Morse register it is advisable to use it. With a recorder at every important point (such as a branching, distributing or repeating point) responsibility for error or failure can be located quickly and satisfactorily.

Failures or errors in the signals have been repeatedly reported to the writer at the Observatory from distant points, and the Observatory chronograph showed conclusively that at the times of the errors the signals had been sent out absolutely correctly from that point.

Fourth. I submit for consideration, in the light of your experience as telegraphers, this: Wherever possible, the use of duplex or quadruplex instruments should be avoided, and that for the receiving, repeating, and distributing of the signals, instruments should be temporarily substituted which are simple in construction, sure in operation and easily kept in adjustment.

In respect to the final or exact noon signal, this seems to me to be of importance. It must be borne in mind that this is unlike ordinary business telegraphing, for if that final signal is lost it is impossible to regain it by the methods ordinarily employed to regain a lost signal. This final impulse leaves the Observatory a full second in length, but at many distant points, to the writer's knowledge, it has, on occasions, been delayed in its commencement and sometimes prolonged more than the second; errors undoubtedly traceable to mal-adjustment of receiving and repeating instruments, and as I have sometimes thought, possibly due to the more delicately adjusted and variable instruments of the duplex and the quadruplex characters. These time signals are all going in one direction only over the wires and do not require instruments capable of using the wires in the opposite direction. And, therefore, instruments of the simplest sort can be employed for advancing them from one section to another. And a simple switch at the time-signaling period can cause the cutting out of the ordinary sets and the inserting of a time set.

Mr. Eugene F. Carpenter has resigned his position at Farmington, Me., to accept a new one as electrical engineer and superintendent for the Concord, N. H., Land & Water Power Co., which has contracted to supply Concord and vicinity with 5,000 incandescents, 200 arc lights and 600 h. p. of motors. The plan has already been outlined in our columns. The new factories of the Page Belting Co. in Concord will be equipped throughout with electric motors supplied with current by the company.

BROOKLYN EAGLE'S NEW HOUSE—A PUBLIC RECEPTION—

1842-1892.

That time-honored newspaper the *Brooklyn Daily Eagle* celebrates its jubilee year by entering into the possession and enjoyment of its superb new building, at Washington and Johnson streets. Through the invitation of Col. Wm. Hester, for the Eagle Corporation, of which he is president, some three thousand citizens visited the new quarters Wednesday afternoon, July 27, where they were handsomely entertained by music and at luncheon. The entire establishment, from roof to cellar was thrown open to the visitors, every department being in operation as usual in a daily paper office. All fortunute enough to be present were impressed by the completeness and elegance of every appointment for the work and comfort of the staff and employees. The composing-room, on the top floor of the lofty building, is a model of convenient arrangement and is equipped with the most modern forms of stands and cases. Below, the editors and reporters are found with rooms and desks resembling more those found in prosperous mercantile or banking offices than the customary dens and deal tables of editorial departments.

The executive apartments and the business offices—the latter on the ground floor—are in every respect equal in design and finish to the present high standard of the best business and office buildings in New York or elsewhere.

Col. Hester and a number of the staff gave up the afternoon to gracious attentions to their visitors, all of whom will recall with pleasure the hour spent under the *Eagle's* roof, and wish they might live to enjoy a similar pleasure when the centennial anniversary of that excellent journal arrives.

Society and Club Notes.

TORONTO CONVENTION OF EDISON ILLUMINATING COMPANIES.

All the arrangements have now been perfected for the annual convention of the Association of Edison Illuminating Companies, to be held at Toronto, Can., on August 9 and 10. Secretary W. J. Jenks states that the headquarters will be established at the Rossin House, with rooms at $3 and $4 per day. The meetings will also be held there.

The Toronto Incandescent Electric Light Company (Frederick Nicholls, manager and secretary) has arranged an attractive programme for the entertainment of the delegates in the form of a moonlight sail on Toronto Bay, calling at Toronto Island, where refreshments will be provided for the delegates at Hanlan's Hotel, the home of the ex-champion oarsman; also a drive in carriages around the principal parts of the city.

It is probable that a trip to Peterborough, where the shops of the Canadian Department are located, may be made by those in attendance at the convention who may desire to visit them. It is feasible to make such an excursion in one day, leaving Toronto at 9 a. m., arriving in Peterborough at 11.45; taking lunch at the Oriental and spending the afternoon at the Works; leaving at 5.45 and arriving in Toronto at 8.10 p. m. This trip will probably be made on Thursday, August 11. There is every prospect of a large attendance and of some excellent work. The Edison Association has always been noted for the way it sticks to work while the convention lasts. Some little curiosity has been felt as to whether the association will take any action governing its future under the new conditions that affect its parent company; but there are many who see no good reason why the association should not maintain its independent existence.

The present officers of the association are: President, John I. Beggs; vice-president, C. L. Edgar; secretary, W. J. Jenks; treasurer, Wilson S. Howell; executive committee, A. L. Smith, C. P. Gilbert, T. P. Merritt, H. J. Smith.

THE SOUTHERN BELL TELEPHONE CO.—MEETING OF SUPERINTENDENTS AND MANAGERS.

A meeting of the superintendents and managers of the Southern Bell Telephone and Telegraph Company was held last week, on the 13th and 14th inst., at Asheville, N. C.

This meeting was the first of exactly the kind that has been held in the history of the company. The object was to impart some instruction upon details of the business and service common to all the exchanges, large and small; to enable the managers from remote points to become acquainted with each other and to promote a feeling of common interest and ambition. Messrs. Thos. D. Lockwood and Geo. K. Thompson, of the electrical staff of The American Bell Telephone Company, were present, and gave instructive and entertaining lectures. Papers were also read by several of the Southern Bell force.

The Southern Bell Company's officials in attendance were: D. I. Carson, general superintendent, New York; D. G. Black, special agent, New York; J. A. Wotton, electrician, Atlanta, Ga.; C. E. McCluer, superintendent first district, Richmond, Va.; W. C. Hutt, foreman of construction first district, Richmond, Va.; C. P. McCluer, district inspector, Richmond, Va.; J. D. Easterlin, superintendent second district, Atlanta, Ga.; J. A. Owen, foreman of construction second district, Atlanta, Ga.; I. O. Utsey, district inspector, Atlanta, Ga.

There were also in attendance the managers of nearly all the exchanges of the company.

About twelve hours were spent in session work, consisting of the reading of papers and discussions, together with instructive addresses by experts, on Wednesday and Thursday; after which came a drive around the beautiful suburbs of Asheville, and a dinner in the evening, at which speeches were made by Mr. Lockwood, Supt. McCluer, Supt. Easterlin and others. The banquet was festive and memorable in every sense. Mr. Lockwood who began with some weighty and valuable remarks on practical and business topics proceeded to let loose a large installment of his quips and quiddities as a little relaxation after the serious talk of two days, and to the manifest enjoyment of the company. Messrs. McCluer and Easterlin exhibited no less acumen and good sense as after-dinner talkers than they have always shown as practical telephonists.

Secretary and General Superintendent Carson presided over the meetings with his accustomed suavity and dignity, and as chairman at the dinner, amply fulfilled the proper function of drawing out the best and brightest from the speakers of the evening.

DR. ELISHA GRAY ON THE ELECTRICAL CONGRESS.

MR. BONNEY, who has charge of the various congresses connected with the World's Fair of 1893, has received the following interesting letter from Dr. Elisha Gray, chairman of the electrical congress, who is now in London:

(Copy).

LONDON, July 14, 1892.

My dear MR. BONNEY:

I promised to drop you a line from this side and tell you how things seemed to be shaping for our electrical congress to be held in Chicago next year. I have had an extended trip on the Continent, including Italy, Greece, Turkey, Austria, France, etc. Of course, there is not much to be expected from those far off countries in the matter of electricity, but everywhere I found preparations of some kind going on for the great Fair. Casts were being made of the celebrated pieces of statuary in Rome, Athens, Constantinople and other cities.

I passed hurriedly through England and France to join my family in Rome, leaving the work to be done on my return trip. I have had a warm reception in every city, but notably in Vienna, Paris and London, where many electricians reside and where I am best known.

I was presented to the scientific societies in France, which gave me an opportunity to present the matter of electrical congress in the most favorable way. While France and Austria were very cordial in their support, and did everything they could, they are still not able to give that support, in numbers at least, that England will. I find the scientific people here very cordial and quite in earnest, and anxious to make the World's Congress of Electricians the most notable ever held. An active branch of the advisory council will be organized here to co-operate with the American branch in organizing the congress.

One word about the time. It will be fatal to the congress, so far as Europe is concerned, to hold it earlier than the last week in August, but preferably the first week in September. Many of the schools do not close till the last of July, and then the British Association meets early in August this year, and will undoubtedly meet early as possible next year so as to get over to Chicago by the latter part of August—if we accommodate them in the matter of time. Very many of the best electricians here are engaged in college and university work, and it would be very bad policy not to accommodate them. So, if possible, make it the first week in September, but not earlier than the last week in August.

Sincerely yours,
ELISHA GRAY,
Chairman World's Electrical Congress Committee.

NEW YORK ELECTRIC CLUB.

AT a meeting of the board of managers, held at the club-house, July 21, the following were elected members: J. F. Hughes, D. A. Patten, Alex. H. Bauer, H. J. Stanbaugh, J. H. Enholm, Harry S. Marlor, W. S. Hine, Edward Peck, Leonard F. Requa, J. H. Long, George E. Kent, A. G. Greenburg, F. H. Leonard, Jr., and E. W. Seymour.

Letters to the Editor.

IS ACCUMULATOR TRACTION A FAILURE?

I SEE by the papers that there are to be attempts made to revive on the Second Avenue Railway, of this city, and on the Elevated Road in Brooklyn, electric traction by means of the secondary battery.

Remembering the effect that every unsuccessful experiment has on would-be investors in electrical enterprises, and considering the fact that the history of traction, by means of accumulators, is that of one financial disaster after another, is there not some electrical paper that will show the true state of that subject and confer a lasting benefit on would-be investors?

I do not mean this letter for publication, but hope that you may be induced to at least print a list of the disastrous failures attending former attempts in this direction. You can do electrical enterprise no greater service.

ALBERT STETSON.

ROOM 61 DREXEL BUILDING, CITY,
July 25, 1892.

TRANSFORMER TESTS BY DR. J. HOPKINSON.

I HAVE just read your editorial upon the recent tests of Westinghouse transformers by Dr. John Hopkinson. You call especial attention to the high efficiency at light load which is shown in this test. This point can be emphasized even more strongly, as an error is made in the report of Dr. Hopkinson in stating that the efficiency at quarter load is 84.7 per cent. This figure, upon examination of the tests, is found to correspond to the efficiency of the two transformers taken together, so that the efficiency of the single transformer is something over 92 per cent. at quarter load. I have just been informed of a letter from Dr. Hopkinson to the company in London, for whom the test was made, calling attention to this oversight in the report.

I have calculated from Dr. Hopkinson's data the efficiencies for smaller loads than those for which figures are given in the report. The iron loss of 114 watts is practically the same for all loads, and the copper loss at one-tenth load and less does not exceed one watt. When the output is 650 watts, or one-tenth of the capacity of the converter, the energy delivered to the converter is 765 watts, and the efficiency is therefore 85 per cent. At one per cent. of full load the efficiency exceeds 36 per cent., and when only one 50-watt lamp is supplied by the transformer, which is capable of carrying 130 such lamps, the efficiency is over 30 per cent.

There is a very great satisfaction in noting that an American transformer is found to show such favorable results after a most searching and impartial test by an English electrician of such high reputation as Dr. Hopkinson.

CHAS. F. SCOTT,
Westinghouse Electric and Mfg. Co.

PITTSBURGH, PA., July 22, 1892.

STORAGE BATTERIES IN RAILWAY WORK.

I HAVE read with the greatest interest the article of Mr. Macrae, in THE ELECTRICAL ENGINEER of June 29, entitled "The Storage Battery in Railway Work." The example chosen allows him to defend successfully a proposition which merits serious examination and judicious study. By all means possible electric central stations ought to seek to utilize completely their motive power every day of the year and every hour of the day, imitating in this respect the wise example set them by the gas works. To sleep all the summer day under canvas covers, according to the picturesque expression of Mr. Macrae, is for them a harmful rest.

As regards the conclusions given at the end of the article referred to, I may be permitted to recall the fact that I have, quite some time ago, promulgated the same idea. By referring to Vol. XX, page 492, 1886, of *La Lumière Electrique*, you will read the following lines in the course of an article on the Metropolitan Road of Paris: "The use of storage batteries seems much more likely to be indicated on long railway lines passing in proximity to natural sources of power." And then follow several examples for France.

As on this point I am in perfect accord with Mr. Macrae, I would be obliged to you for publishing this short note in your esteemed journal.

EMILE DIEUDONNÉ,
Editor *L'Electricien*.

PARIS July 15, 1892.

ST. JOHNS SINGED; NOT ST. JOHN.

I BEG to state for the information of the electrical trade generally and to many of our friends from whom we have received inquiries, condolences, etc., that the recent destructive fire which occurred in St. Johns, Newfoundland, was at an entirely different place from St. John, New Brunswick, where our electrical plant is located; and that instead of being burned out, we are now making additions to the building in order to accommodate machinery to supply an increasing business.

A. A. KNUDSON,
Electrician.

THE CONSOLIDATED ELECTRIC CO., LTD., OF ST. JOHN, N. B.
New York, July 28, 1892.

THE VACUUM LIGHTNING ARRESTER.

I SEE on page 50 of your last issue, an inquiry that I can answer if no other response is forthcoming. A lightning protector consisting of a partially exhausted globe, with two electrodes sealed in it opposite to each other, one connected to line and the other to ground, was invented by the late Mr. C. F. Varley about twenty years ago I believe, and is still in use in connection with submarine cables under the name of the Varley protector. It is credited with being very sensitive, but formerly had the disadvantage that occasionally—I presume from imperfect sealing before the days of electric lamps—the vacuum would disappear.

A. E. KENNELLY.

EDISON LABORATORY, ORANGE, N. J.

[We have received other communications in the response to our inquiry. EDS. E. E.]

THE MECHANICAL EXHAUSTION OF INCANDESCENT LAMP BULBS.

THERE appeared in the issue of your esteemed journal of July 20th an article under the signature of J. W. Packard upon the subject of "Exhausting Incandescent Lamps by Means of Mercury Pumps." We have carefully perused this article and desire to call your attention, as well as that of the public generally, to several statements which occur therein.

In the first place the manner in which Mr. Packard summarizes from an article by Prof. Thomas, of the Ohio State University, is noteworthy.

This will become evident from the two following paragraphs, the first quoted from Prof. Thomas's article which appeared in THE ELECTRICAL ENGINEER of July 13th, and the other from the article of Mr. Packard, above referred to. On page 39, column 2d, of your July 13 issue appears the following statement by Prof. Thomas:

> When the sorting and grading were satisfactorily completed and the letters on the lamp bases examined, it was remarked that the two lots which were least blackened were of the makes which are advertised as exhausted by mechanical pumps. That they should both be so much alike in blackening, and both only one-half as much blackened as the least blackened of the mercurial exhausted lamps, is, to say the least, worthy of notice. It is, of course, not established that the observed freedom from blackening is due to the absence of mercury vapor in the lamps, as the makers claim, but if investigation should establish the claim the mercury pump will probably become once more a laboratory instrument.

On page 57, column 2d, of your July 20th issue appears the following statement by Mr. Packard:

> In the recent test by Prof. Thomas at the Ohio State University, the "Packard" lamps, which are exhausted by the mercurial process, showed considerably less blackening than any of the other makes, among which was the "Beacon," which is exhausted by the mechanical process.

We leave it to your judgment, and to that of the public generally, whether Mr. Packard has correctly interpreted Prof. Thomas.

In the second place, in estimating the cost of exhausting lamps by mercurial pumps, Mr. Packard fails to take into account at least three very important items, which, when added to his column, will materially increase the sum total.

These items consist of: First, the power required to run the air pumps by which the mercury pumps are operated. Second, the electrical energy consumed in incandescing the filaments during exhaustion; and, third, the rent for the large floor space necessary for the mercurial pump plant.

Furthermore, Mr. Packard has given very low figures for the expense items which he has mentioned, so low indeed that it is very doubtful if they could be attained under the most favorable circumstances.

It is incontestable that lamps can be more economically exhausted on our metallic pump than by mercury, but it is not alone in the saving of expense in the pumping department that our metallic vacuum pump is of the greatest advantage.

We consider that the superior quality of lamps, which is largely due to our method of exhausting, is of more consequence to us as manufacturers and to the public generally than the mere saving of a few cents per lamp in the cost of manufacture.

The standard quality of our lamp, which the public is rapidly coming to appreciate, ought to be taken as sufficient proof of the above statement.

The difficulty with which Mr. Packard invests the detection of leaky lamps, among the large number which we simultaneously exhaust, is purely imaginary, since our improved appliances render such detection an easy matter. In addition, the improved mechanical construction of our lamps renders leaks of rare occurrence.

It should also be borne in mind that the amount of carbonaceous vapor which is left in our lamps is much less than the mercurial vapor remaining in those exhausted by mercurial pumps.

This trace of carbonaceous vapor, small as it is, disappears on burning the lamp, leaving a practically absolute vacuum, while the mercurial vapor exercises its injurious effects throughout the life of the lamp, being the most potent cause of blackening, since it acts as a conveyer for the transmission of minute particles of carbon from the filament to the interior wall of the bulb.

BEACON VACUUM PUMP AND ELECTRICAL COMPANY.

BOSTON, July 26, 1892.

Literature.

Die elektrische Beleuchtung industrieller Anlagen, etc., für Nicht-Elektrotechniker. By H. Blessinger. *Kiel and Leipzig,* 1892. Lipsius & Tischer. 140 pp. 6¼ x 9¼ inches. Paper. Price, $1.

THIS is a short treatise on electric lighting, giving the description of the principal types of apparatus now in use in Germany. An appendix gives very complete information as regards dimensions, cost, etc., of the principal German machines, and also full information regarding the Hagen accumulator. We are hardly prepared to acknowledge that the work is well adapted for non-electricians, as the title implies.

INDIVIDUAL SELECTION OF ELECTRICAL OBJECTS.[1]

BY S. S. BOGART.

THE application of a selector to any circuit to reach any of the objects desired and the necessity for such a device is doubtless as apparent to you all as is the application of the current to telegraph, lighting and power. In the individual call-bell circuit we have a combination of electrical impulses on a transmitter (or sent by an ordinary Morse key) and selector shaft that correspond with each other. Any other than the combination for that instrument throws in a false combination, upsets the pawls and restores the selector's sector to zero. This principle applied to all the other selectors on the circuit acts in a like manner. The call-bell set consists of a key, transmitter, relay, sounder, answer-back and bell. When the combination has properly completed its phase the answer-back is vitalized and it automatically transmits the assurance back over the wire that the object has been reached and the bell is ringing. The sounder is always in circuit, except, when the bell is ringing, then all of the battery is transferred to the bell. But three cells of ordinary Callaud or gravity battery are necessary for the entire circuit. The advantages of this system in saving time in calling offices has been carefully gone over, and it is an undisputed fact that upwards of one-third of the time is spent in calling. The greater the number of wires the more difficult the problem of raising the one or two operators at some points. As we increase the number of wires on the poles, we increase the cross-fire or induction and escape When the relay adjustments change to such an extent as to affect the sounder, the selector will work so long as the armature of the relay moves to its contacts.

In connection with the use of arc lights, the selector system affords a simple and effectual means of starting and extinguishing lights at various hours upon the same circuit. Incandescent circuits and those used for the transmission of power are equally subject to the control of the "combination selector," and in all branches of lighting and power work the system may be applied to advantage. The automatic attachment both insures safety of operation and announces to the transmitting point the completion of the desired work, while the economy resulting from its use on circuits of wide extent of great activity will be an important consideration to every company employing electric lights or power.

The use of these instruments on the police and fire circuits of cities enables an alarm to be confined to such posts or stations as are at the moment required, instead of arousing the entire department, as is generally the case. The call may be limited to a single station, or to a group of them, or to a whole district, according to the "combinations" employed.

In "Village and Town" telephone exchanges, and upon long-distance and all private lines, the application of these selectors will insure complete privacy by the exclusion of all intermediate telephones. In circuits of minor importance the central office may be entirely dispensed with, each subscriber being supplied with his own combination and those of the others upon the same circuit. This system permits calls to pass noiselessly through intermediate telephones, thus avoiding the vexatious ringing of all bells which now occurs when one subscriber sends a signal to another. The fact that no message will be audible to any subscriber other than the one immediately interested, opens what is practically a new field for the development of the telephone.

While for obvious reasons, it is not convenient to discuss in detail the use to which this system is now applied in connection with military and other government service, it may be pointed out that it (1) gives at any moment to headquarters, or other proper authority the control of the line; (2) allows confidential intercourse between any two points on a circuit without including intermediate stations; (3) gives to the commander of a battery of guns or torpedoes the faculty of discharging at will any one weapon upon a circuit without danger of affecting the others, thus dispensing with the necessity of having a separate wire for each individual weapon; (4) places in the hands of headquarters or its delegates the exclusive power of effecting any electrical circuit, by giving them the means of changing the combinations of the various stations at pleasure, by which no station can be actuated except by one familiar with the respective "combination."

---

[1] Abstract of a paper read at the meeting of the Railway Telegraph Superintendents, Denver, Col., June 16, 1892.

A more recent connection and one that is received with marked favor by leading railroad men is its application to the Leonard interlocking block signal and the Leonard train order signal. In the former it enables us to use a wire for other than blocking trains, thus saving a duplication of wires. In the latter the train dispatcher is master of the situation, and controls as many signals as he desires from his table; and receives assurance of the fact from the return signal that the object sought has been attained.

CONDENSING WITH TRIPLE-EXPANSION ENGINES—A CORRECTION.

I FIND in my article a typograpical error, which should be corrected. The Kuhn engine (page 79) has a low-pressure cylinder diameter of 48 inches, not 78 inches. Further, the capacity of the Van Vleck engine is 600 to 800 h. p., not 500 to 800 h. p.

E. EGGER.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

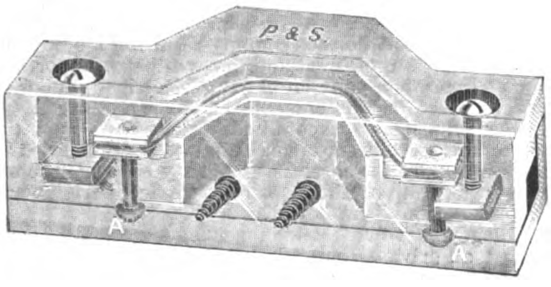
Advertising tells, like hot weather, and in spite of it.

THE BEACON VACUUM PUMP AND ELECTRICAL CO. IN CANADA.

MR. H. S. KALISKE, business manager, and Mr. W. E. Nickerson have recently visited Ottawa, Ont., on a prospecting tour, with a view to establishing an electrical factory in the dominion, and preferably in Ottawa. The Beacon Vacuum Pump and Electrical Company, after a business of one year in the manufacture of their mechanically exhausted lamps, are contemplating the establishment of several factories in various parts of the continent. Owing to tariff restrictions they must manufacture in Canada in order to avail themselves of the markets in British America for their lamps. It is significant to observe the reaching out into new fields by this enterprising company.

THE PASS & SEYMOUR COVERED MOTOR CUT-OUT.

AMONG the ingenious and useful specialties recently introduced by Messrs. Pass & Seymour, of Syracuse, N. Y., is the new covered single-pole motor cut-out, shown in the accompanying illustration. This cut-out is designed for motors on power circuits, and as it has a fuse 3 inches long it is especially adapted for 500-volt circuits. The channel which encases the fuse is of such a shape as to cause the fuse to be bent at four angles, which adds to the efficiency, as it is difficult to get a fuse to arc around an angle. In order to remove the cover for the purpose of renewing the fuse it is only necessary to loosen the screws A A half a turn.



PASS & SEYMOUR COVERED MOTOR CUT-OUT.

In common with other goods manufactured by this company, the cut-out is made of highly vitrified Syracuse china.

NEW ENGLAND NOTES.

THE AMERICAN MICA COMPANY, of Boston, are calling attention in this week's issue to the large stock of mica which they always keep on hand for electrical purposes. Their office is in 620 Atlantic avenue, and they are now right amongst the electrical trade, and guarantee prompt service, best material and lowest prices.

S. C. NIGHTINGALE & CHILDS, of Boston, have recently supplied their magnesia sectional steam pipe covering to the following plants: U. S. Marine Hospital, Chelsea; the Cambridge Power House of the West End Street Railway Company, of Boston; the Lowell and Suburban Street Railway Company, Lowell, Mass.; New Haven & West Haven Street Railway Company, New Haven, Conn.; State Capital, Hartford, Conn., besides a large amount of work in mills, as much as $2,500 worth of magnesia having been used in the Arlington mills, Lawrence. In the Lowell station they also covered with magnesia in addition to the steam pipes, the steam drums, heaters, receivers, cylinder connections, and all steam heated surfaces, and in New Haven they covered the whole surface of the three Manning boilers recently installed by Westinghouse, Church, Kerr & Company.

MR. NEWTON L. SCHLOSS, of the Ries Electric Specialty Company, of Baltimore, was in Boston this week and has established a number of agencies in this territory for the Ries regulating socket, the demand for which is becoming quite large.

THE IRON GRAVITY CELL OF THE STANDARD BATTERY CO.

FOR many decades the gravity cell has held pre-eminence as the most suitable one for producing electric current for local batteries in telegraphy. When we mention gravity cell we refer directly to that which is commonly known as the "crowfoot" battery or Callaud, which is the only closed-circuit battery that has heretofore been used for the purpose referred to. It is not necessary to state that the cost of running the battery described, *i. e.*, loss of zinc, amount of care required for its attention, low potential, high internal resistance, and the same increasing as the battery diminishes in force. With the new discovery in chemical electricity made by Mr. A. P. Willoughby of Chicago, Ill., the zinc crowfoot or electrode is entirely dispensed with and an electrode of iron, under peculiar alloy treatment is substituted for the same. Among the special advantages of this discovery are the saving between the cost of iron and zinc as electrodes, and the avoidance of the cost of cleaning the crowfoot or zinc electrode, from time to time, of the corrosion that takes place in the action of the gravity battery. The iron electrodes need no care, and no cleaning; when the iron electrode is used up all that is necessary is the replacing of another electrode.

Last and not least, of the advantages is the reliable, constant current, increasing in strength gradually from month to month. This is shown by the battery which has been in practical use in telegraph work on the C. B. & Q. Railway for over seven months. The current is higher in its potential and its amperes and very much lower in its internal resistance than at any time since the batteries were set up.

A test was made by one of the most prominent professors of chemical electricity in the Northwest, which demonstrated the following: "Two of your iron gravity cells were placed on a closed circuit through 5 ohms resistance in the early part of May, and up to the present date, June 10, 1892, they have been running constantly. The internal resistance has fallen from 3.5 ohms per cell to a little less than .9 of an ohm, while the current has increased from .6 to 1.08 ampere. The internal resistance fell rapidly during the first few days, and the current increased in the same manner. The cells promise a great deal for telegraphic and similar purposes."

In corroboration of the statement made concerning the action of the battery with the C. B. & Q. R. R., the inventor refers any one to Mr. W. W. Rider, of Chicago, the superintendent of the telegraph system of the road mentioned. There are quite a number of superintendents of different telegraph systems in the United States who have been testing this battery in their own service from one to nearly three months. There are now over 40 of the superintendents of the different trunks line throughout the United States testing these batteries under their own supervision and reporting favorably on their experiments.

The simplicity of the introduction or adoption of this battery by any company is one of its most remarkable features. The iron electrode, as described, has simply to be put in place of the zinc. There is no change of cells, and no change of elements excepting the iron electrode.

The Standard Battery Company of Chicago, Ill., 324 Dearborn street, have purchased the rights and franchises of Mr. Willoughby to this discovery and will soon be prepared to fill orders for these batteries. The battery is known as the Standard Battery Company's iron gravity battery. All correspondence referring to this battery should be addressed to the company.

VOL. XIV. AUGUST 10, 1892. No. 223.

ELECTRIC LIGHTING IN ENGLAND.

BY

H Scholey

IT was reasonably expected that last year would have seen in England a large increase in electric light generating stations, but such expectations were not realized, for outside the metropolis there was scarce any attempt to undertake a public supply of electricity.

The progress that has been made during the last twelve months has been for the most part confined to London, and here there has been a quiet but none the less remarkable development of electric lighting business. There is scarce an important street in London in which electric light cables are not already laid, and in many places a supply of electricity has been running uninterruptedly for many months. But the larger companies must make many more lamp connections before they run their stations economically; judging from appearances, however, this consummation will be soon reached.

Having regard to all circumstances, it is yet too early to expect the London companies to show much profit, and with the exception of the St. James Company only nominal dividends have been declared. There is great praise due to the electric light companies for the manner in which they have pushed on their work, but it is to be feared that some of them will have an up-hill struggle before they stand on a firm commercial foundation. They may prove scientifically the correctness of certain theories, but unfortunately it may be electric light companies will only be deemed successful in London according to the size of the dividends they may earn. Electric light companies again, like other commercial concerns, are governed solely by the law of supply and demand. At the present price of electricity, the most remunerative customers are the clubs, shops, and theatres, and it seems most probable that the companies which were formed to supply purely residential districts will not make great profits. The householder who takes the electric light knows that it costs him much more than gas; he is therefore sparing in its use. For this reason it may happen that his electric light bill is no bigger than his old gas bills; but while this is very satisfactory from the consumer's point of view, it is more than doubtful from that of the supply companies. It is difficult to obtain figures as to the increase of lamps, but it would not be an exaggeration to say that there are nearly three times as many lamps burning in London at the present moment as there were last year.

A curious fact in the extension of the electric light is that the large provincial towns have practically done nothing. The smaller towns—in some cases villages—have shown greater appreciation of the advantages of electric light. This may be in a great measure owing to the action, or rather want of action, of the municipal bodies throughout the country.

The inquiry made by the Board of Trade in 1889 into the various schemes for the electric lighting of London did much to stimulate in the minds of the public a desire for the electric light; there was then displayed great eagerness on the part of municipal bodies and joint stock companies to secure provisional orders which would enable them to start a public supply. The Board of Trade, having prominently before their minds, the burdensome results of the gas and water monopolies, encouraged municipal authorities to undertake the supply of electricity; this encouragement, together with an exaggerated notion of the value of a provisional electric light order, led many town authorities to take powers.

Since 1888 over 120 provisional orders have been granted; of these 78 are in the possession of local authorities and 37 are owned by companies. Such figures might betoken an unwonted activity, but when we come to follow them to their results, they are disappointing. For of the 78 orders obtained by municipal authorities, not one has been proceeded with; they are for the most part shelved. There are perhaps at the outside, four cases where it has been decided to build central stations. Throughout the whole of the country, there are only two central stations worked by municipal authorities, Bradford and St. Pancras, powers for which were obtained in 1882.

The work carried out by the companies under their provisional orders shows most favorably when compared with the municipal bodies, for under 37 orders 22 generating stations have been built and are working; were it not that local restrictions of an onerous nature had been imposed, the number would have been much higher. These facts on the face of them are significant, and the advocates of joint stock enterprises are at no loss for arguments in favor of electric lighting work being carried out by companies. It cannot be denied that local authorities have shown little regard to their duties under their orders, but I believe this apathy is mostly due to the fact that they never intended to supply electricity. Municipal authorities opposed companies entering their districts, because it was thought they could make a handsome bargain by offering the concession to a company, with special provisions for their own advantage. A glaring instance of this trafficking occurred recently when a provisional order was sold by a municipal authority to a company for £1,500. Electric light companies have been well tied down by Parliament, and to be forced to buy provisional orders will not enhance their future prosperity. However, it will be found perhaps that the municipal authority has entered upon a mistaken policy.

There is no doubt that the shelving of electric light orders by municipal bodies has had a most deterrent effect on the progress of electric lighting, for it is clearly shown that had these orders been in the possession of companies a good deal would have been done. At the same time there is perhaps something to be said on behalf of the municipal authorities not undertaking lighting, for it may be claimed that until quite recently there was no instance of municipal work to guide them; it is only within the last few months that the stations of the corporations of Bradford and St. Pancras were able to show a return on the money sunk.

The Board of Trade have power to revoke a provisional order, if at the end of two years from date of the order, it is found that compulsory works have not been carried out. Now, as many of these orders have been in existence two years at the end of June, 1892, a firm attitude on the part of the Board of Trade, together with the good results obtained at Bradford and St. Pancras will do much to press forward electrical matters. At the same time it is not to be expected that the Board of Trade will act hastily in the matter, for there are many district, for which provisional orders have been obtained, which could not give a fair return on an electric lighting station.

It is an open question who can best supply the electric light; certainly a municipal body with its grip of local wants, and an organized staff at its command, holds a strong position; but the danger will be in selecting a system best adapted to its requirements. The instance of Bradford successfully carrying out a system of low tension is very well as far it goes, but when they speak of supplying the whole of the town, five miles by three, with a feeder system, it seems as if there were matter for serious consideration.

On the other hand a company brings usually an accumulated experience without which no town lighting can be well carried out. To sum up, electric lighting in London may be considered to be rapidly advancing, but in the country, generally, much remains to be done before there is a good public supply.

THE BLACKENING OF INCANDESCENT LAMPS.

BY

E. E. Cary,

The recently published life tests of incandescent lamps, by Prof. Thomas of the Ohio State University, have brought prominently and disinterestedly to the notice of the electrical fraternity the wide range in the blackening of the lamps during life, even when they have not been subjected to the wide variation in voltage which occurs in many of the central stations, and with which all lamp manufacturers have to contend.

Prof. Thomas' scale of blackening runs from 10 to 100, the latter representing the most blackened lamps, and he adds in his article on page 39 of The Electrical Engineer of July 13, the following: "It was remarked that the two lots which were least blackened were of the makes which are advertised as exhausted by mechanical pumps. That they should both be so much alike in blackening, and both only one-half as much blackened as the least blackened of the mercurially exhausted lamps, is, to say the least, worthy of notice. It is, of course, not established that the observed freedom from blackening is due to the absence of mercury vapor in the lamps, as the makers claim, but if investigation should establish the claim the mercury pump will probably become once more a laboratory instrument."

Naturally Prof. Thomas does not wish to affirm that the excessive blackening in mercurially exhausted lamps is due to the presence of mercurial vapor, but does state most positively that the lamps pumped by the metallic non-mercurial process showed but one-half of the blackening of the least blackened of any of the others. As this matter is of much importance to central stations, doing away almost entirely with seconds, which have to be used about the stations, and also with the many complaints from consumers on the score of blackened lamps and diminished light, it has naturally awakened much speculation as to whether the blackening is really due to the presence of mercurial vapor or not.

Further, the question arises, Why should there be such a variation in the blackening of individual lamps exhausted by the mercurial process? The latter question is readily answered, as it has to do entirely with the construction of the filament.

In a properly constructed filament three important conditions must be fulfilled. 1. It must be as dense as possible. 2. It must be uniform. 3. It must be elastic. That is to say, should all filaments be equally dense, uniform and elastic, and treated alike during exhaustion, the blackening would not vary. The wide range in blackening shows how far lamp manufacturers are at variance.

The writer after a year's experience with the metallic non-mercurial pump, in the exhaustion of several hundred thousand lamps, feels confident that ultimately it will be proven to the satisfaction of all, that the blackening in the lamps pumped by the old process, in a great measure is due to the presence of mercurial vapor. Repeated life tests have shown that with the same kind of filaments, the blackening is invariably greater when the lamps are mercurially exhausted. The vapor of mercury never disappears even if the lamp attains a life of from 2,000 to 3,000 hours. Its nature may be changed, for, when the lamp is broken under mercury, the vapor does not condense, but a small bubble from $\frac{6}{64}$ to $\frac{10}{64}$ of an inch is always visible.

The bubble of residual carbonaceous vapor in a lamp exhausted by the metallic non-mercurial pump may vary from $\frac{3}{64}$ to $\frac{5}{64}$ of an inch in diameter but after 75 to 100 hours' burning it entirely disappears, and no trace of one is visible even with the aid of a magnifying glass. In consequence, there is attained practically a perfect vacuum and no medium exists to assist in carrying the minute particles of carbon from the filament to the inner walls of the bulb. When this medium does exist in the form of mercury vapor, it affords an easy passage for the loosened particles of the filament to the bulb.

One important matter must be borne in mind when speaking of the blackening of lamps. Ordinarily one might think that the diminution of light is entirely due to absorption by the blackened walls of the bulb, whereas in reality this accounts for but part of the loss, for the filament is reduced in mass proportional to the blackening and consequently offers an increasing resistance to the E. M. F. which latter we may assume constant. Therefore the filament itself constantly emits less and less light, which, together with the increasing absorption, rapidly destroys the value of the lamp. This will impress upon the mind that if disintegration of the filament can be stopped, the normal strength of the filament will be retained, the lamp will not blacken, but will remain bright to the eye till broken.

Since but one company has operated the metallic non-mercurial pump (though their lamps have appeared under different names), others interested have been unable to determine the matter for themselves. It is to be hoped however that disinterested tests will be made during the coming year, to prove to the satisfaction of all interested parties the causes of the great *bête-noir* of blackening.

AN EPISODE IN THE LIFE OF THE LATE CYRUS W. FIELD.

A correspondent of the London *Times* thus describes the scene on board the "Great Eastern" at the moment of the breaking of the first Atlantic cable on August 2, 1865. The cry, "The cable is gone!" produced an effect, he says, not short of consternation on every one save one man —Cyrus Field. He rushed up on deck when the fatal announcement reached his ears in the saloon, made his way through the silent despairing group astern who were gazing into the sea in which thousands of fathoms deep their hopes were buried, satisfied himself that the cable was broken beyond remedy, and then, calmly surveying his associates without a trace of agitation on his face, said, "Well, it's so. I must go down and prepare a new prospectus immediately. This thing is to be done," and stalked quietly back to his cabin, where he set to work to write out the proposals for a new cable ere the end of the other had well settled down in the Atlantic.

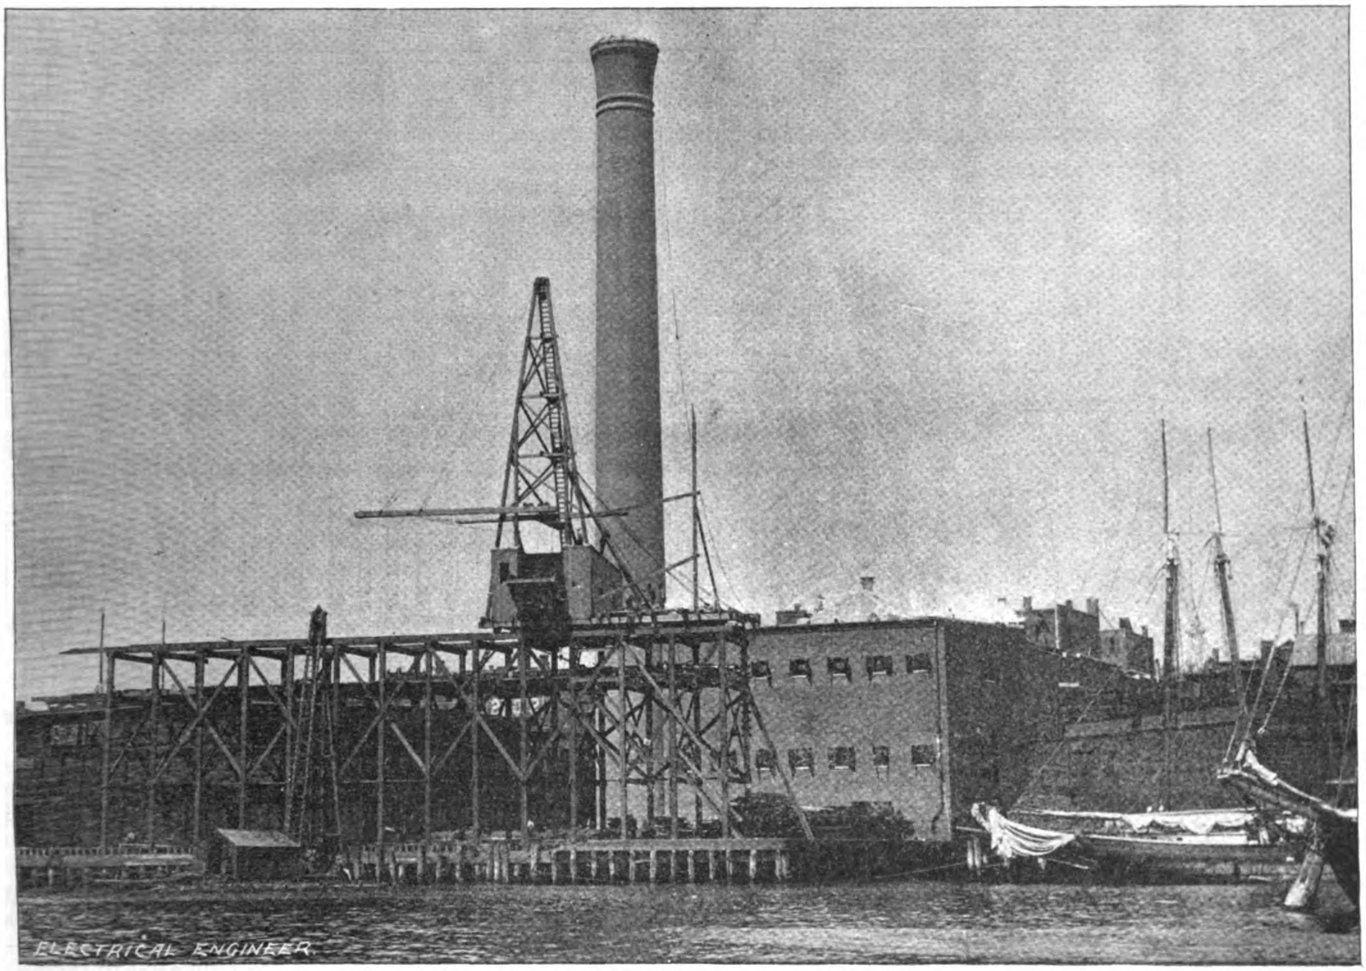
The New Station of The Edison Electric Illuminating Company of Boston.

BY

A. C. Shaw.

I.—INTRODUCTION.

IN the history of the development of electric lighting, as represented by the incandescent lamp, much of the interest is due to the fact of its immense and growing popularity. Incandescent lighting sprang into existence little more than a decade ago, when the combination of an engine and a dynamo furnishing current to a hundred incandescent lamps was looked upon as a wonderful thing, whereas, to-day, a company may commence to erect a station of from 10,000 to 25,000 h. p. without exciting any great attention except from those directly interested. Such a station it is proposed to describe in the following article, a station which may be looked upon as a model of the most advanced ideas in electrical engineering, and which has been designed after a vast amount of investigation and personal examination of the most noted central stations in this country and in Europe.

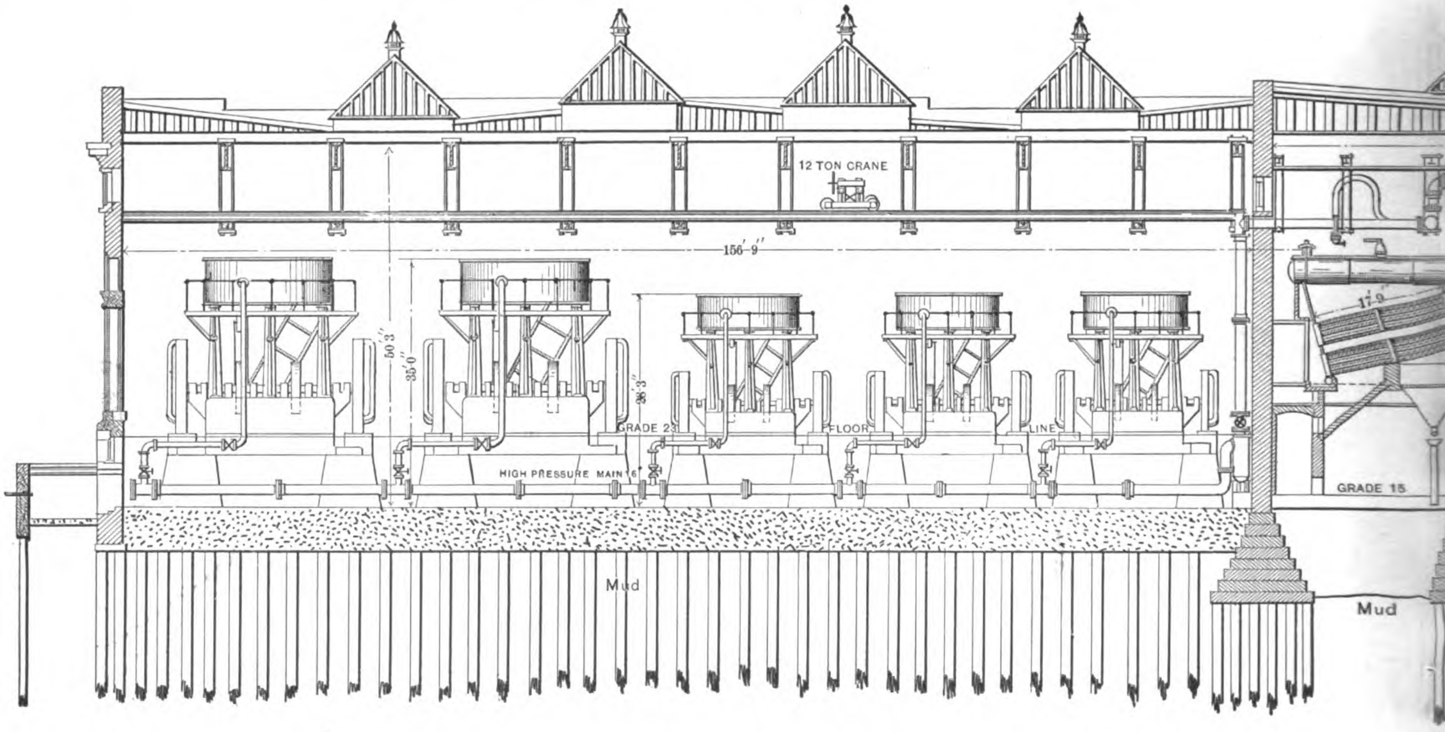


THE STATION FROM THE HARBOR.

The new Edison station in Boston is distinctly new in all its designs, as applied in this country, and it is interesting to note the different phases of central station design leading up to the plant to be described. In the first days of electric lighting, in 1881, the high speed engine of small unit was used and for many years reigned supreme. It is worthy of note that the advent of the incandescent light gave a wonderful and marked impetus to steam engineering from the necessity for an absolutely uniform speed. Gradually the size of the units was increased until many of the more modern stations are equipped with generators up to 200 h. p., two of them being driven from a 400 h. p.

engine. The Corliss engine has also come into very extensive use, though more for arc than incandescent lighting, as it can be readily seen that in an incandescent station the electrical unit can be as large as desired, whereas, in an arc station, it can never be over 50 or 60 h. p.

About four years ago the Philadelphia and New York style of Edison station was designed, and though these have given excellent satisfaction, yet the more progressive of electrical engineers have still thought that important improvements could be made, and have gradually developed the large multipolar type of generator, coupled direct to a triple-expansion condensing engine of the vertical or steam hammer type. The larger unit, with engine and generator combined, has long been in use abroad, and there are many magnificent stations of this type in all parts of Europe. In Berlin all the central stations have triple-expansion engines, and English and Scotch engineers have well sustained the reputation of this high type of engine by their unrivaled successes in ocean steam engineering, where the vertical engine is seen in perfection. In America, the economy of a station from the engineering point of view has been somewhat neglected in the past, but of late years more engineering ability has been devoted to the steam practice in electric stations, and better and more carefully designed stations are now becoming more general in this country. The new Boston Edison station may be looked upon as an example of the highest type of central station yet designed, and is therefore well worthy of a thorough description.



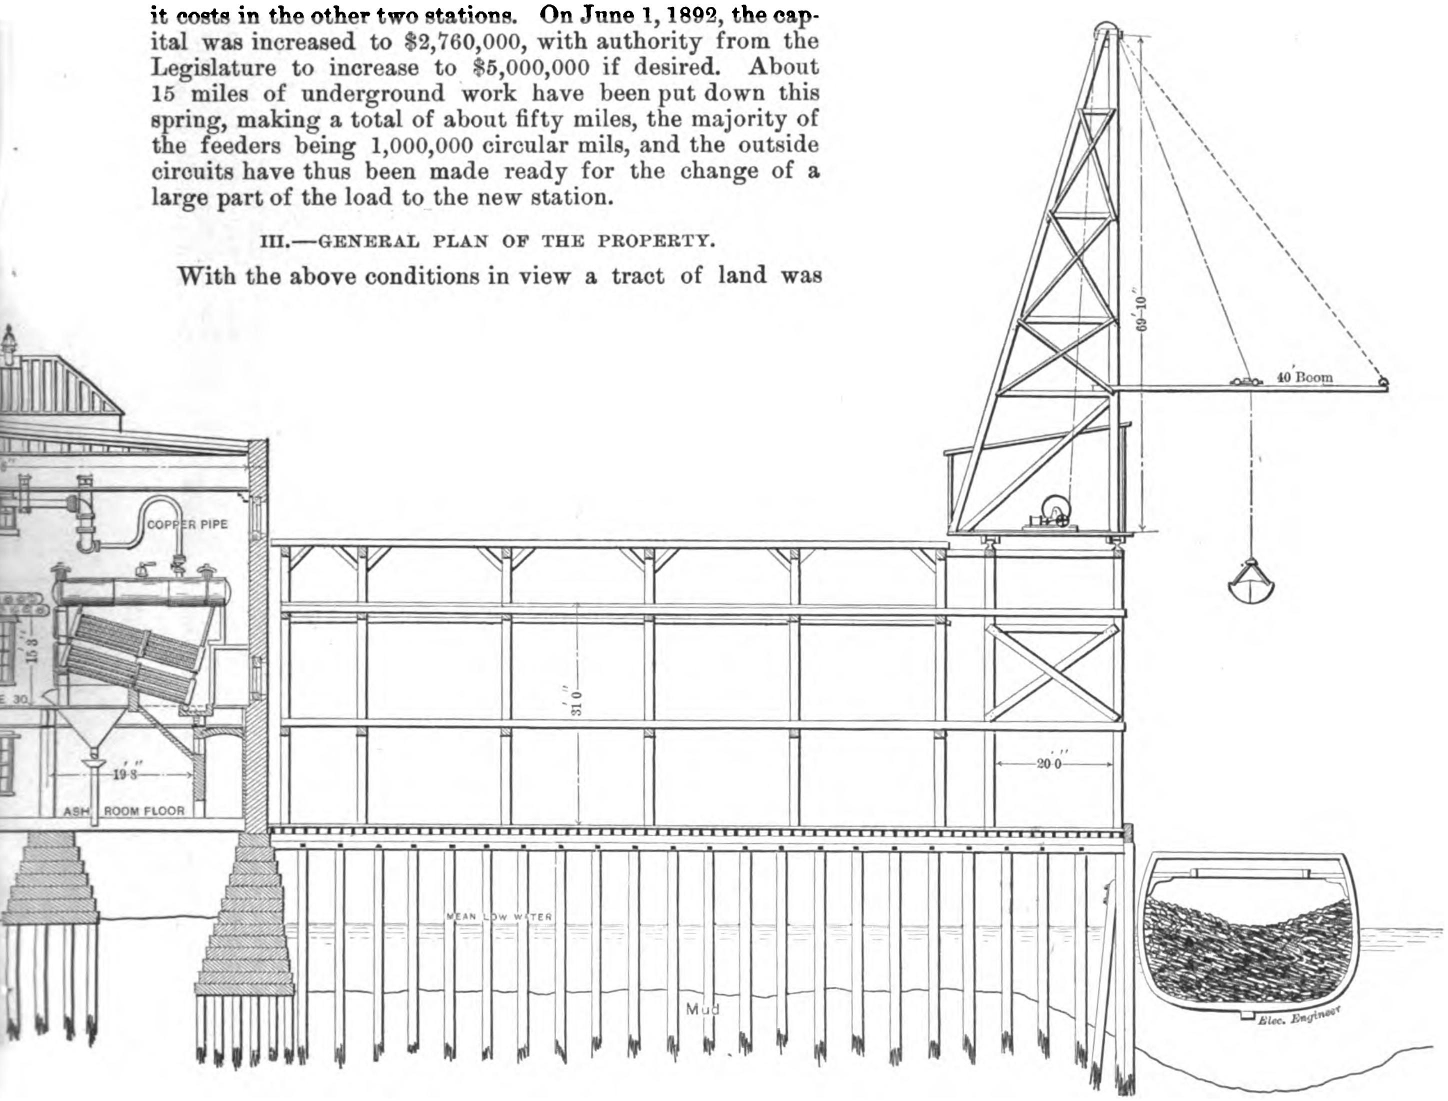
LONGITUDINAL SECTION THROUGH THE NEW STATION OF

II.—PREVIOUS HISTORY OF THE COMPANY.

A few words as to the previous history of the Edison Company, of Boston, may be found interesting at this time. The Edison Electric Illuminating Company, of Boston, was formed in the early part of 1886; and was at that time a sort of adjunct to the Bijou Theatre, which building was lighted then from a small plant in the basement of a printing office, consisting of a 75 h. p. Armington & Sims engine and two dynamos. This plant was bought by the company, which was organized with $100,000 capital. More room was soon required, and the plant was removed into an old stable occupying the site of the present boiler-room of the Head Place station. Here a station was laid out for 1,600 lights, with three engines and six old type dynamos. In the summer of 1887, the present station was erected—one story high, and having a capacity for 20 150 h. p. engines and 40 dynamos of the No. 20 type. This was probably the largest incandescent station in the country at that time, and Mr. J. H. Vail, who laid out the station, was looked upon as a very rash and visionary man. In June, 1888, the interior of the dynamo-room, with all the apparatus, was completely destroyed by fire, some fourteen dynamos being consumed at that time. Notwithstanding this, however, current was again turned onto the lines 20 hours after the fire was extinguished, some of the apparatus having been expressed from Schenectady shortly after the fire originated, and the station was made thoroughly fireproof. The capital about this time was increased by several stages to $500,000. In September, 1887, Mr. C. L. Edgar, a young electrician who had already had a wide experience in Edison central station work, was appointed general manager of the company. From that time the work has steadily increased, and the business has prospered in his hands. In 1887, about ten miles of underground work was laid down, and the overhead lines gradually abandoned. In January, 1888, the second station, on Hawkins street, was started with a capacity of 12 engines and 24 dynamos of the usual type then in use. In the fall of 1890 three more stories were added to the Head Place station and the capital increased to $2,000,000. This was not sufficient, however, to meet the growing demand for incandescent light, and in the spring of 1890 the company determined that the two existing stations were not large enough—that a large and modern station must be built, and Mr. Edgar was requested to investigate the matter thoroughly. Accordingly, in February, 1890, Mr. Edgar made a trip to Europe and examined carefully many of the important stations in that country, returning in April, 1890, with certain definite and fixed ideas as to the construction of the new station. In the spring of 1891 the property upon which their new station is situated was purchased and ground was broken on Oct. 10, 1891. Mr. Edgar had already determined to have triple-condensing engines of the vertical type, that the new station should be of one story, and that it must be situated on the water front even at the sacrifice of being at a reasonable distance from the electrical centre of distribution. The site of the new station is on Atlantic Avenue opposite the foot of Pearl Street, occupying the old historic spot of the Boston Tea Party, where the tea was thrown overboard from English ships, on December 16th, 1773, by the citizens of Boston, and though, at first sight, it may appear to be far from the centre, yet, in connection with the other two stations, by actual calculation, it is within 500 feet of the electrical centre. It is expected that in the new station steam can be made for less than one-half what it costs in the other two stations. On June 1, 1892, the capital was increased to $2,760,000, with authority from the Legislature to increase to $5,000,000 if desired. About 15 miles of underground work have been put down this spring, making a total of about fifty miles, the majority of the feeders being 1,000,000 circular mils, and the outside circuits have thus been made ready for the change of a large part of the load to the new station.

III.—GENERAL PLAN OF THE PROPERTY.

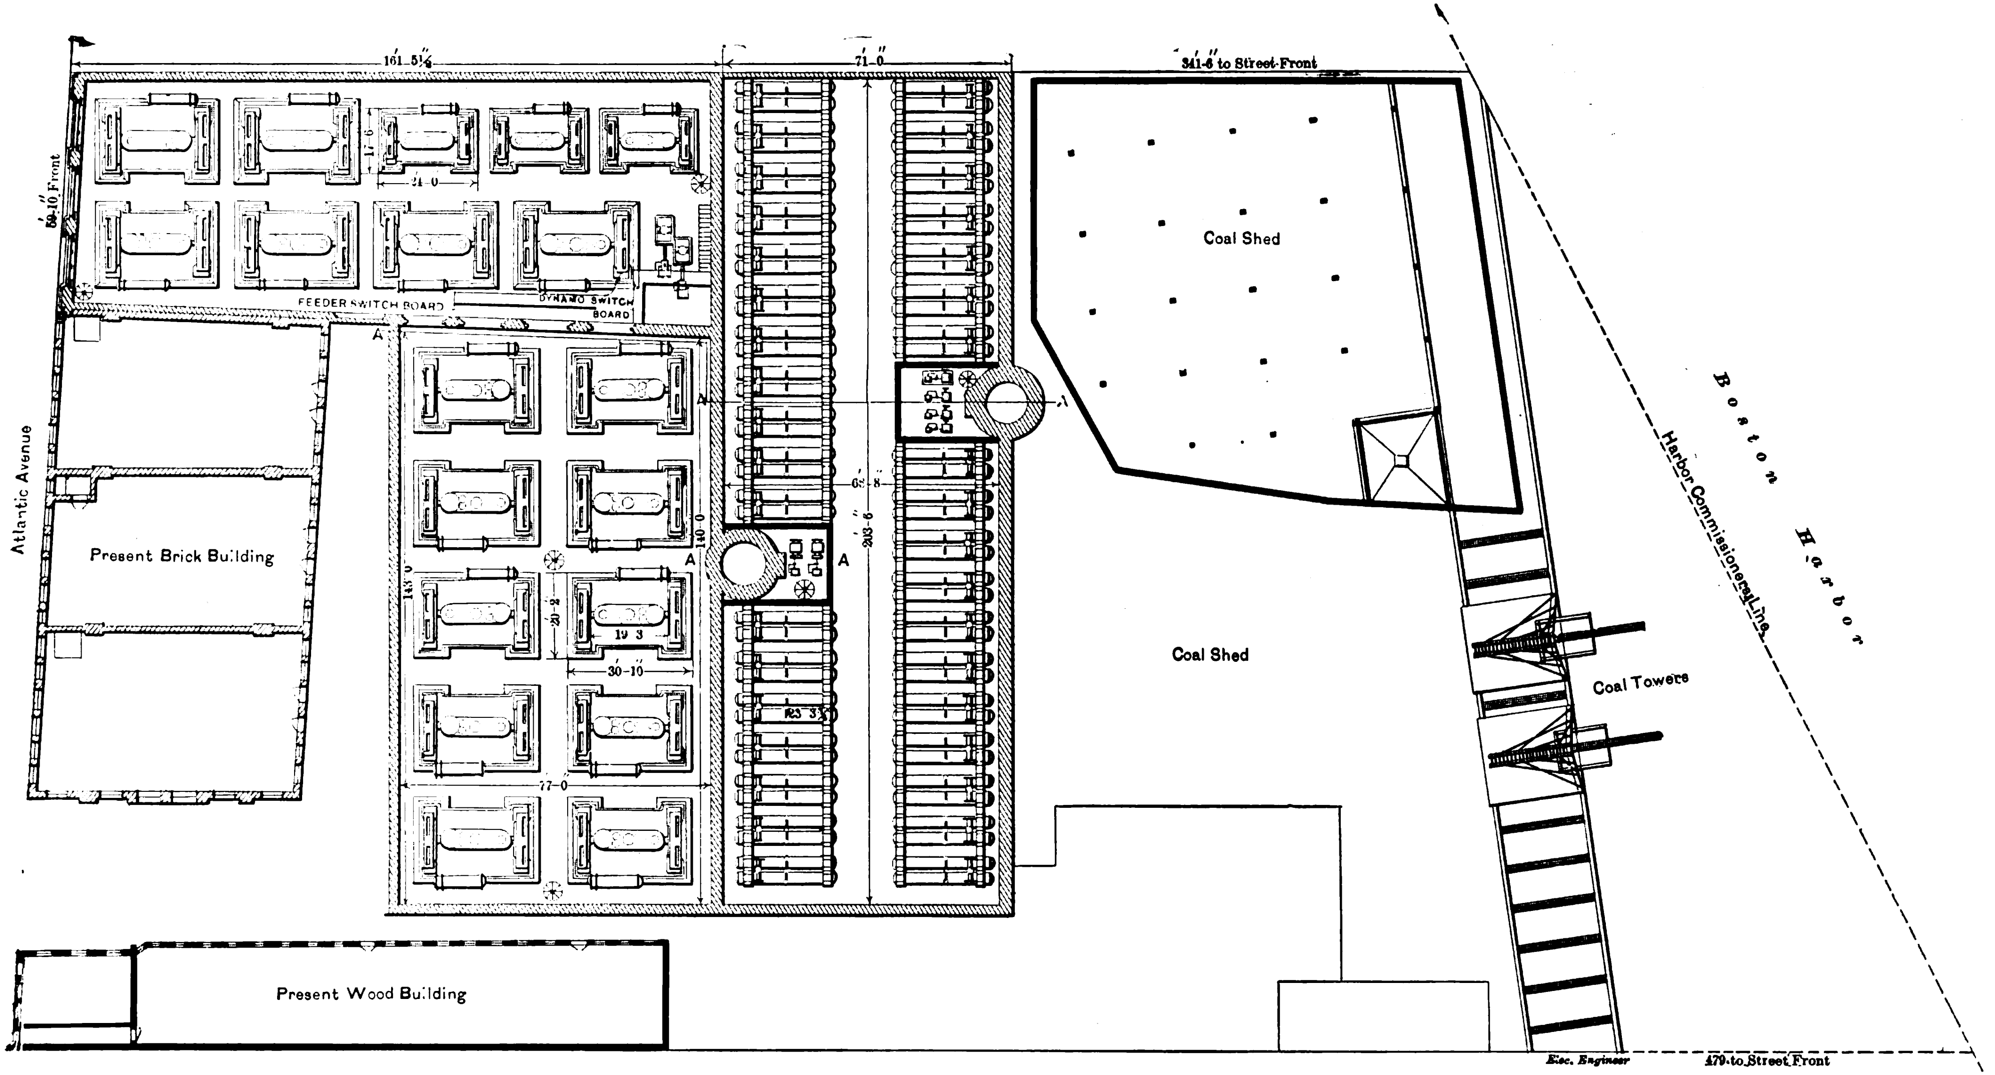
With the above conditions in view a tract of land was secured on Atlantic avenue, the widest street in Boston, where abundant water could be procured for condensing purposes. The property as shown on the engraving on page 122 covers 100,000 square feet, is 240 feet wide on Atlantic avenue, and extends back 341½ feet to the harbor commissioners' line on the North side, and 479 feet on the South side, being 250 feet wide at that point. Eventually the station will occupy the whole of this area but only about one-fifth of this is being built on at present, the dotted line A, A, A, showing the present dimensions of the station, all to the right of this line being for future extension. The present station has a frontage on Atlantic avenue of 60 feet, the engine-room extending back 160 feet, and the boiler-room 70 feet, behind which extends a coal dock about 135 feet. On the end of this are two coal-hoisting derricks, so that coal can be unloaded from the largest coal vessels, the depth of water at that point at high tide being 30 feet. The dock will be covered in with a shed, and will accommodate 5,000 tons of coal. The general plan of the station when the L addition is completed will contain 25,000 h. p., capable of furnishing current equivalent to 600,000–16 c. p. incandescent lamps connected. At present, however, the station is built for 11,250 h. p., consisting of six 1,500 h. p. engines and generators, and three 750 h. p. engines and generators, with fifteen 325 h. p. boilers at 30 pounds of water per horse power per hour. With the increased economy in steam consumption of the triple expansion engines, these boilers will, however, be able to deliver steam for nearly double their rated capacity.



THE EDISON ELECTRIC ILLUMINATING COMPANY OF BOSTON.

IV.—THE WHARF.

The station being built on the harbor front, and there being ample depth of water for large coal vessels, it was an easy matter to provide a large and commodious wharf for the storage of coal, equipped with apparatus for unloading the vessels. A large wharf, therefore, has been built, immediately in the rear of the boiler-room, an excellent idea of the construction being given in the elevation shown on this page, and a photographic view of which is shown on page 119, which shows the entire back of the building and chimney. It has an area of about 18,000 square feet, and can easily accommodate 5,000 tons of coal, the coal being delivered here not only for the Atlantic avenue station, but for the other two stations in other parts of the city. It is built on piles of first quality oak, driven in rows parallel to the stream and ten feet apart, the piles being placed at 4-foot centres. On top of the piles are



bolted two 7 x 14 inch hard pine girder caps, to which are bolted by 1-inch bolts 12 x 14 inch hard pine riders. To these are secured by $\frac{5}{8}$ inch bolts hard pine stringers 6 x 14 inches, running crosswise on the riders, to which is fastened 4-inch spruce plank, securely held in place by 8-inch steel wire nails. On the front of the wharf is built a trestle of hard pine, 20 feet wide and 40 feet high, with iron rails on top, on which the two coal towers travel. Two of these towers, extending above the rails 70 feet, are provided, each containing two Lidgerwood hoisting engines for operating the coal buckets. The wharf will be covered from the boiler-room wall to within 5 feet from the front, by a coal storage shed 30 feet high, and, as has already been stated, some automatic system of conveyors will be adopted, not only for delivering the coal to the adjacent boiler-room, but for loading wagons by which the coal is transported across the city to the other two stations.

General Plan of the Property

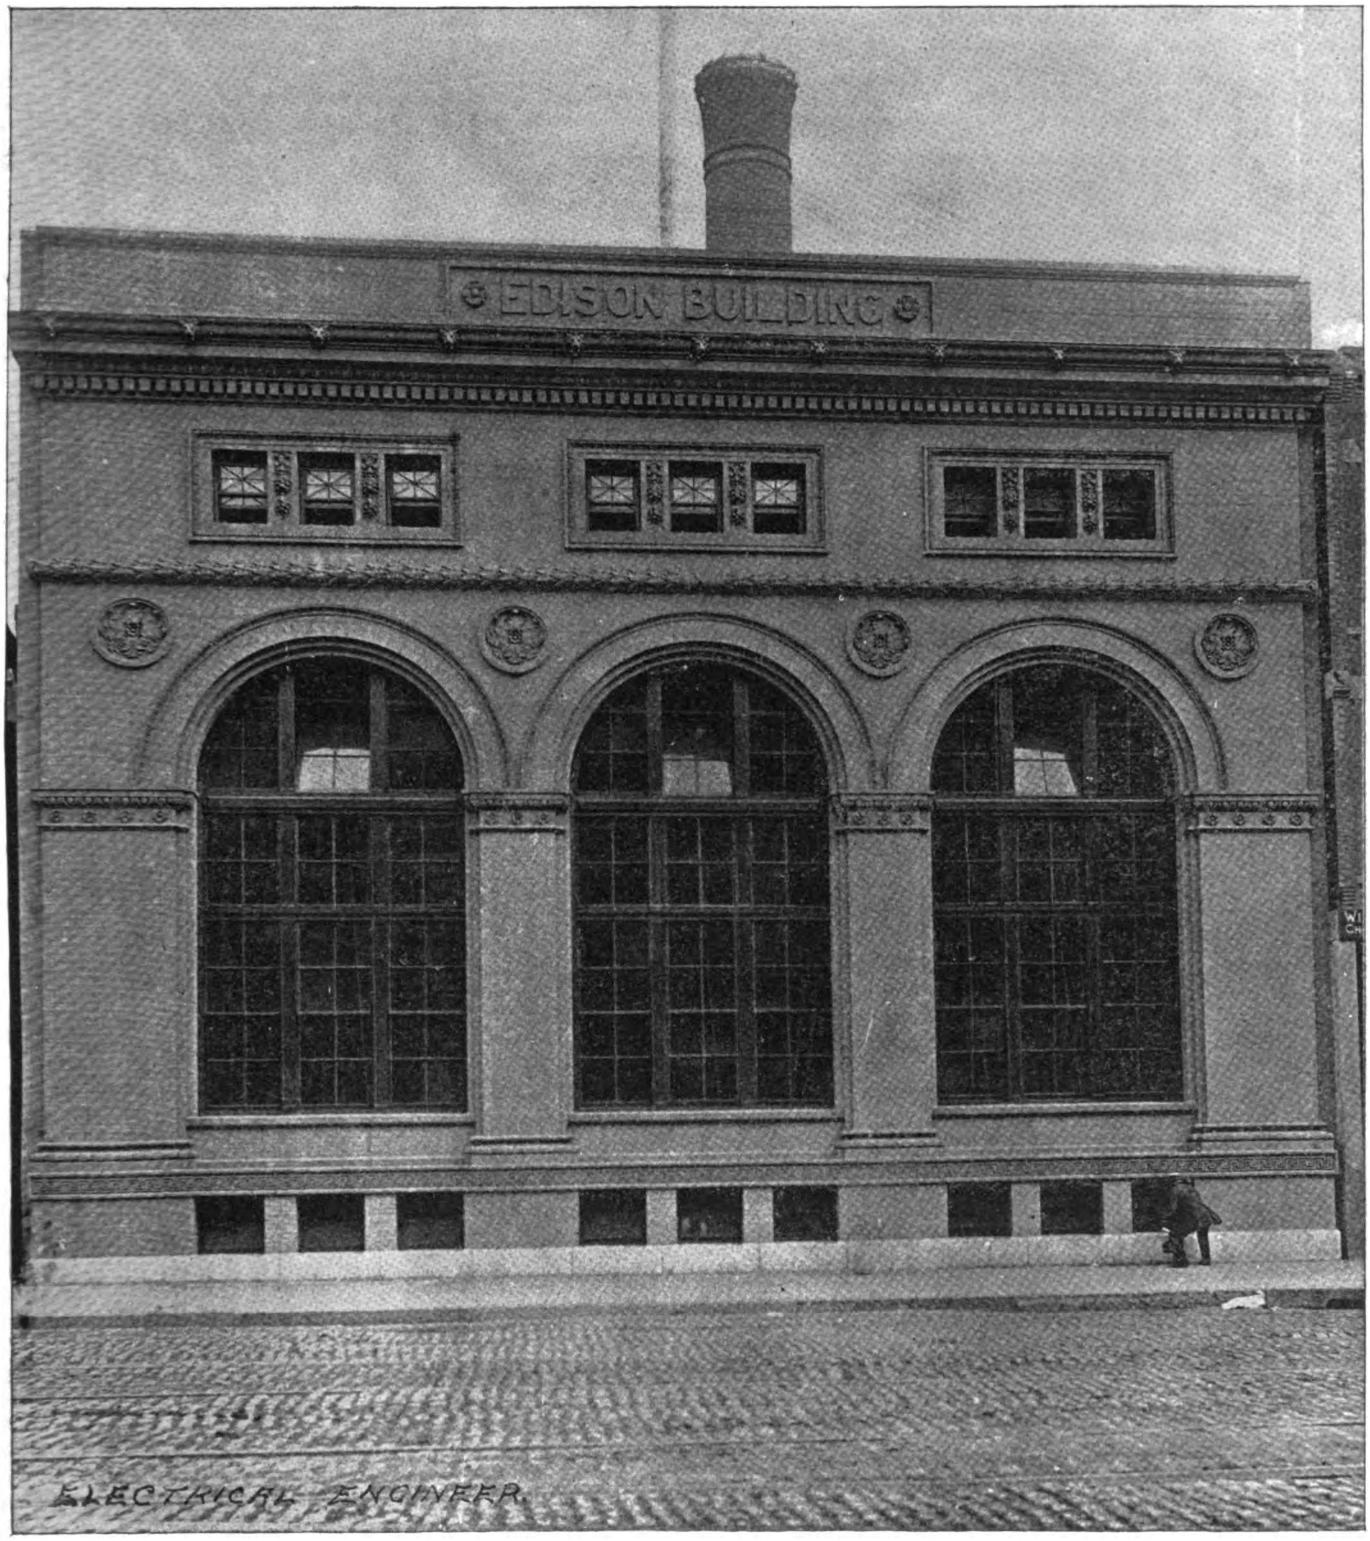
of

The Edison Electric Illuminating Company,

of Boston.

V.—THE FOUNDATIONS.

The station having been built on the water's edge, the solid ground only extending about 88 feet from the front wall, a vast amount of foundation work became necessary. The land had all to be carefully piled first, the piles being driven most thickly under the engine-room floor. Under the engine-room spruce piles, not less than 7 inches at the smaller end, and varying from 25 to 35 feet in length, according to their position, were driven, their centres being four feet apart. Under the walls the piles were placed at two foot centres. Under the boiler-room are eight piers of solid masonry, and each of these rests on 30 piles 35 feet long, being driven to a solid bearing and then cut off at one foot below mean low water. At the back of the boiler-room is a heavy masonry sea wall, resting on seven rows of piles on two-foot centres. The piles in the engine-room were cut off at seven feet above mean low water, and the mud levelled off. On top of the piles is six feet of solid concrete covering the entire engine-room floor, no concrete, however, being used under the walls, the granite foundations of the walls about six feet high resting on top of the piles. The concrete was composed of one part of Portland cement, two parts of sand, and four parts of broken stone.



FAÇADE OF THE NEW BOSTON EDISON STATION.

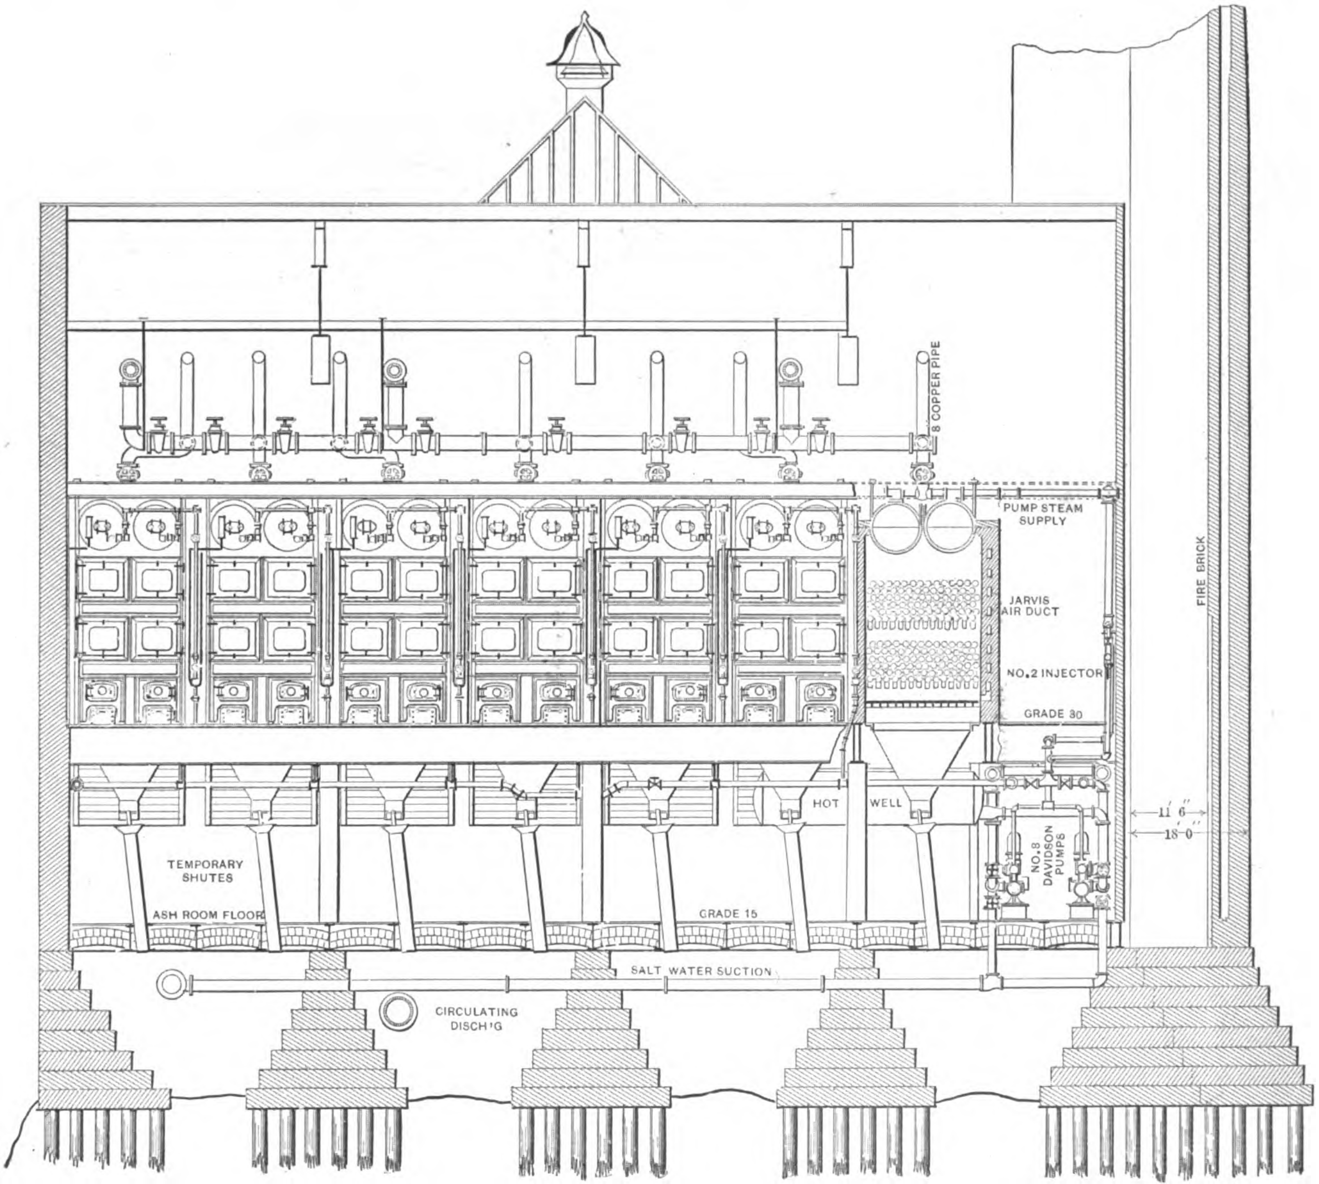
VI.—GENERAL DESCRIPTION OF THE BUILDING.

The entire building above the foundations has been built of brick, and has been erected in a most substantial manner. The front on Atlantic avenue shown on this page is of a very pleasing and graceful design, and is part of the complete plan to occupy the entire 240 feet front. It is built of a special Perth Amboy yellow brick, with terra cotta trimmings, with graceful festoon work round the three large arches, above which appears the name "Edison Building," the whole being surmounted by a substantial flagstaff which carries a flag bearing on it the name of the company. The roof is carried on nine iron girders built by the Smith-Carleton Iron Works, of Boston, 3 feet 9 inches deep and spanning the entire 60 feet. On top of these is a tar-and-gravel roof, the inside finish being of iron lathing with ¾ inch plaster. The building is extra well lighted from the roof, in addition to the windows in the front by four skylight ventilators which occupy about one-third of the entire roof area. In the engine-room and traveling the entire length has been erected a Yale & Towne 12-ton traveling crane operated by hand chains, which runs on rails near the roof supported on brackets from the walls, capable of lifting the heaviest piece of machinery which will be installed and placing it in position. The architects of the building are Winslow & Wetherell of Boston, who also designed the other two stations, the contractors being Whidden & Co., of Boston, who also built the central power station of the West End Street Railway Company, of Boston, which was illustrated in our columns October 21, 1891.

VII.—THE BOILER-ROOM.

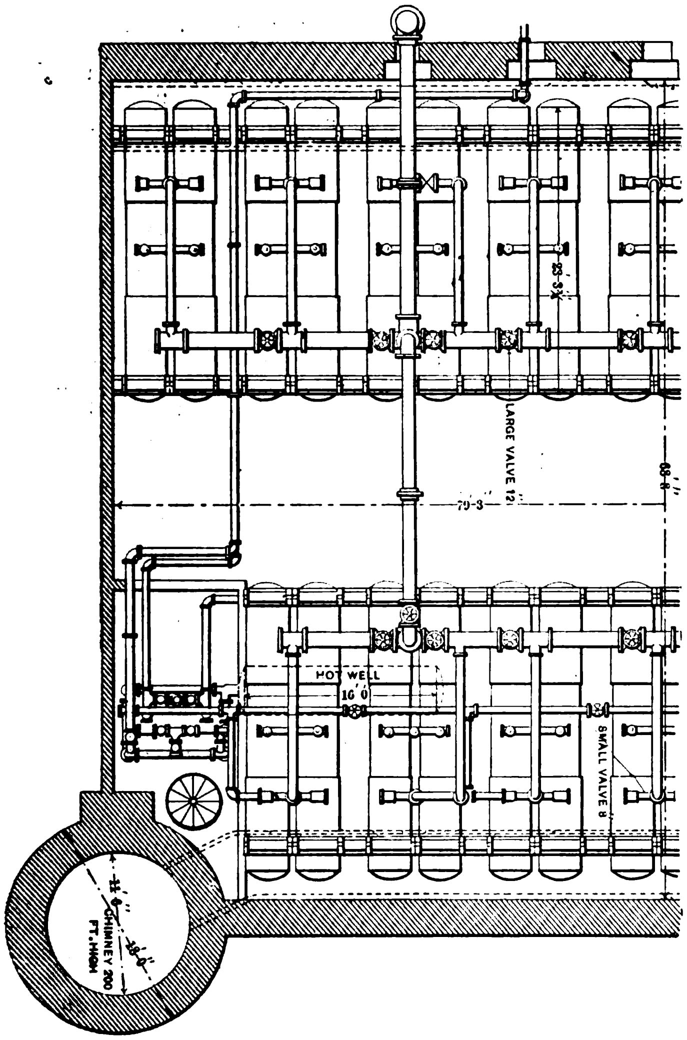
Having thus finished the general description of the property and given an idea of the necessary foundation work, the boiler-room next demands attention. In describing the station the part which is at present erected will alone be alluded to leaving out any detailed description of the proposed increase.

The boiler-room is 68 feet 8 inches deep by 79 feet 3 inches wide and is 33 feet 9 inches high from the boiler-room floor to the roof which has two large skylight ventilators. It has a capacity at present for fifteen 325 h. p. Babcock & Wilcox boilers, seven of these boilers being arranged on the sea-wall side of the room and eight on the engine-room side. The remaining space on the sea-wall side is occupied by the chimney which has sufficient capacity for the fifteen boilers. As will be seen by a look at the side elevation of the property on pages 120 and 121, the boiler-room floor is considerably above the level of the engine-room floor and is 15 feet above the ash-room floor. It is supported on two rows of box columns 18 inches square, there being five columns in each row. These columns support horizontal box girders 18 inches wide by 31 inches deep running the entire length of the boilers and these girders are in turn tied together by plate girders running transversely, 16 inches wide by 36 inches deep. These girders support the whole weight of



TRANSVERSE SECTION THROUGH THE BOILER ROOM.

the boilers, the floor being supported by light tie beams between the girders.



Half Plan of the Boiler Room.

The setting of the boilers is peculiar, owing to their situation on the second floor, each being fitted with Jarvis air ducts to aid combustion. The smoke flue, placed below and in the rear of the boilers, is the same size throughout, being 11 feet high by 5 feet 4 inches wide, and a damper is provided in each downtake, which is regulated by hand; there is also a main damper in each of the two main flues so that each battery of boilers can be shut off at will. The main damper is controlled by a Locke damper regulator situated in the pump-room.

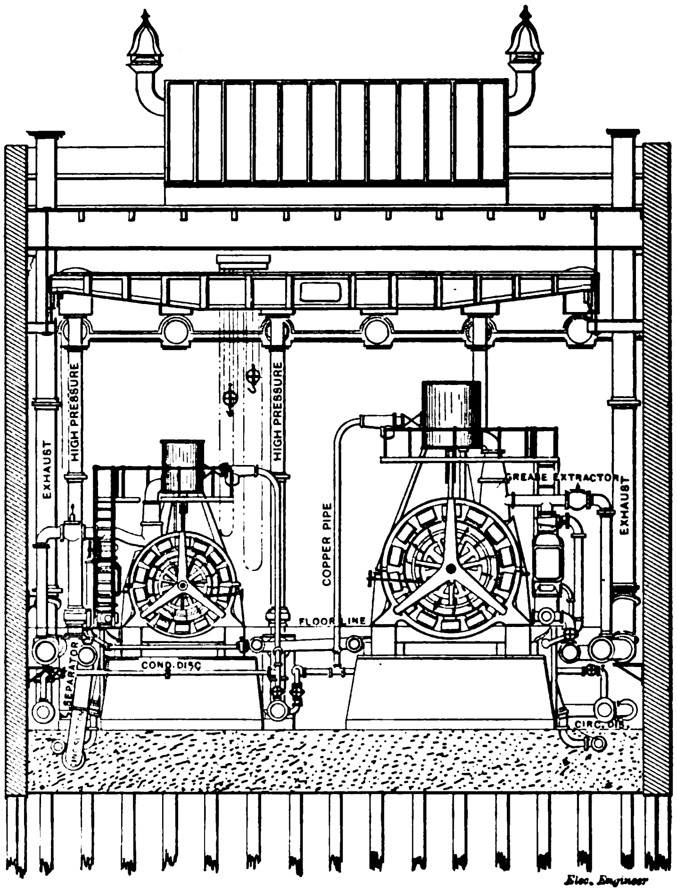
The boilers are 24 feet long, having each two steam drums 42 inches in diameter, connected by a cross-connection from which a copper bend leads to the main steam pipe. The wrought-steel headers for the boilers were imported from the shops of the Babcock & Wilcox Co. in Glasgow, Scotland, there being no means in this country for making them sufficiently strong to withstand the pressure of 225 lbs. at which these boilers can be worked, though at present they will be worked at 160 pounds. Each boiler has 168 tubes 4 inches in diameter by 18 feet long. No steam gauges have been placed on the boilers, but these are all arranged, as shown in the drawing, on the side wall so that the engineer can see at a glance the pressure on each boiler. The usual water gauges and other appurtenances are fitted on the boilers and the pipe connections are all made of polished brass, giving the room a very attractive appearance.

Coal will be run into the boiler-room automatically from the large coal wharf at the rear of the building by some system not yet decided upon. Under each boiler, directly under the grate bars, is an ash chute, shown in detail on page 129, and lined throughout with firebrick, which will hold the ashes as they drop from the firebars, and which can be emptied into trucks on the ash-room floor below by simply pulling a lever which opens a gate on the mouth of the chute. At present, however, this will not require to be done, as there is so much space around the foundation piers of the boiler room, that the ashes will be dumped through temporary chutes into the space below. It is estimated that there is room here for four years' accumulation of ashes, so that the hauling of ashes will not enter into the expense of running for some time to come.

VIII.—THE CHIMNEY.

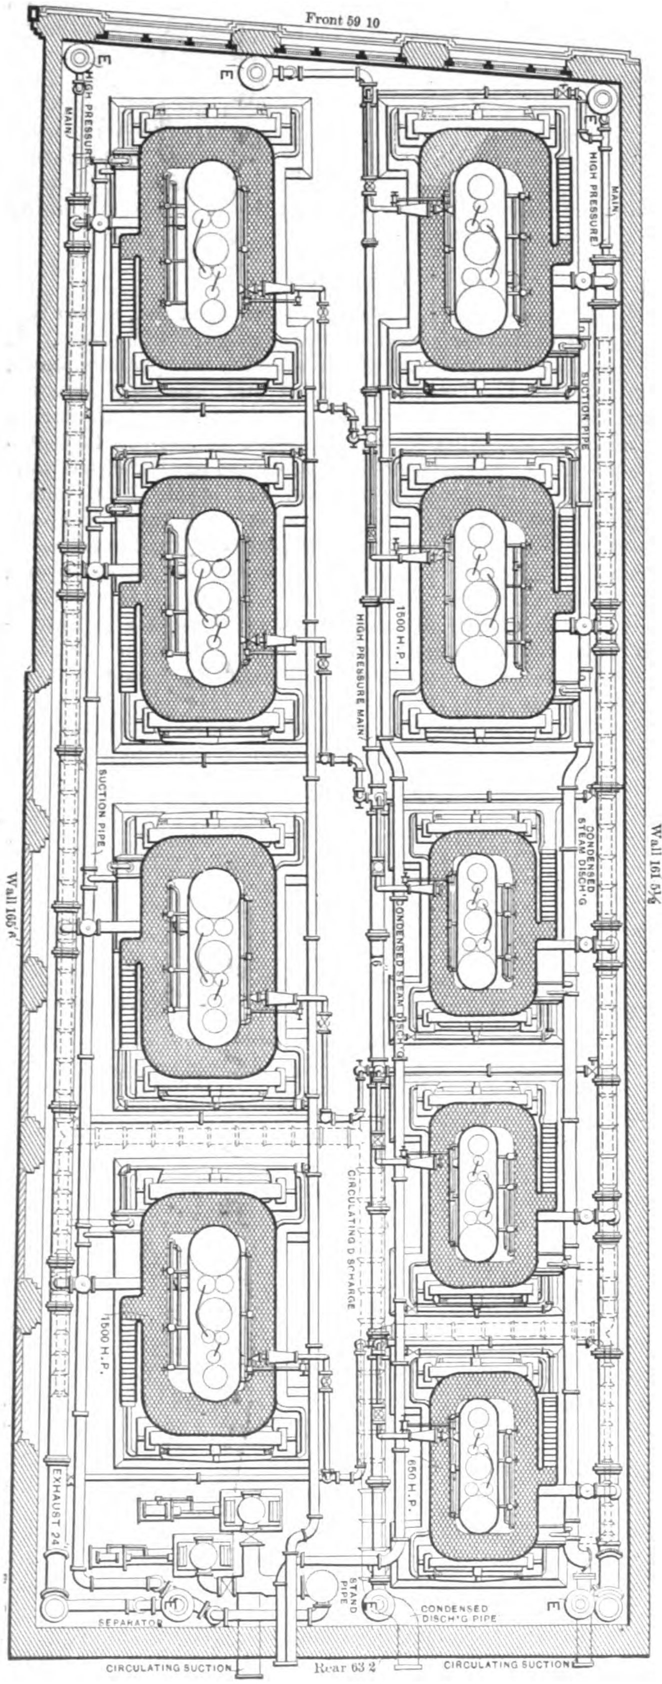
The chimney, which has already been erected, is 200 feet high, and as has been said, has capacity for 15 boilers. It has been built as large as possible under the circumstances, and when the station has increased and necessity demands it another stack will be built. The outside diameter of the stack at the bottom is 18 feet and at the top 14 feet 6 inches, being 17 feet 8 inches in diameter at the widest part of the cap. The outside wall of the stack is 20 inches thick at the bottom, maintaining this thickness to about one-third of its height. At this point it is reduced to 16 inches and about two-thirds of the way up to 12 inches, continuing at this thickness to the top. Corbels are built on the inside 8 inches wide, there being six in the circumference, and these occur the entire height of the core at intervals of 10 feet apart, but do not touch it by a quarter of an inch.

The inside shell or core is 12 inches thick at the bottom, maintaining this thickness for 80 feet, from which point it is reduced on the outside to eight inches and continues this thickness to the top. It is 125 feet high over all and has a firebrick lining on the inside extending 25 feet from



Sectional Elevation of Engine Room.

the bottom. The inside diameter of the core is 11 feet 6 inches, the inside diameter of the top of the chimney being 11 feet 11 inches. The cap is composed of 16 cast iron sections bolted together by flanges, the joints being packed with oakum and covered with red lead and the whole afterwards painted. Two half-inch lightning rods will be placed on the chimney when ready and attached at the bottom to a large plate, immersed in the harbor under the wharf.



Plan of Engine Room.

IX.—THE ENGINE-ROOM AND ENGINES.

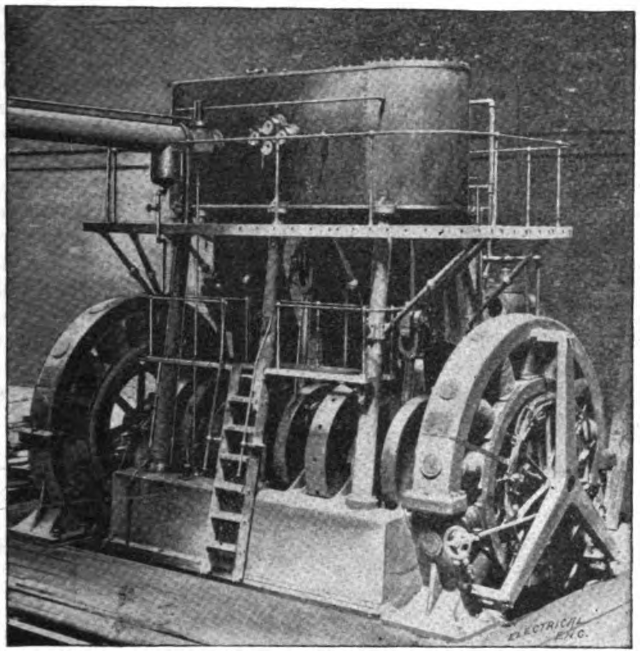
The engine-room is a plain but handsome rectangular building 59 feet 10 inches wide by 156 feet 9 inches long, with a height of 38 feet 3 inches from the floor to the ceiling, the floor being raised 10 feet above the concrete. The walls of the engine-room are of plain red brick, unrelieved by any buttresses, giving a very handsome and solid appearance. At the place where the extension will begin, however, blind arches have been provided for future communication, though it is not expected that these will require to be opened for some years. The engine-room, as finished to-day, will contain nine engines, six being of 1,500 h. p., and three of 750 h. p. The foundations are of brick and rest on top of the concrete floor, being 7 feet high, 14 feet 4 inches wide by 22 feet 6 inches long at the top for the smaller engines, and 19 feet wide by 28 feet long for the larger engines, each foundation having a batter of 9 inches. A plan is shown on this page.

The engines are all of the triple expansion, condensing, vertical type, directly connected to the generators, one at each end, the armatures acting as flywheels. The arrangement is shown on page 127. The dimennsions of the 750 h. p. engine are as follows, none of the 1,500 h. p. size having yet been installed: High pressure cylinder, 16½ inches diameter; intermediate cylinder, 23¾ inches diameter; low pressure cylinder, 38½ inches diameter; all having a stroke of 30 inches. The engines will run with 160 pounds pressure, at 120 revolutions per minute, at which speed they are guaranteed to develop one horse power on not more than 15 pounds of water per hour.

The engine stands 18 feet 3 inches in height from the floor to the top of the cylinders, the foundation box extending three feet below the floor to the top of the brick foundation. They are fitted with piston valves, and have centrifugal governors on the crank-shafts between the crank discs. The cylinders are all steam jacketed, and covered with magnesia, to prevent radiation, the whole being protected with a sheet iron casing. Each engine is provided with a Wheeler surface condenser and a combined air and circulating pump. This condenser and pump sits directly behind the engine on a cast iron drip pan supported by cast iron columns from the concrete floor and heavy cast iron brackets from the foundation box of the engine. All drip from the condensers is caught in this pan and drained off into a proper receptacle. The large engines, which will stand about 25 feet high, will also each have a Wheeler condenser with air pump underneath, the circulating water for these engines being supplied by two compound condensing pumps, each pump being capable of taking care of the entire plant alone. These pumps will be situated in the corner of the engine-room near the door leading into the ash-room.

X.—THE ELECTRIC GENERATORS.

The electric generators, as has already been stated, are coupled direct to the engine, the armatures acting as the flywheels, and making 120 revolutions per minute, at which speed each generator will develop 160 volts and 1,333 amperes, making a total of 2,666 amperes for each engine, or an equivalent of about 5,800 16 c. p. lamps. The two generators on each engine are connected on the three-wire system, one being connected to the positive side of the system, and the other to the negative. They are of the multipolar type having each 14 poles, and were built by the Edison General Electric Company, at their Schenectady factories. The foundation box of the engine serves also for the foundation for the heavy circular castings carrying the fields. The field casting is adjustable vertically so as to allow for the wearing down of the engine shaft bearings, and is entirely insulated from the foundation box. The field spools are all connected in multiple, and, together with

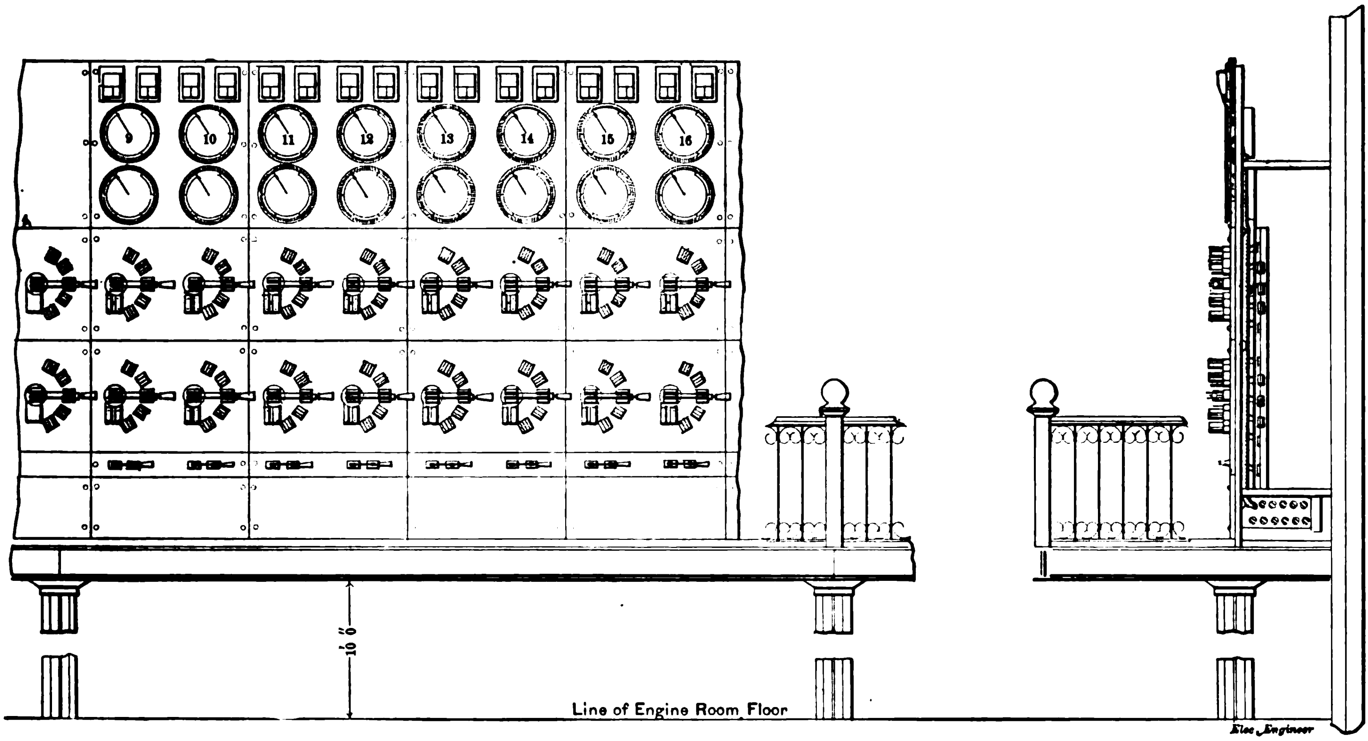


Direct Connected Engines and Generators.

the field casting and all the fittings except the armature, weigh 32,400 pounds. The armature consists of a cast iron pulley, on the outside circumference of which is bolted and keyed a brass rim about 1 inch thick, having spokes which carry the laminated core and the winding. The winding consists of 980 sections, each being composed of a heavy **U**-shaped bar of copper which with one section of the commutator forms one complete turn around the laminated core, the commutator on these dynamos being on the side of the armature. The armature weighs alone 10,900 pounds making the total weight of each generator 43,300 pounds. The fourteen sets of brushes are supported on a circular frame, which revolves on a hub supported by three heavy cast iron arms, radiating from the centre, and attached at the outer ends to the field casting. There are two brushes on each holder composed of fine copper wire gauze, making a light but sure contact. A lever is provided on the front of the dynamo by which all the brushes can be lifted from the commutator simultaneously by an ingenious system of levers. By means of a hand wheel all the brushes can be adjusted simultaneously and in addition each brush can be adjusted individually. The dimensions of the generators are as follows: Diameter over fields, 10 feet $3\frac{3}{4}$ inches; height from floor to top of field, 9 feet $1\frac{7}{8}$ inches; diameter of armature, 7 feet $\frac{5}{16}$ inch; bore of field, 7 feet $\frac{11}{16}$ inch; diameter of shaft, 8 inches; face of commutator, $5\frac{1}{2}$ inches wide and having about the same outside diameter as the armature. Every alternate brush is of opposite polarity, and the brushes of similar polarity are connected together by three strands of copper cable. The brushes of similar polarity are connected by means of heavy flexible cables to terminals one on each side of the frame of the dynamo, into which are soldered the cables which lead to the electrical gallery where are situated the controlling switches.

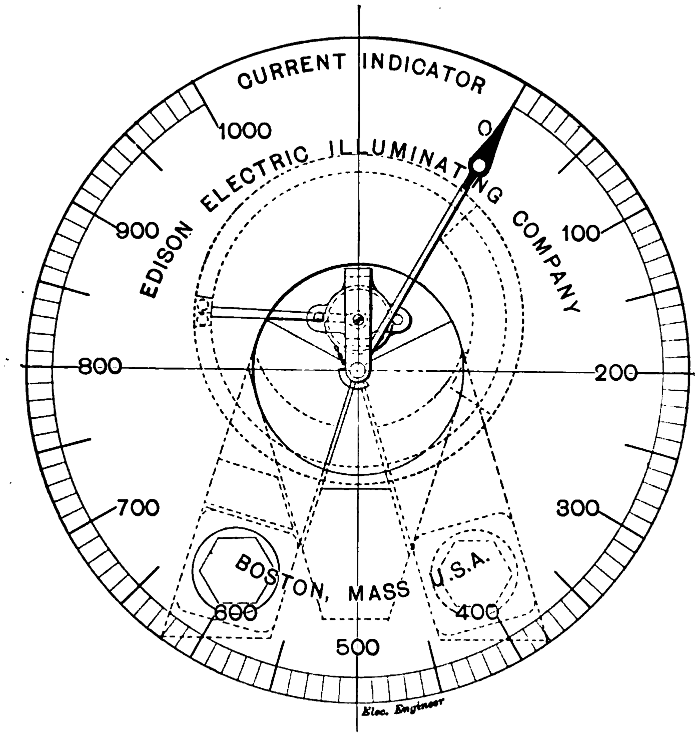
XI.—THE ELECTRICAL GALLERY AND FEEDER SWITCHBOARD.

One of the most important features in any station is the switchboard or series of boards, from which the electrical output is controlled, and in a station as large as the one described it becomes necessary to have a well-designed electrical gallery in which all the controlling devices may be installed, and where they can readily be handled. As will be seen in the general plan of the station on page 122, the electrical gallery has been erected on the side of the wall, at the place where occur the blind arches leading to the proposed extension. Thus, when the extension is built another gallery can be put on the other side of the wall, and so have all the controlling devices together. The

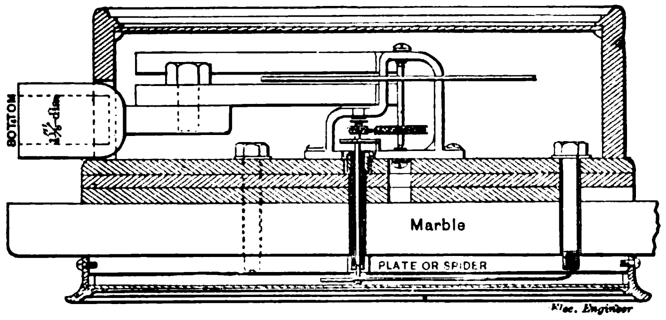


The Feeder Switch Board.

gallery is supported on iron columns from the concrete floor below, and is 10 feet above the engine room floor. It is composed of iron girders, is six feet wide, and has a slate floor two inches thick and four feet wide from the front of the feeder board, leaving a passage way at the back of the board. The length of the gallery is about 40 feet, and from the boiler-room end extends at right angles a short gallery for the dynamo switchboard, the whole being surrounded by a handsome iron railing. In designing the feeder switchboard it was determined at the very outset to have five different bus wires on each side of the system, so that five different pressures could be used. In this way a much better distribution of potential could be made on the feeders of various lengths, a long feeder being connected to a bus wire carrying the highest voltage in the station, while a short feeder would be connected to a bus wire carrying a somewhat lower voltage. By this method the feeder ends would always be maintained at a uniform potential, and the necessity for equalizers on the feeders be entirely eliminated. Two of these bus wires will probably be used to run the circuits of the other two stations, should it ever be deemed wise to shut these down in times of light load or for any other purpose. The feeder switchboard is vertical, and the framework consists of four-inch channel irons bolted to the gallery floor beams at the bottom and the top to horizontal channels fastened to I beams let into the wall. The board itself is made of marble and stands 10 feet high, the height being divided into four sections of marble. The three top ones are a light chocolate-color Knoxville marble on which are mounted the switches, amperemeters and indicators, while the bottom strip resting on the slate is black, so as not to show any discoloration. At the back of the framework are two horizontal channels, one near the bottom and one near the top, both of which form floors upon which to work, and, at the same time, form receptacles for the cables leading to and from the switchboard. The bus bars are at the back of the board supported about 6 inches behind the marble in hard maplewood clamps held together by bolts which also fasten them to the iron rods which serve as supports. When it is deemed necessary to increase the capacity of the bars, it is only necessary to slacken the bolts, cut the clamps and slip in an additional bar. The board is divided vertically into sections 40 inches wide, each section taking care of two complete feeders.

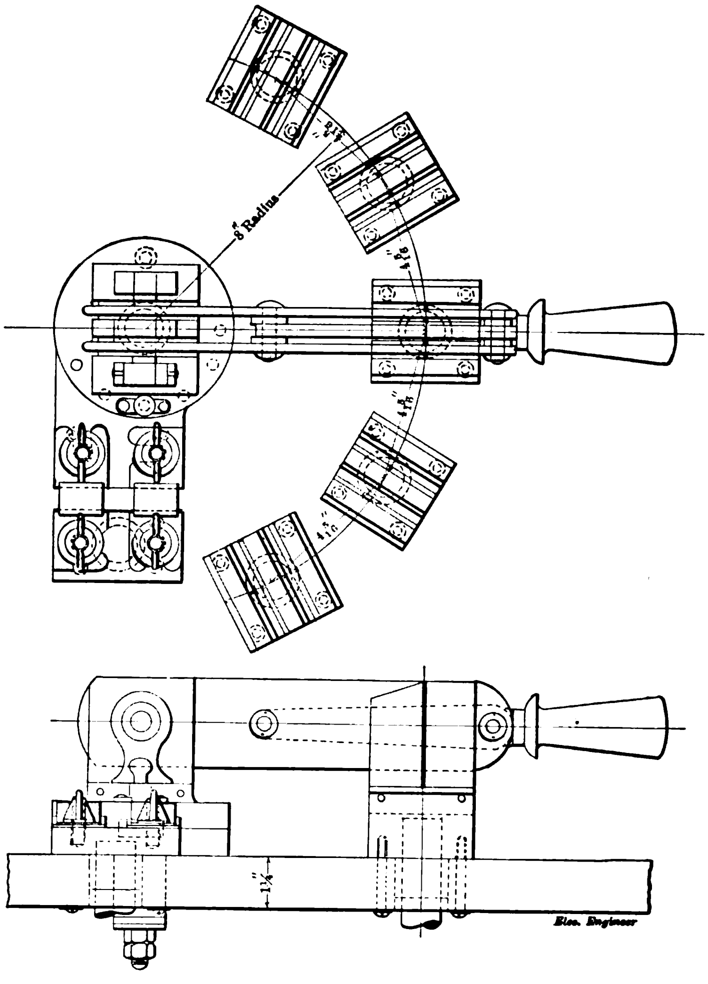


DETAIL OF AMPEREMETER.



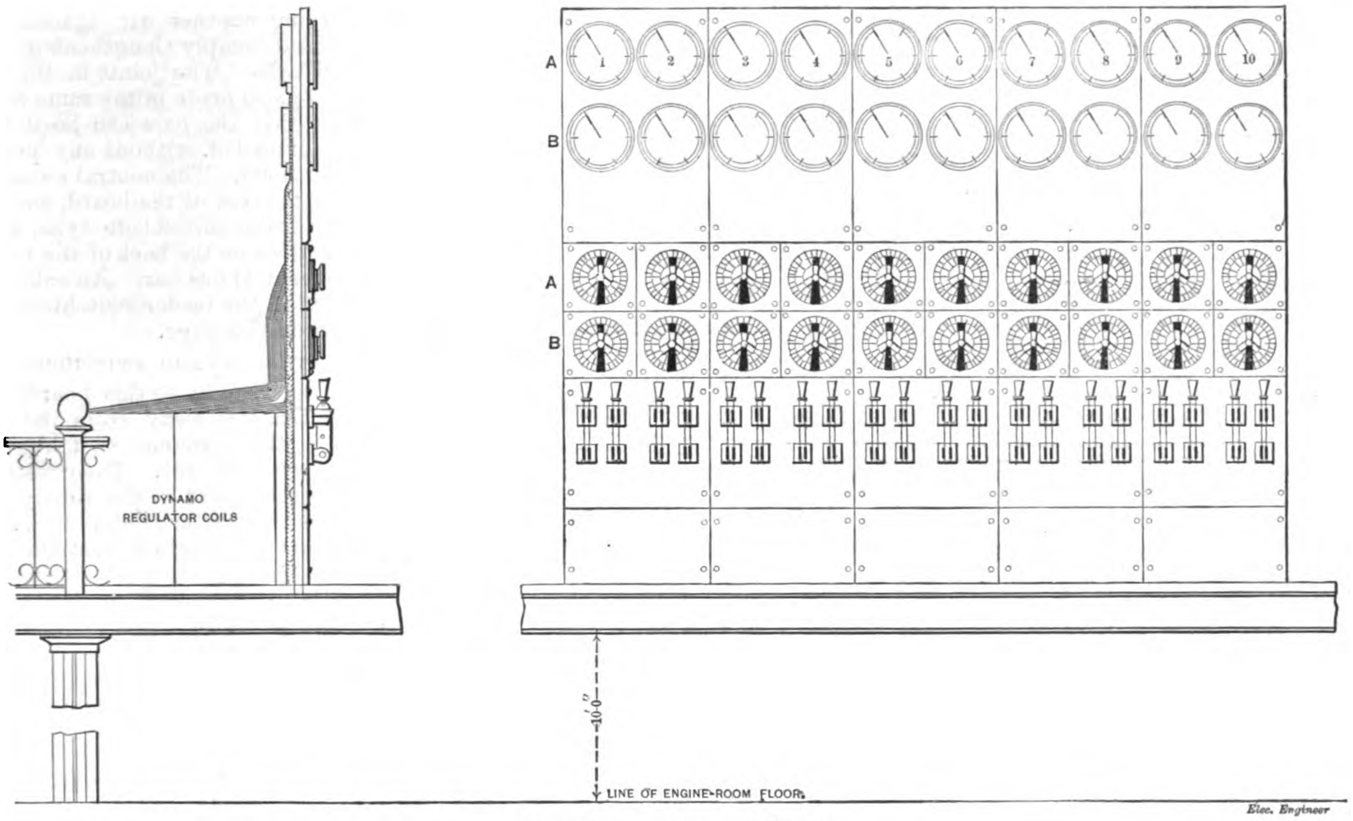
SECTION OF AMPEREMETER.

The engraving on page 127 shows the board with 16 sections, which has been specially designed by the Edison Illuminating Company, and the details of which have been manufactured by A. & J. M. Anderson, of Boston, who make a specialty of this class of work. At the top of each section, are two new type pressure indicators, which are connected to the feeder boxes by pressure wires, and indicate the pressure at the end of each feeder. Immediately below these are placed the positive amperemeters, and below them again are the negative amperemeters. Below these are placed the positive feeder switches, and still lower down the negative feeder witches, the lowest switches connected horizontally being on the neutral feeders. At the bottom is a 16-inch strip



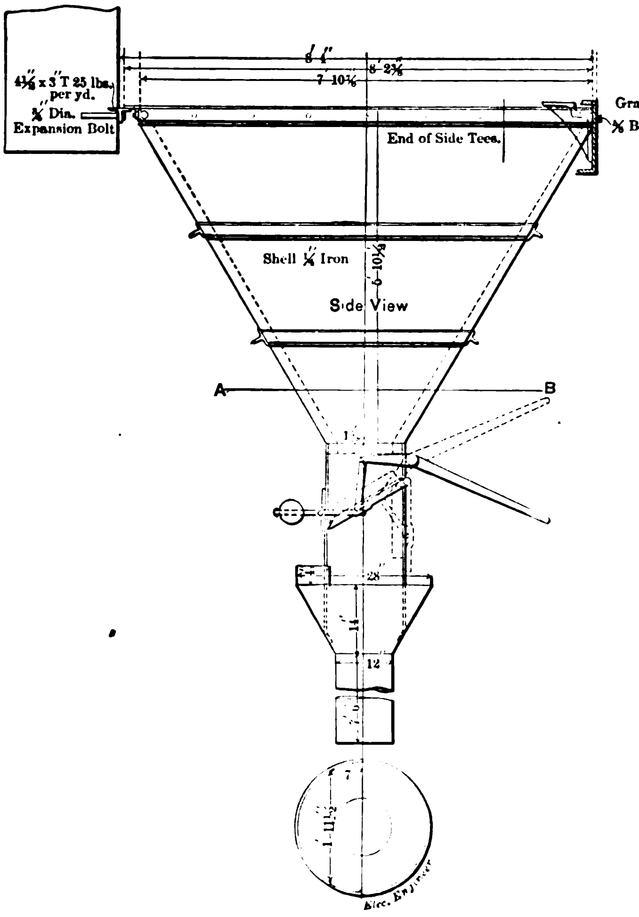
DETAIL OF FIVE-WAY SWITCH.

of black marble on which there is no apparatus, and which only serves as an ornament, being black to prevent any discoloration from oil or dirt. The two sections shown in the engraving without ammeters, carry the dynamo switches, each having five different contacts by which any dynamo can be switched onto any of the five buses. The board, as will be seen, therefore, accommodates at present 16 feeders and four engines or eight generators. The feeder switches, positive and negative, also having five different contacts, throw any feeder onto any of the five bus wires and are each fitted with a double set of fuses; the neutral switches throw the neutral feeder onto the neutral bus.



THE DYNAMO SWITCH BOARD.

The amperemeters shown in detail on page 128 have been specially designed for this board, and are 14 inches in diameter on the face, which is the only part of the ammeter on the front of the board, the working parts being all on the back and cased in. They are constructed on the solenoid principle, and have two flat convolutions through which the current passes, which act on a flat piece of iron suspended on a brass disc. This disc turns on a pivot, which carries a small chain wheel geared to another smaller chain wheel, to multiply the motion of an arbor passing through the marble to the front and carrying the pointer which makes nearly a complete revolution for the full capacity of the ammeter. The face of the ammeter is in a brass case with a glass front. The switch used, an enlarged view of which is shown on page 128 is of an entirely new design, and was invented especially for the purpose of connecting one point with any of the other five points, so that any feeder or dynamo can be connected with any of the five bus bars. This is the first knife-blade switch of large capacity ever made capable of being shifted from one point to another, fastening itself into the contact clips, and making solid contact at the revolving point. There is a spring stop which holds the blade opposite any contact, so that when shut quickly the blade will enter truly and surely into the clip. To each of the five contacts there is a short piece of cable soldered, running through the marble, the other end being soldered to a composition block of the same width as the bus bar, and long enough to give proper contact. This block is clamped to the bus bar by two cast iron plates bolted together, so that connection can be made at any point on the bus, avoiding



DETAIL OF ASH CHUTE.

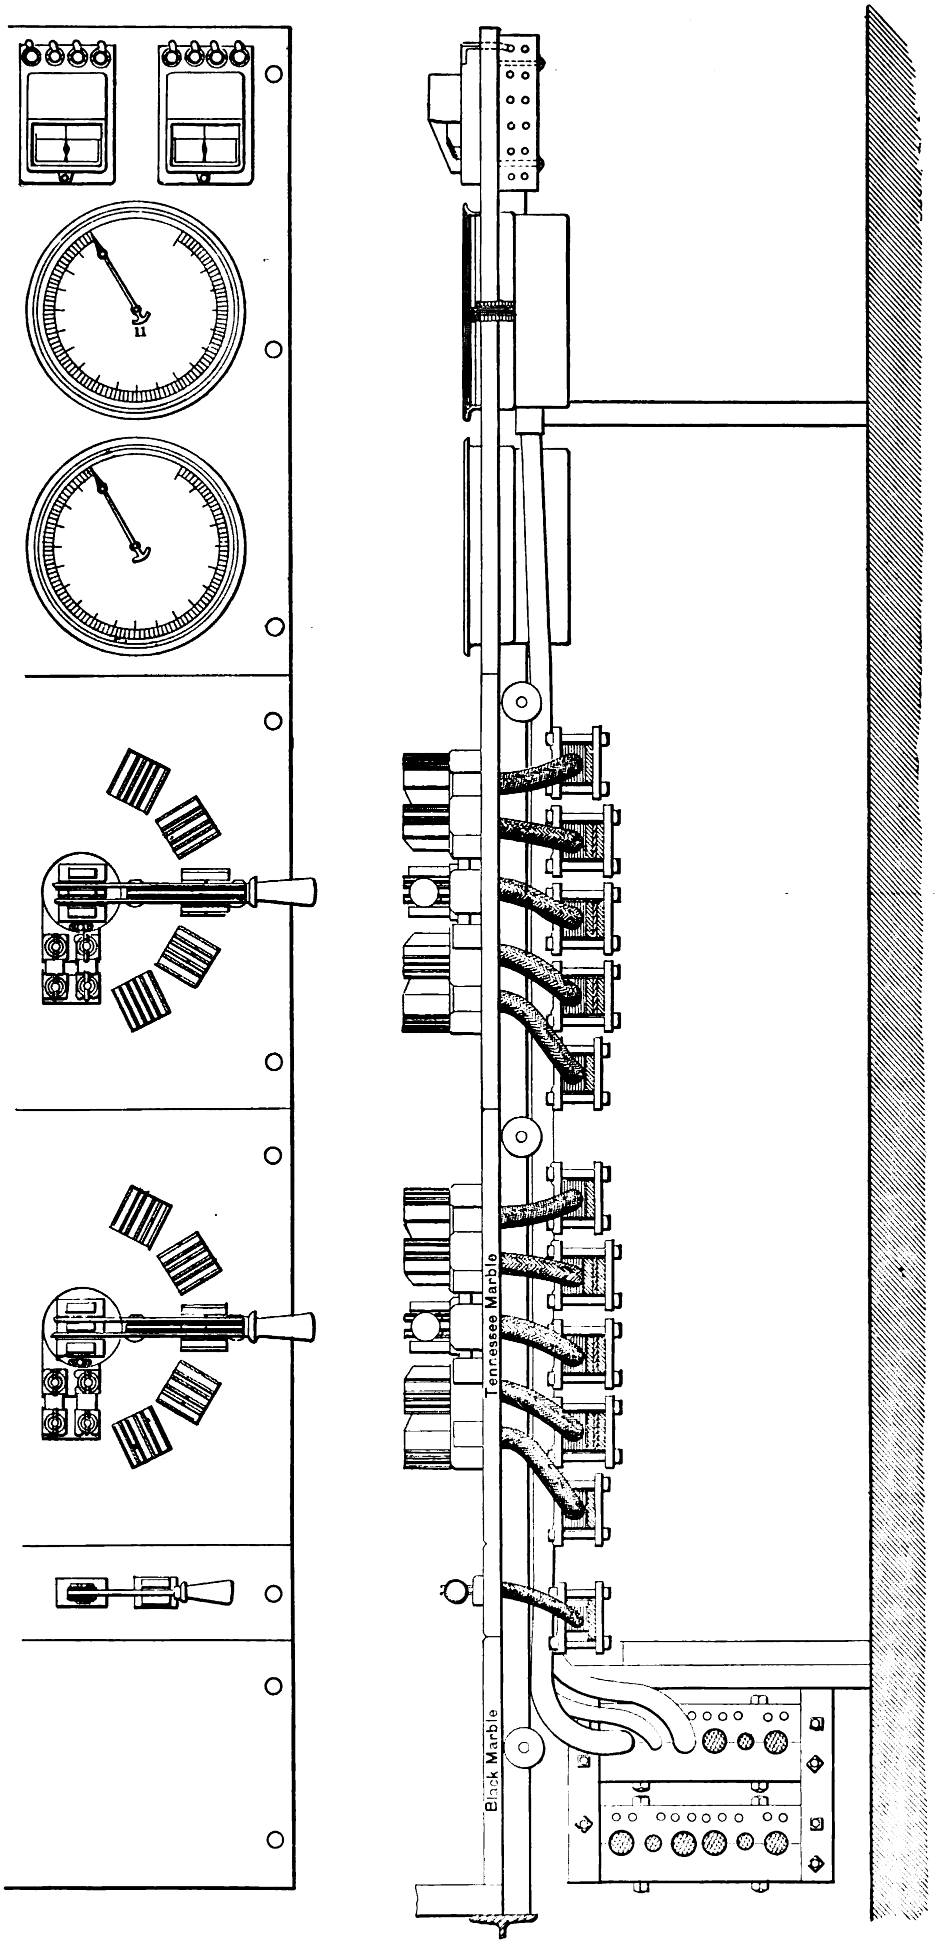
all necessity for holes. This arrangement also allows for any increase in the bus bar, which would be made by laying another bar against the first and simply lengthening the clamp bolts. The joints in the bus bars are also made in the same manner, so that the bars can be indefinitely extended, without any necessity for holes. The neutral switches are on the foot of the board, and are of the plain knife-blade type, with connections on the back of the board to the neutral bus bar. An enlarged section of the feeder switchboard is shown on this page.

XII.—THE DYNAMO SWITCHBOARD.

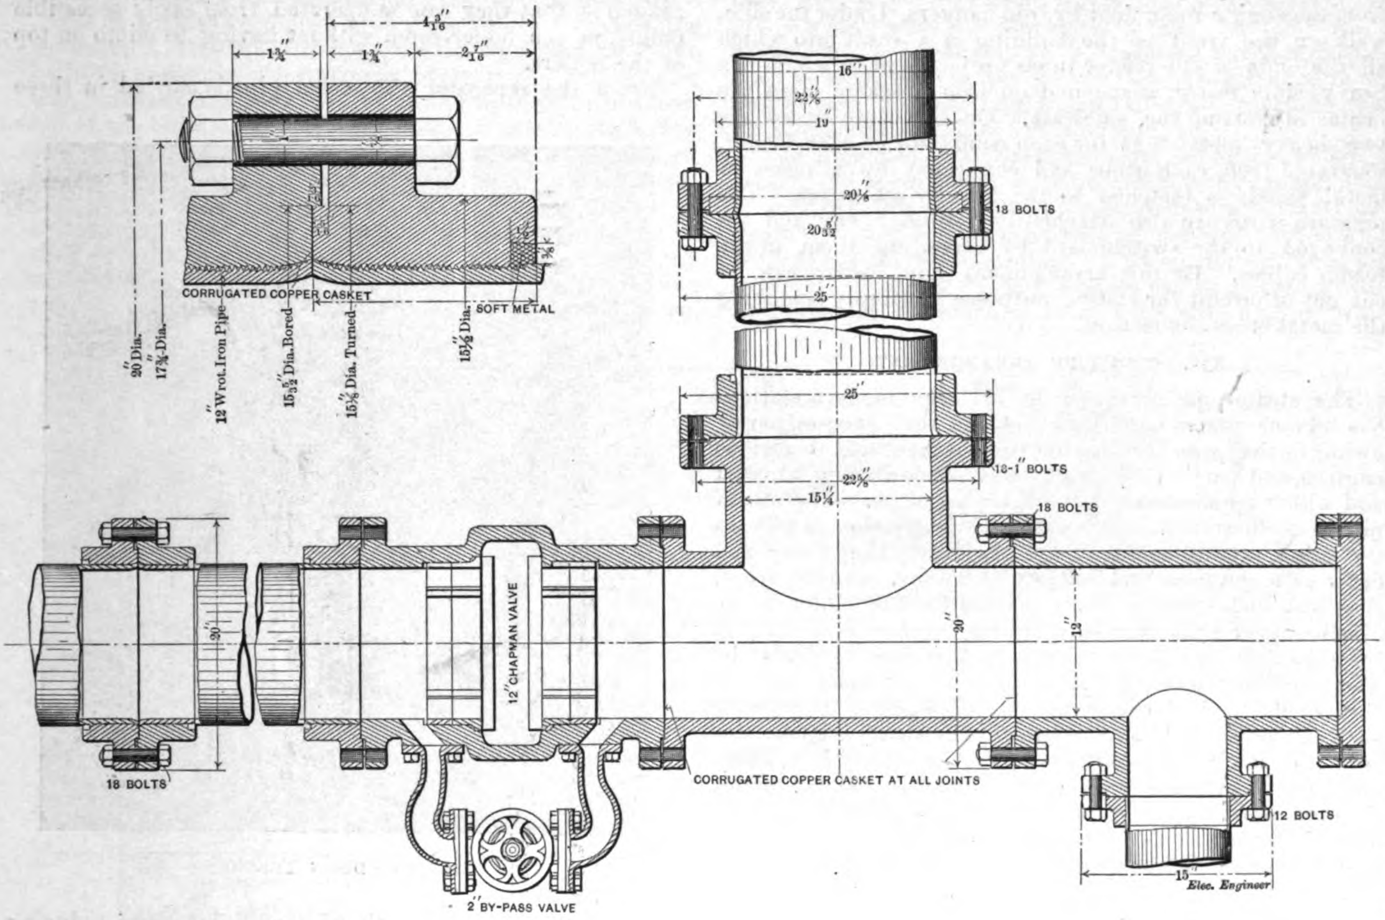
At right angles to this board and about ten feet away from the end of it is the dynamo switchboard, shown on page 129. The construction of this board is practically the same as that of the feeder board, except that the vertical sections are 30 inches wide instead of 40 inches. It is also composed of Knoxville chocolate-colored marble with a black strip at the bottom. At the top of the board are the dynamo amperemeters of the same construction as the feeder amperemeters, though of greater capacity, having been built for 200 kilowatt generators. Immediately below these are the pilot lamps and small switches for galvanometers for comparing the pressure on the dynamos when starting up. Below these are the rheostat hand wheels and contacts for regulating the fields of the dynamos, two to each engine, or one to each generator, the rheostat itself being situated behind the board on the floor of the gallery. Each section of the board accommodates two complete engines or four generators, the drawing showing accommodation for ten engines. Below the regulator hand wheels is a double knife-blade switch, the two blades being on the same handle, which is capable of transmitting about 1,800 amperes. These amperemeters and switches are necessarily on the neutral connections between the two generators, and the bus bar of the dynamo board is connected to the neutral bus on the feeder switchboard by a cable with a neutral ammeter in circuit which shows at all times the balance on both sides of the system.

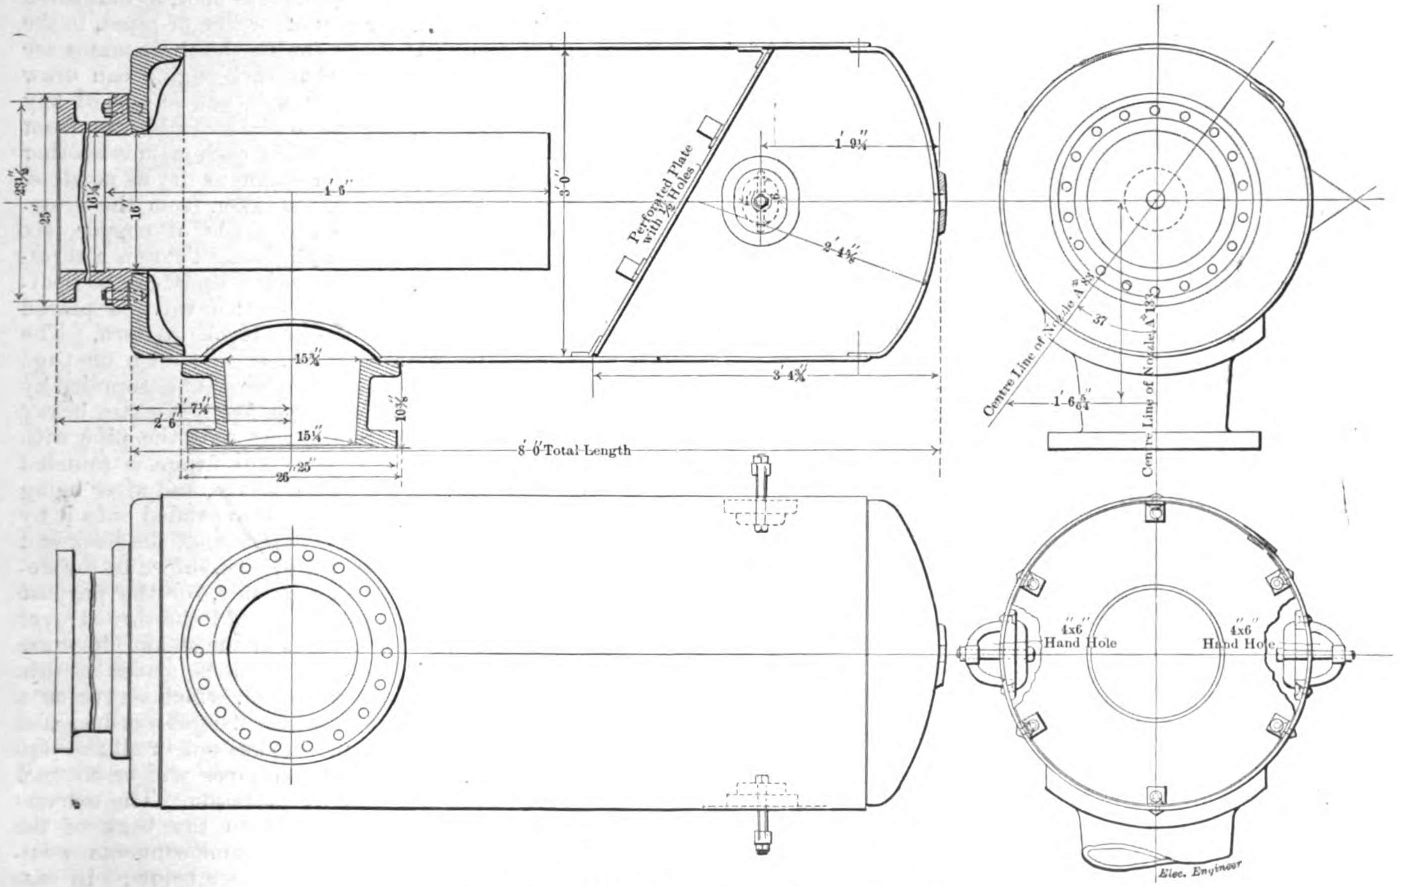
XIII.—INSIDE UNDERGROUND CONNECTIONS.

The cables connecting the generators with the electrical gallery, and the electrical gallery with the underground tubes are all of the Habirshaw manufacture and run underneath the engine-room floor from the gallery through hard maplewood clamps supported on wrought iron wall brackets, the whole being boxed in with slate. They are then supported on maple clamps suspended



DETAIL OF FEEDER SWITCH-BOARD.



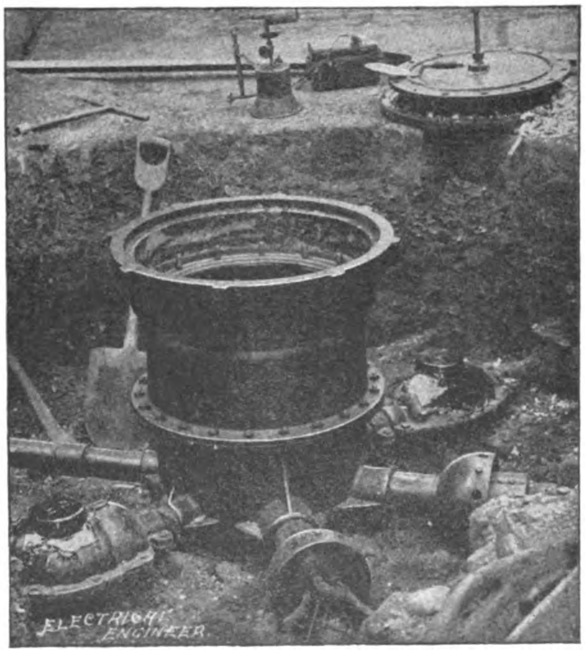


DETAILS OF MAIN STEAM PIPE AND SEPARATOR.

from the engine-room floor by iron hangers. Under the sidewalk on the front of the building is a vault into which all the ends of the feeder tubes project, and in which is a heavy slate board, suspended on iron brackets from the beams supporting the sidewalk. On this slate board are two heavy metal lugs for each conductor of each feeder, separated from each other, and connected by a piece of metal which is fastened to the lugs by set-screws. The pressure wires are also attached in a similar way and are conveyed to the switchboard by stranding them in the feeder cables. By this arrangement any feeder can be cut out of circuit for testing purposes by simply removing the metal cross-connection.

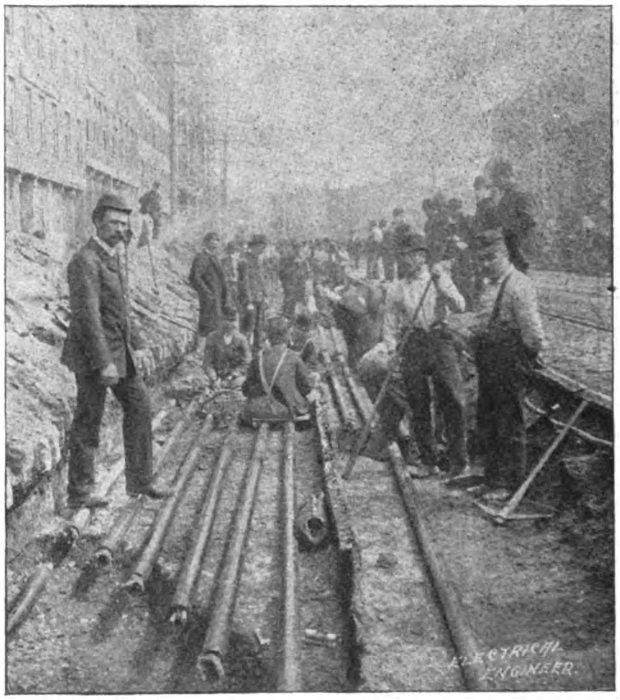
XIV.—THE PIPE ARRANGEMENT.

The steam-pipe arrangement in large modern stations has become a most important factor of their success, partly owing to the large horse power to be transmitted to various engines, and partly to the high pressures now being adopted and which are necessary for triple expansion. The steam piping is, therefore, well worthy of description as well as the other piping necessary for the circulating water and other uses. Across each battery of boilers, near the front, runs a 12-inch steam main, connected to each boiler by an 8-inch copper pipe, having a double bend so as to provide for expansion and contraction. In this line of pipes the valves are so placed that any section of the main, with its corresponding boiler can be cut off without interfering with the action of the remainder of the steam system; this is in addition to the usual stop valve on each boiler. These two lines of pipe are tied together by three 12-inch mains, situated above, near the roof-girders, and are carried, as are also the other pipes in the boiler-room, on iron hangers suspended from I beams which run between the roof girders. From the line of pipe over the battery of boilers nearest to the engine-room and opposite the point where the cross-lines are tied, run three 16-inch mains horizontally through the engine-room wall. Here they turn down on the inside of the engine-room wall into the steam separator, which rests on a brick foundation on the concrete floor below the engine-room floor. On top of each separator is placed a 16-inch Chapman heavy pressure by-pass valve, so arranged that it can be opened or closed from the engine-room or boiler-room. All the valves on the pipes in the boiler-room, which are also Chapman valves, are arranged so that they can be operated from easily accessible points in the boiler-room without having to climb on top of the boilers.



An Edison Feeder Box.

From the separator the steam pipe is carried in three heavy lines the full length of the engine-room, reducing from 16-inch nearest the separators to smaller sizes at the further end. These pipes are supported on iron rollers in iron brackets which rest on the concrete floor, so that there are no main steam pipes, nor any other line of pipes, in the engine-room proper. At each engine the three mains are tied across in such a manner that each engine can draw steam from either of two mains at will, and in case of any one main being disabled, the entire plant can be run from the other two. At the extreme end of each main is another steam separator, so as to keep the steam as dry as possible. The steam pipe for each engine is taken from the cross-pipe connecting two mains, and is made of copper, six inches in diameter for the smaller engines. There is a throttle valve on each engine, so arranged that it can be operated from the floor, and just outside this valve is placed another steam separator of the De Rycke pattern. The main steam pipe, the details of which are shown on page 131, is made of extra heavy wrought iron tube, supplied by the National Tube Works, the flanges being of extra heavy gun iron of special design and screwed onto the pipe with a fine thread cut on a slight taper. The flange is rounded out on the end of the bore at the face, and after being screwed onto the tube the latter is expanded into it by hammering. As an additional precaution, at the back end of the hub of each flange is cast a groove, shown in the detail, larger on the inside than the outside, for the purpose of caulking in a soft metal gasket should the thread ever show signs of leaking. The flanges of the steam pipes are fitted with a "recess" joint, in which is placed a thin corrugated Wainwright copper gasket, which serves as a packing. The whole arrangement of the flanges was designed by Wm. H. Gallison of Boston, who has put in all the piping in the station. All the steam pipes will be covered with magnesia to prevent loss by radiation. The exhaust pipe on each engine is attached to the back of the engine on the low pressure cylinder and connects vertically with the Wheeler surface condenser below. In case of accident to the condensing apparatus, however, there



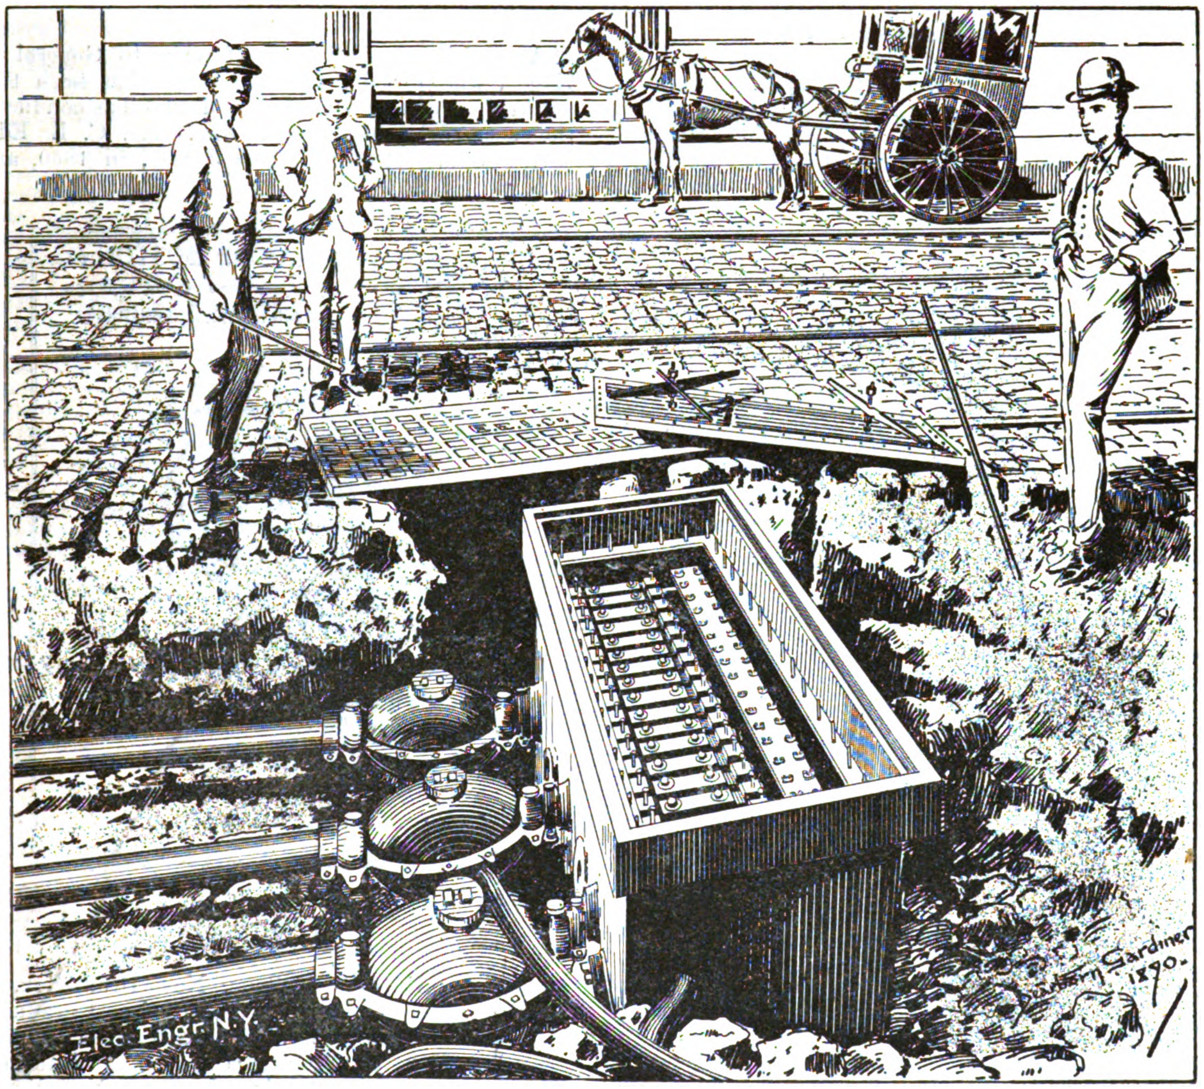
ELECTRICAL ENGINEER.

Laying Edison Tubing.

is also provided a free exhaust into the atmosphere, which connects with the exhaust pipe just before it enters the condenser. This free exhaust runs the whole length of the building under the floor, supported from the wall by cast iron brackets, and then runs vertically upward in one corner of the building to the roof, where it discharges a few feet above. This pipe, having to stand but little pressure, is built of spirally riveted galvanized steel. Close to the engine, on the exhaust pipe, is a De Rycke grease extractor, and between the condenser and the connection to the free exhaust is an automatic relief valve in case of any trouble with the condenser. Ordinarily this valve is closed to the free exhaust, but, should the condenser break down, the steam pressure would automatically open the valve and the engine would exhaust through the free exhaust pipe into the atmosphere, the engine running non-condensing.

From the condenser the condensed steam is discharged through pipes provided for the purpose, 4 inches in diameter, of which there is one for each condenser, connecting with a 12-inch pipe, one on each side of the engine-room floor suspended from the floor beams. These pipes lead to the hot well, situated in the ash-room, and are suspended from the boiler-room girders close to the pump-room. The hot well, which has capacity sufficient for five engines, is a cylindrical tank 4 feet in diameter by 16 feet long, and is made of $\frac{5}{16}$-inch iron, with dished heads $\frac{3}{8}$-inch thick. From the hot well the water flows by gravity to the boiler-feed pumps situated below on the ash-room floor, and is pumped back again into the boilers. Two No. 8 heavy-pressure Davidson pumps, built by M. T. Davidson, of Brooklyn, N. Y., are used for this purpose, and, as auxiliaries to the pumps there are attached in the boiler-room two No. 12 Korting universal injectors, made by L. Schutte & Co., of Philadelphia.

The circulating water is taken from the harbor under the wharf, and is conveyed to the condensers by means of an 18-inch cast-iron pipe, which descends into the water to a depth of 2 feet below the surface at low tide, and is fitted with a foot valve and strainer. The entrance to this pipe is further protected by enclosing its end in a large wooden box, one side of which is fitted with wire netting, which will pass all the water necessary but prevents any hard substance from entering. The suction pipe for the circulating water is suspended from the wharf and runs under the ash-room floor through the wall into the engine-room, where it is suspended from the floor girders. In the ash-room is an 18-inch Chapman valve and a T connection to the boiler feed pumps, so that the boilers can be fed with sea water should any accident occur to the city water pipes at the same time that the condensers might be out of order. At each condenser is an 8-inch connection fitted with a Chapman valve. The discharge from each condenser is by means of a 6-inch cast iron pipe, which connects with a line of vitrified pipe buried in the concrete foundations. There are two lines of these pipes, one for each side of the engine-room, varying from 15 to 18 inches in diameter,



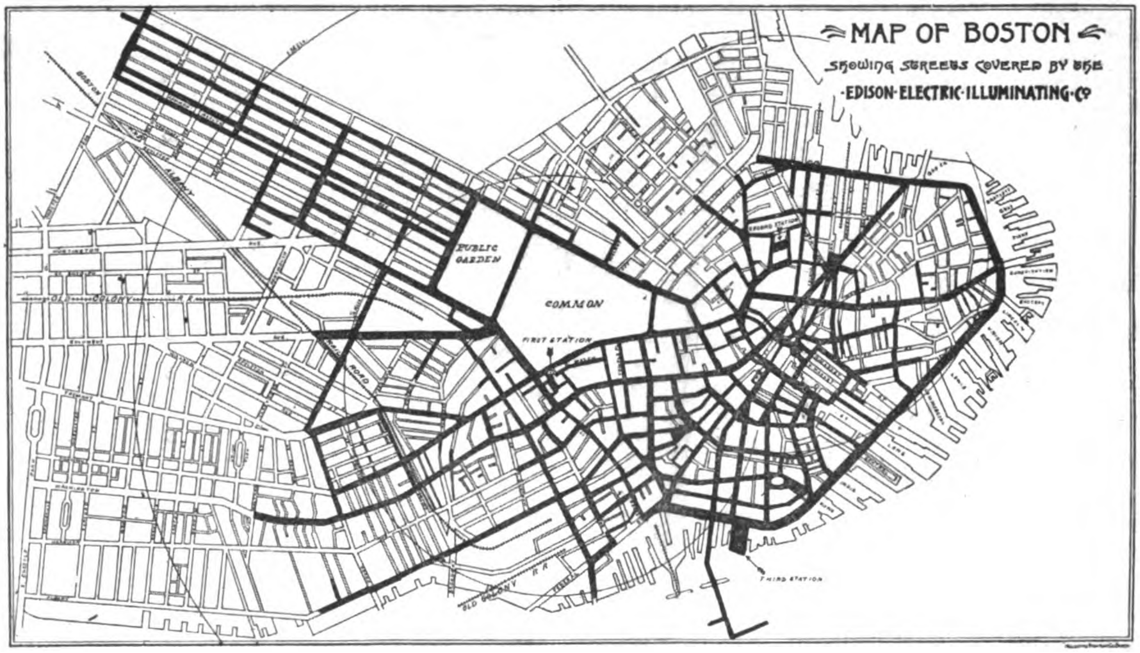
Elec. Engr N.Y.
Gardiner 1890.

A FEEDER TESTING BOX.

and connected to a 24-inch cast-iron pipe, commencing at the ash-room, and running 80 feet out underneath the wharf, where the end turns down and is submerged two feet under water at low tide, thus relieving the pump of a large part of the friction of the water. The discharge pipes are all pitched 6 inches to the hundred feet. All the drips from the high-pressure steam pipes are returned to the boilers by means of the Westinghouse, Church, Kerr & Co.'s patent steam loops, which are attached to each separator, and also at intermediate points in the line whereever the water might collect. All other drips from the engines, pumps, etc., are collected to some central point, where the oil is extracted and re-used, and the water returned to the hot well.

XV.—OUTSIDE CONNECTIONS.

Having thus described in detail the salient features of the new station, and the reasons for building it, it will be interesting to give a few notes regarding the amount of current which the Edison Illuminating Company of Boston is furnishing, and a few details of their outside circuits. There are at present connected to their mains about 65,000 incandescent lamps, or their equivalent in 16 c. p. lamps, about 400 arc lamps, and 3,000 h. p. in motors varying from $\frac{1}{12}$ h. p. to 60 h. p. Connecting all three stations a special 19 conductor cable has been run, which may be used for pressure wires, for telephonic communication, for watch clocks or for any purpose for which it may be required. There are about 50 miles of underground feeders and mains, many of them of the largest size, and these now have a capacity of double the amount of current at present used. All the old style of tubes have been replaced by those of the most recent manufacture, and many new feeder boxes of the latest design, a view of one of which is shown on page 132, have recently been put in. The feeder testing boxes, one of which is shown on page 133, are of their own design, and is used to subdivide long feeders into sections, for convenience in testing, and for locating and overcoming trouble. From the new station have been run about ten miles of underground work, as many as eleven new feeders having been laid in one ditch, as shown on page 132, eight of them being of 1,000,000, and three of 750,000 circular mils. There is still left about 2½ miles of overhead conductor, and this is used chiefly as a power circuit around the wharves. A good idea of the amount of territory covered by the mains of the Edison Company may be had by consulting the diagram of the city of Boston on this page, the deep black lines representing the streets in which these mains exist, and, as will be seen, not only covering nearly every important street in the city but spreading out like the branches of a tree, to the outskirts, from the lower class streets in the North End, and the magnificent avenues and streets of the Back Bay district on which are situated the residences of Boston's wealthiest citizens.



EDISON MAINS IN BOSTON.

XVI.—MR. C. L. EDGAR.

A word in conclusion in reference to General Manager Edgar, who for the past five years, has been the living mainspring of this company, and who has conducted it to the successful position of to-day. Mr. C. L. Edgar was born in Somerset county, New Jersey, in 1860, and graduated from Rutgers' College, New Brunswick, N. J., in 1882, afterwards taking a six months' post-graduate course in electrical engineering. Soon afterward he became connected with the testing department of the Edison Machine Works, then situated in Goerck street, New York, and in the fall of 1883 joined the engineering department, receiving an invaluable training in traveling all over the country for the purpose of inspecting the numerous Edison stations then in existence. About that time, also, Mr. Edgar designed and built a number of small central stations in Pennsylvania, so that when in September, 1887, he came to Boston, as manager of the Edison Electric Illuminating Company of Boston, it would have been difficult to find any one with a wider and more general knowledge of central station work on the Edison system. Since that time, the work of building up the Edison system in Boston has been faithfully carried out by Mr. Edgar, who from the first has shown himself to be a most progressive electrical engineer. That his work has been successful, and eminently calculated to improve the condition of central station design, is amply proven by the magnificent new station which marks his latest achievement.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 208 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, AUGUST 10, 1892. No. 228.

No one can do harm but only good, who works with an earnest and truthful spirit.—Faraday.

THE EVOLUTION OF THE CENTRAL STATION.

WHILE the doctrine of evolution in nature may still be the subject of discussion in certain quarters, the operation of its laws in the domain of the arts and sciences is so apparent as to require no special demonstration at this late day. What is termed progress in the arts is, indeed, nothing but evolution—a discarding of parts and processes made useless or cumbersome by changed conditions and, on the other hand, an accretion of new ones, resulting from the same causes and the result of accumulated experiences of utility. If one were to seek for an example of rapid evolution in the engineering world, it is doubtful if a more strikingly characteristic one could be found than that presented by the American central electric station. Called into existence after the apparatus which it was destined to operate had scarcely emerged from the experimental stage, it is not to be wondered at that stations were erected which, after the lapse of ten years, are antiquated and fail to show returns equal to those built on modern lines. But for all that, it does not by any means follow that all these stations suffered from bad engineering alone, though not a few glaring examples of this nature could be pointed out; for much of the improvement in the engineering of modern central stations is due to the progress made in the construction of electrical apparatus which has made possible corresponding improvements in the engineering designs of such stations. In proof of this we need only recall the fact that in the early days high efficiency and output in dynamos were considered to be attainable only with the highest peripheral speeds, machines running at 1,200 to 1,800 revolutions and developing 25 to 50 h. p. being of common occurrence. The first effect of this condition, imposed by the electrician, was to stimulate engine builders to construct high-speed engines, to avoid the employment of countershafting; a stimulus, we may add, which has resulted in developing a type of engine which has been of incalculable benefit not only to electrical engineering but to all kindred branches. But there were those who still adhered to the slow-speed Corliss type of engine, with its countershafting, and many a wordy battle has been fought at the meetings of the National Electric Light Association between the champions of both methods.

It remained for the electrical engineer, however, to silence these disputes by adapting the dynamo to the conditions indicated for obtaining maximum economy in operation; which were soon discerned to involve a dynamo coupled directly to the most economical type of engine for the particular service required. The solution was effected by the introduction of the multipolar machine, the advent of which may be said to have marked an epoch in the history of electrical distribution.

While it has been admitted that some central stations of the early type suffered from the conditions imposed at the time by the electrical engineer, it cannot, on the other hand, be denied that in many cases the most ordinary engineering rules of economic steam power generation were totally ignored and that the electrical engineer has been held responsible for failures brought about by conditions over which he had no control.

The era of the direct-connected engine and dynamo, of which the Edison "Jumbo" combination was the forerunner, is now thoroughly established in Europe, and we are glad to note that American electrical engineers are gradually but surely drifting in the direction of the triple-expansion direct-connected engine. The pioneer work done by Mr. Van Vleck in New York has borne good fruit, and the Boston Edison station designed by Mr. C. L. Edgar, which is described by Mr. A. C. Shaw in this issue, will undoubtedly serve as an excellent example of what a modern electric central station ought to be; and will, it is to be hoped, help to place American central station engineering on a level with the best practice abroad. Mr. Edgar is to be congratulated in having at his back a board of directors far sighted enough to discern the advantages of the improved methods adopted, and it is safe to say that the large new stations contemplated in other cities, such as Chicago, will be similarly equipped with the most modern appliances.

ELECTRIC LIGHTING IN ENGLAND.

ELSEWHERE in this issue Mr. H. Scholey gives a review of the condition of electric lighting in England at the present time, which is deserving of study for more than one reason. It proves above all things the blighting influence of municipal interference on the progress of electric lighting, and from the figures given it is safe to say that but for private enterprise electric lighting in England would still be a dream. Notwithstanding the fact that 78 cities obtained Parliamentary powers to operate their own plants, only two city plants are actually in operation, while on the other hand of the 37 powers obtained by private corporations 22 have resulted in the erection of central stations. Further comment on this state of affairs is unnecessary.

AUTHORITATIVE CREDIT AND DATES FOR PRINCIPAL ELECTRICAL INVENTIONS AND ENGINEERING METHODS.

WE have received the following communication from Mr. Allen R. Foote, special census agent:

IT seems to me desirable that whatever publication may be made by the United States Census Office pertaining to electrical invention and development, shall, whenever practicable, give official recognition to those justly entitled to the honor of having been the first to invent or to bring into practical commercial use the various electrical inventions and engineering methods that are marked features of the present condition of electrical science and art. This is due to those entitled to the credit, as the judgment of their contemporaries. It is due to our successors, who are entitled to correct records made for the present date. It is due to the enterprise and skill of the American people, who need no greater praise than proper historical statements of their achievements in peace or in war.

That it may be demonstrated whether or not this idea can be practically carried out at the present time, I desire to invite, through THE ELECTRICAL ENGINEER, persons having knowledge of the subjects to advise me, giving full name and date, who first invented or used commercially in America continuous current, constant voltage and variable current dynamos, lamps and motors; continuous current, variable voltage and constant current dynamos, lamps and motors; alternating current, constant voltage and variable current dynamos, lamps and motors; and alternating current, variable voltage and constant current dynamos, lamps and motors; also trolley contacts, single or double.

In addition to this information, similar credit and dates for the following engineering methods would be of great present interest and of increasing value, following which should be a description of the first isolated and central station plants and electric railroad.

BY WHOM AND DATE WHEN FIRST COMMERCIAL USE WAS MADE IN THE UNITED STATES OF:

Incandescent Lamps.—Operated by continuous currents; by alternating currents; wired in multiple; in series; to converters; to accumulators; on arc lamp circuits; on power circuits.

Arc Lamps, Single Carbon.—Operated by continuous currents; by alternating currents; wired in multiple; in series; to converters; to accumulators; on incandescent lamp circuits; on power circuits.

Arc Lamps, Double Carbon.—Operated by continuous currents; by alternating currents; connected in multiple; in series; to converters; to accumulators; on incandescent lamp circuits; on power circuits.

Stationary Motors.—Operated by continuous currents; by alternating currents; connected in multiple; in series; to converters; to accumulators; on incandescent lamp circuits; on arc lamp circuits; on power circuits.

Electric Locomotives.—Operated by continuous currents; by alternating currents; connected in multiple; in series; to converters; to accumulators; on incandescent lamp circuits; on arc lamp circuits; wired on power circuits.

Converters.—Used for incandescent lighting; for arc lighting; for stationary power; for locomotive power.

Accumulators.—Used for incandescent lighting; for arc lighting; for stationary power; for locomotive power.

I shall be glad to receive suggestions pertaining to this subject from those who have given it thought or are interested in it.

Society and Club Notes.

THE SOCIETY OF THE U. S. MILITARY TELEGRAPH CORPS AND OLD TIME TELEGRAPHERS' ASSOCIATION.

THE twelth reunion of these two societies will take place at Omaha, Neb., September 14 and 15. The committee of arrangements, of which Mr. E. Rosewater is chairman, has made every effort to make this first reunion west of the Missouri River a pleasant and profitable one. The headquarters of both societies will be at the *Bee* Building, Omaha, and members and intending visitors are requested to notify L. M. Rheem, secretary of the reception committee, Omaha, Neb., of their intention to be present. The festivities will include a trip to Denver, and a complimentary banquet at Millard's Hotel, Omaha.

MR. C. PURCELL TAYLOR, D. Sc., patent expert, of London, England, desires us to announce that although all his tools and instruments were destroyed by fire on July 22, his valuable library is intact, as are also all the most valuable papers, so that his business will not be interfered with.

MR. JAS. UHL, formerly of St. Louis, has been appointed superintendent of the Toledo, Ohio, Electric Street Railway.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JULY 19, 1892.

Alarms and Signals:—

Electric Signal for Mine Shafts, F. W. Bacorn, 479,046. Filed Feb. 27, 1892.

A signaling device for mine elevators and hoists.

Signal for Electric Railways, F. F. Loomis, 479,138. Filed April 8, 1892.

A signal system energized by a portion of the main railway circuit simultaneously operating a number of signals at different points as the car passes some given point.

Switch and Signal Apparatus, J. C. Schreuder, 479,225. Filed Jan. 20, 1892.

An automatic electric switch signal for railways.

Electric Alarm, R. L. Keith 479,282. Filed May 26, 1892.

An electric alarm for shelves, cabinets etc.

Individual Alarm Signal Apparatus, P. Seiler, 479,308. Filed Aug. 1, 1891.

Employs a polarized relay, the armature of which is adapted to stand in three different positions, in connection with a disc moved by clockwork and governed by a magnet.

Electric Railway Signal, T. A. B. Putnam, 479,333. Filed April 15, 1889.

A railway signal in which a partial circuit is carried on the locomotive and co-operates with other partial circuits arranged along the track.

Alarm Lock, F. Mahannah, 479,394. Filed Sept. 29, 1891.

Conductors, Conduits and Insulators:—

Insulator, C. E. Conover, 479,134. Filed Jan. 20, 1892.

An insulator having a diagonal slot opening into the line wire groove.

Clamp for Electric Conductors, J. Ingmanson and R. Lorang. 479,216. Filed July 13, 1891.

Employs a pair of jaws, a tongue laterally projecting from one of them and having a cam-face for engaging the other, and means of locking the jaws against lateral movement.

Connector for Electric Circuits, J. F. Wollensak, 479,322. Filed April 26, 1892.

Employs an insulating piece secured to a face-plate and provided with two sockets for portable electric lights, etc.

Connector for Electric Circuits, W. E. Gill, 479,325. Filed April 26, 1892.

Similar in its object to 479,322.

Cast Joint for Armored Conductors, F. M. Bennett, 479,386. Filed March 28, 1890.

Claim 5 follows:

A combination with two or more metal armored conductors of a hollow cast metal joint and of a hollow core, both provided with perforations and stopping devices.

Dynamos and Motors:—

Armature for Electric Machines, E. A. Sperry, 479,030. Filed Dec. 17, 1891.

Employs a core of thin rings or discs and axially extending projections secured to the end discs or rings through which the tie bolts pass and from which they are insulated.

Dynamo Electric Machine, R. Eickemeyer, 479,118. Filed Dec. 21, 1889.

Employs a drum armature having an iron core and field coils surrounding it longitudinally, and an iron shell surrounding the field and armature in a continuous plane at right angles to the axis of the armature.

Electromagnetic Machine, A. E. Kennelly and J. F. Ott, 479,169. Filed Oct. 21, 1891.

Claim 1 follows:

The combination in a magnet, of a main body, a separate pole-piece, and a strap securing said body and pole-piece together.

Compound-Wound Alternating Current Dynamo, H. Lemp, 479,170. Filed Oct. 17, 1889.

Employs two armatures or armature coils in series with one another, one being the source of current for the work circuit, and a connection leading across from one side to the other of the series circuit and containing an artificial resistance.

Armature for Dynamo Electric Machines, M. J. Wightman, 479,179. Filed Oct. 28, 1891.

Employs flexible lead wires attached directly to the armature winding, each clamped at the point of connection by the wire of the succeeding section.

Alternating Current Motor, T. H. Hicks, 479,187. Filed Mar. 9, 1891.

Employs field magnets, wound with two distinct conductors, one traversed by impulses of one direction and the other by those of opposite direction, and a commutator to separate these impulses.

Lamps and Appurtenances:—

Electric Arc Lamp, M.S. Logan, 479,207. Filed Aug. 29, 1891.

Employs a coil permanently located in the arc circuit, and a feed regulating coil in a branch circuit, an auxiliary coil in a second branch circuit, and means for switching the auxiliary coil in the arc circuit in multiple with the coil permanently located therein.

Hanger for Electric Arc Lamp, C. A. Pfluger, 479,017. Filed Jan. 23, 1891.

Incandescent Electric Lamp, M. A. Richter and J. G. Nolen, 479,090. Filed Feb. 10, 1892.

Claim 8 follows:

A combination incandescent lamp and shade, comprising a shade provided with pendant stem and bulb, having its neck drawn to form a suitable concavity in which the stem of the shade is secured.

Electric Arc Lamp, W. E. Irish, 479,121. Filed Jan. 2, 1892.

Employs a thermo-expansive strip to automatically operate the clutch.

Electric Arc Lamp, E. A. Sperry, 479,029. Filed Apr. 18, 1890.

Employs two pairs of carbons with feeding clamps for the two upper carbon rods and a suspending clamp for one of said carbon rods, which is also provided with a groove encircled by the clamp, so that one carbon will be fed at a time.

Reflector for Arc Lamps, R. S. Dobbie, 479,183. Filed Apr. 8, 1891.

Employs a hollow refractory body, within which the arc is formed, having a refractory block, adapted to become incandescent, supported within it.

Shade for Incandescent Electric Lamps, W. J. Edmond and T. J. Keon, 479,207. Filed Feb. 29, 1892.

Incandescent Lamp Socket, I. Goldkind, 479,359. Filed Dec. 15, 1891.

Employs a rachet wheel, pawl, lever and clutch device in the socket of the lamp for turning the current off or on.

Incandescent Electric Lamp, H. Green, 479,360. Filed Sept. 2, 1891.

Employs a seal connected with the neck of the bulb and comprising depending legs in which platinum leading-in tubes are incased, the filament having its ends secured to the lower ends of the tubes.

Measurement:—

Electrical Meter, A. E. Kennelly, 479,157. Filed Oct. 17, 1891.

Consists of a motor whose armature has one or more coils forming a closed circuit, and second winding forming the ordinary armature coil.

Electrical Meter for Three-Wire System, A. E. Kennelly, 479,168. Filed Oct. 21, 1891.

Employs a coil to which the positive main is connected, and another connected with the negative main, both coils operating on the same indicator.

Electric Meter, J. F. Ott and A. E. Kennelly, 479,171. Filed Sept. 7, 1891.

A meter in which recording counters are moved forward by a motor mechanism, the extent of whose movement depends upon the strength of the current.

Electric Current Meter, J. F. Ott and A. E. Kennelly, 479,172. Filed Nov. 30, 1891.

Similar to 479,171.

Miscellaneous :—

Safety Device for Electric Circuits, M. Thum, 479,035. Filed June 5, 1891.

Consists of a safety device comprising a second or guard conductor adapted to complete the circuit upon an undue displacement of the main conductor.

Electric Wire Support, W. B. Bragdon, 479,052. Filed Mar. 4, 1892.

Rheostat, J. Waring, 479,101. Filed Apr. 28, 1892.

Consists of an insulating slab having binding screws, switches, coils and contacts, with bridges movably supported adjacent to the contacts and held therefrom by a counterbalance.

Thimble for Light-Fixtures, J. J. Miller, 479,139 Filed Apr. 6, 1892.

Electric Belt, D. P. Andrus, 479,147. Filed Dec. 14, 1891.

Electric Brush, R. E. Williams, 479,321. Filed Jan. 2, 1892.

Electric Stop-Motion for Textile Machinery, S. L. Foster, 479,358. Filed July 29, 1891.

Railways and Appliances :—

Conduit Trolley for Street Cars, A. H. Hieatzman, 479,327. Filed Mar. 24, 1891.

Employs a conductor support consisting of a stem and two downwardly inclined plates forming an inverted V, the stem being secured to or formed on the apex of this iron and the plates being provided with openings to receive the securing screws.

Telegraphs:—

Telegraph Repeater, R H, Weiny, 479,178. Filed Feb. 8, 1892.

Employs an independent auxiliary differential magnet, one winding of which is included in a circuit controlled by the armature of the opposite receiving magnet.

Fac-Simile Telegraph, T. A. Edison, 479,184. Filed Dec. 6, 1881.

Claim 1 follows:

A fac simile telegraph having transmitting and receiving instruments, the transmitting circuit being controlled by the depressions produced by marking autographically upon paper or other material.

Telephones and Apparatus :—

Speaking Attachment for Telephones, D. Eldredge, 479,062. Filed Feb. 26, 1892.

Telephone Switchboard, W. Oesterreich, 479,107. Filed Aug. 7, 1889.

The invention consists in the connection between the switches of the different boards and the telephone lines, and with the annunciator drops and the switchman's call and test apparatus, and also in the construction of the jack switches, etc.

Telephone, G. F. Shaver, 479,226. Filed Mar. 2, 1892.

Employs one or more magnets, each forming an incomplete ring and having pole-pieces extending into the ring, the magnets being reversed and laid one upon the other, and a diaphragm adjacent to the pole-pieces.

Telephony, G. F. Shaver, 479,227. Filed Apr. 8, 1892.

A duplex system of telephony over one wire by means of mechanical and electrical vibrations.

Letters to the Editor.

PROF. THOMAS' INCANDESCENT LAMP TESTS.

In The Electrical Engineer for July 27, page 85, Mr. E. G. Willyoung quotes a part of a statement by Mr. J. W. Packard in his articles in your preceding issue, page 57, and also my statement from your issue of July 13, page 39; you add an explanatory note, in which you quote from a letter by Mr. Packard, as follows:

"I had Prof. Thomas' letter as authority for the statement made in this paragraph, but judging from his later publication, there is apparently some mistake about it. * * *" This leaves me under the imputation of saying one thing in correspondence, and exactly the opposite in print. To relieve me of this imputation, I quote from the letter referred to, which was written June 25, in answer to Mr. Packard's request for information as to the performance of the "Packard" lamp in the test as follows:

"I send you to-day copy of paper on lamp test. The Packard lamp is designated by the letter ("—") in the tables and curves. It stood ("——") in the order of blackening, (least blackened being first, etc.;) with a grade of ("—"), the worst blackened lot being graded 100."

The last sentence is the one referred to as authority by Mr. Packard, but it could only be authority for his statement if the word "first" had been written for the dash ("——"). But the word written in place of the dash ("——") as quoted was neither "first" nor "second," but a higher ordinal. My letter and published statement are therefore perfectly consistent.

In making this explanation, I do not wish in any way to criticise Mr. Packard, who has explained that he wrote under a misunderstanding of the sentence quoted.

Benj. F. Thomas.

Ohio State University; Columbus, Ohio.

Mr. Clarence E. Stump, vice-president and manager of the *Street Railway Journal*, was in Chicago last week and was accorded a happy welcome by his many friends.

OPENING CEREMONY OF THE NEW ELECTRIC LIGHT STATION AT PAWTUCKET, R. I.

About fifty gentlemen responded to the recent invitation of Manager S. G. Stiness, to attend the ceremony at the opening of the magnificent new station of the Pawtucket Gas and Electric Company, at Pawtucket, R. I. The new station is situated on the Pawtucket River, about half a mile from the centre of the city, where it has abundant water for condensing. The station has been finished in the most tasteful way, and is surrounded by neatly laid out grounds. In the boiler-room are six Bigelow boilers furnishing steam at present to one 600 h. p. Harris Corliss engine.

From the engine-room an unobstructed view may also be had of the countershafting, which is situated in the basement underneath the dynamo-room floor. The dynamo-room is one large room without pillars, or any other obstruction, and is perfectly lighted and ventilated. An overhead traveling crane of six tons lifting capacity has been installed, and which runs the whole length of the building. On the water front there is ample room for wharfage and about 10 or 12 feet of water, so that coal vessels can easily unload coal almost at the boiler-room door.

After inspecting the station, a light lunch was served, after which the visitors were invited to partake of a "clam dinner" at Bullock Point, on the Providence River. Accordingly, all boarded one of the small steamers plying between Pawtucket and the home of the clams, and had a most enjoyable sail down the Pawtucket and Providence Rivers, the weather being perfect. Gathering all together on the upper deck, the hour's sail was pleasantly passed, Messrs. William Anderson, of the East Boston Gas Company, and C. M. Coburn, of the Liberty Oil Company, of Chelsea, serving as most efficient "end men," whiling away the time pleasantly with many a darkey song. When the almost insatiable appetites of the clam-eaters had been satisfied the party broke up into small groups and gave themselves up to the enjoyment of the hour.

A return was made in the cool of the evening, and after three rousing cheers for Mr. Stiness for his most enjoyable hospitality, the party broke up, and a happy and profitable day was at an end.

THE WILDER ELECTRIC HOTEL CALL.

Of recent years a number of electrical or pneumatic devices for affording a speedy means of communication between the office and any room of a hotel have been introduced, some of which have possessed considerable merit, but all of which have possessed objectionable features, of one kind or another, sufficient to retard their general introduction. In some cases the apparatus has been too intricate, in others, too expensive; in others, requiring too much attention on the part of the occupant of the room, and so on. In some large hotels, also, speaking tubes are utilized between the various rooms and the main office, but these, apart from the high cost of construction, are also objectionable, by reason of the fact that in order to be satisfactory, a number of clerks must be on hand at the office to answer immediately all calls given simultaneously.

Perhaps the most satisfactory of such devices, of which, however, there have been but few introduced, have been those in which the general principle of the electric multiple call box has been followed, but the vastly greater number of "wants" to be transmitted to the hotel office than are necessary in the case of the ordinary district messenger service, has seemed to call for the exercise of ingenuity on the part of the inventor which has resulted in the production of systems much too intricate and scientific for the matter-of-fact service of a modern hotel.

Realizing the foregoing fact, Mr. E. M. Wilder, the well-known inventor of the Wilder fire-alarm system, the Wilder multiple call box, etc., has devised, and through the Wilder Hotel Call Company is now introducing a hotel call system, which, for simplicity of apparatus and ease of operation, it would seemingly be difficult to improve upon.

As an instance of its simplicity and adaptability to existing circumstances, it may be stated that this system is quite applicable, without any change whatever in the running of the wires, to the ordinary "push" button and annunciator call systems so extensively employed in all of the prominent hotels of the present time. Consequently, but one wire to each room and a neutral return wire are necessary in its operation.

The Wilder hotel call system may be described generally as follows: A dial form of transmitter, one of which is shown in Fig. 1, not much if any larger than the common multiple call box, is placed in each room in the place of the usual push button, the two wires ordinarily connected with that button being attached to the Wilder transmitter. On the face of the dial, arranged in a circle, are printed a large number of "wants," such as "boy," "coupé," "doctor," "bill," "ice-water," etc. On the present dials seventy-five different wants are printed, but any additional number could be readily arranged for. In this transmitter are contained a magnet and a large toothed break wheel, the purpose of which will presently be seen.

To procure any desired service, the occupant of a room, say, No. 24, places a pointer on the face of the dial over a given service and then pulls the crank in the usual way for sending in a call. This is all that is required of the occupant of the room. The pulling of the crank has the effect of closing the circuit leading to the annunciator, precisely as would the pressing of the push button, and consequently the hotel clerk is apprised that a given room has signaled him. The clerk thereupon inserts a metallic plug in a switch which transfers the circuit of room No. 24 from the annunciator to the circuit of a magnet contained in a box termed the "receiver," Fig. 2, and at the same time inserts into the circuit an extra battery. This extra battery has the effect of attracting the armature of the magnet within the transmitter, in room No. 24, and thereby causes the release of the large break wheel. This wheel is capable of causing 75 makes and breaks of the circuit. The number of such makes and breaks that it may cause, however, is regulated entirely by the distance from zero to which the pointer above referred to has been moved by the occupant in placing it over a desired want. In returning to its starting point it makes these specified makes and breaks and remains in its original position until the box has been pulled again by the occupant of the room.

The receiver in the hotel office is also provided with a dial and pointer similar to the dial and wants pointer of the transmitter, and having corresponding wants printed on its dial. The receiver is also provided with a large tooth or pin wheel, corresponding in size and in number of teeth and pins to the teeth of the break wheel of the transmitter. This wheel is given a tendency to rotate by an ordinary recoil spring, but its rotation is regulated by a step-by-step device controlled by the magnet in the receiver. As already stated, this magnet is placed by the action of the clerk in the circuit of any room desired. Normally, the point of the receiver which is mounted on the same shaft as the toothed wheel, is placed at zero. Thus if, for instance, room No. 24 should have desired "ice-water," and assuming that to place the pointer of the transmitter over "ice-water," the break wheel was moved 15 teeth past zero, it is clear that in returning to its starting point it will send in 30 makes and breaks. The circuit having thus been made and broken 30 times, it is obvious that the step-by-step motion of the toothed wheel in the receiver will carry its pointer around to the "ice-water" mark on its dial.

The annunciator thus indicates the room calling, and the receiver dial the nature of the service desired, of both of which the hotel clerk makes note, after which he resets the dial to zero, the act of doing which rewinds the recoil spring. The plug is then removed from the switch and connected with any other room that may, in the meantime, have called.

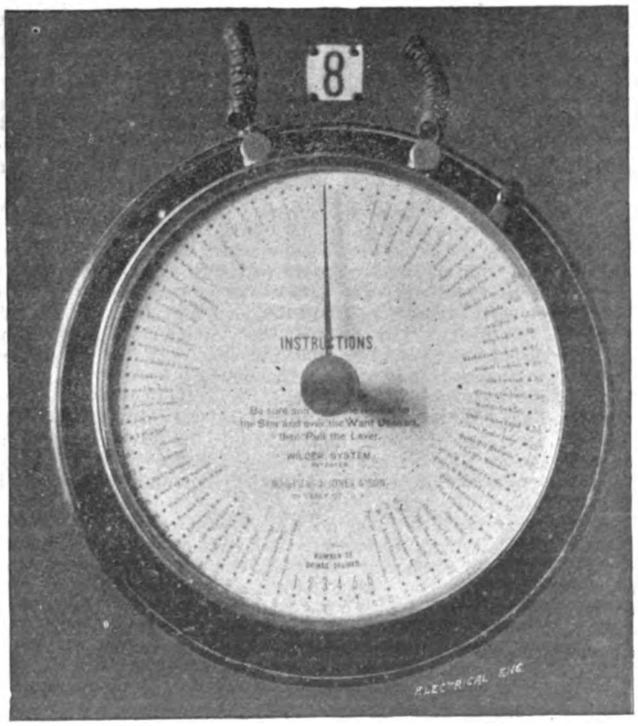

FIG. 1.—THE WILDER HOTEL CALL—TRANSMITTER.

It is thus obvious that any number of simultaneous calls from different rooms may be received in any desired order by the hotel clerk. The movement of the pointer back to its starting point is an indication to the occupant of the room that his call has been received. This system has the advantage that the pointer on the transmitter always returns to the point to which it has been set by the one calling, and thus any question as to proper fulfilment of an order is at once settled by a glance at the dial. Of course this call system is also applicable to apartment houses and other places where numerous different services are continually being demanded.

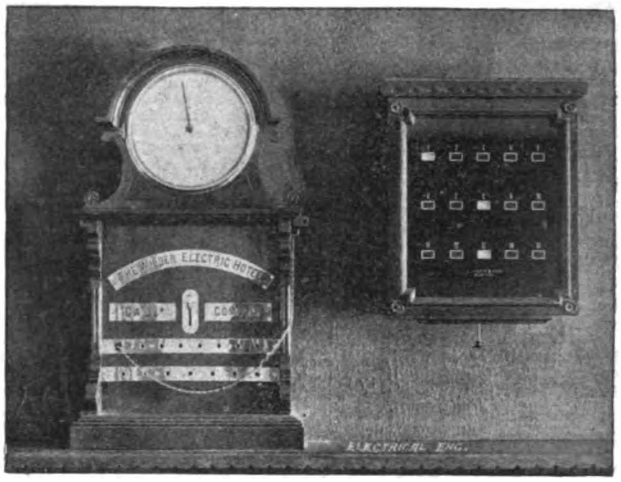

FIG. 2.—THE WILDER HOTEL CALL—RECEIVER.

We understand that arrangements for the placing of this call system in a number of New York hotels have already been completed. It is, we also understand, the intention of this company to sell these transmitters outright, waiving royalties, the simplicity of construction of the mechanism making it possible to manufacture the boxes at quite a low figure. The illustrations furnished herewith are from photographs of an exhibition installation in the main offices of the Wilder Hotel Call Company, Temple Court Building, New York City. The officers of the company are, E. R. Wilder, president; Chas. Shaw, vice-president; Charles J. Pearson, treasurer; L. F. Bostleman, secretary; E. E. White, manager.

Personal.

PROF. GEORGE FORBES, who departed from these shores but a few weeks since, is expected to return by Aug. 17 to look after professional work entrusted to his care on this side. Prof. Forbes' agent makes a brief announcement on this subject in our columns this week.

MR. FRED. RECKENZAUN the well-known electrician, has been spending some time in Chicago.

PHILADELPHIA NOTES.

ORDERS booked by Warren Webster & Co., manufacturers of the Webster vacuum feed-water heater and purifier during the month of July were as follows:

V. D. Anderson Co., Cleveland, Ohio, one 80 h. p.; Mechanical Fabric Co., Providence, R. I., one 400 h. p.; Carlisle Water & Gas Co., Carlisle, Pa., one 200 h. p.; Savannah Gas Works, Savannah, Ga., one 60 h. p.; Penna. Steel Co., Steelton, Pa., first order, one 400 h. p.; second order, one 2,000 h. p.; Detroit Sheet Metal and Brass Works, Detroit, Mich., one 125 h. p., for Telephone Building, Detroit; Onderdonk Heating and Ventilating Co., Philadelphia, one 80 h. p.; Mt. Holyoke Seminary and College, Holyoke, Mass., one 150 h. p.; J. Horace McFarland Co., Harrisburg, Pa., one 30 h. p.; Harrisburg Boot & Shoe Co., Harrisburg, Pa., one 150 h. p.; N. & C. Taylor Co., Philadelphia, one 100 h. p; D. M. Bare & Co., Roaring Spring, Pa., one 1,000 h. p; Lorraine Manufacturing Co., Saylesville, R. I., one 750 h. p.

The orders received for the Williames vacuum system of steam heating without back pressure upon the engine were as follows: Armour & Co., Union Stock Yards, Chicago, Ill.; Galloway College, Searcy, Ark.; Smith Building, Chicago, Ill.; Harrisburg Boot & Shoe Co., Harrisburg, Pa.; J. Horace McFarland Co., Harrisburg, Pa.

They issue a catalogue, and visit plants in any part of the United States at their own expense for the purpose of giving estimates under guarantee.

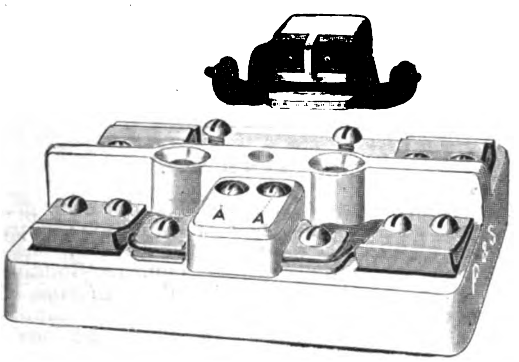
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

It is good policy to strike while the iron is hot; it is still better to adopt Cromwell's procedure, and make the iron hot by striking.—E. L. Magvon.

PASS & SEYMOUR SPECIALTIES.

The accompanying illustration shows the Sawyer-Man main block, made by Messrs. Pass & Seymour, of Syracuse, N. Y.



Pass & Seymour's Sawyer-Man Main Block.

The brass work is mounted on Syracuse china and is furnished with or without the fuse plug as desired. The plug also serves as a cover for the fuse. To attach the fuse the screws A A are loosened and the fuse is fastened between the brasses. The plug is then inserted under the regular screws on the main block.

RECENT SALES OF PURITY OIL FILTERS.

The Purity Oil Filter Manufacturing Co. report that, in regard to sales, "July takes the bakery." They have sold filters recently as follows:

McIntosh-Huntington Co., one No. 3 Purity oil filter; Glens Falls Paper Mill Co., Glens Falls, N. Y., one No. 1 Ideal oil refiner; the Martine Cantine Co., Saugerties, N. Y., one No. 1 Ideal oil refiner; Granite Mountain Mining Co., Rumsey, Mont., one No. 3 Purity, second order in two years; Doylestown, Pa., Elec. Co., one No. 2 Ideal oil refiner; Yonkers, N. Y., R. R. Co., one No. 3 Eureka oil purifier; Wray Elec. Engineering Co., Bradford, England, one No. 2 Purity oil filter; Insane Asylum for Criminals, Fishkill Landing, N. Y., one No. 1 Purity; J. C. Hubinger Co., Keokuk, Ia., one No. 2 Ideal; Metropolitan St. R'y Co., San Francisco, Cal., Industrial Works, Bay City, Mich., one No. 1 Purity; Metropolitan St. R'y Co., Macon, Ga., Silver Bow, Montana, Elec. Light Co., one No. 2 Ideal refiner.

The following is a sample of the letters received by this company:

Purity Oil Filter Company,
Pittsburgh, Pa.

Lakewood, N. J., Aug. 3, 1892.

Dear Sir:—I have been using one of your No. 1, Ideal Steam Oil Refiners for four months past; I am very much pleased with it. I purify the oil from the engine and dynamo without any trouble. The refined oil is in splendid condition.

Yours very truly,
Mike McGravy
Engineer of Water Works and Electric Light Co.

"A MODERN TRIUMVIRATE."

This is not the catching title of a sensational novel, but is the term that has been very neatly applied to the firm of Bartlett & Co., of 21 and 23 Rose street, composed of E. E. Bartlett, the artist; Theo. von de Luhe, the engraver; and Louis H. Orr, the printer. These three talented gentlemen do not aim to run a government or wage a great war, but adapting the idea to modern notions they have ingeniously proposed to carry on and control a central station system for all the work that their individual and collective ability can be applied to. And the triumvirate, under these conditions, is a distinguished success, its work being a pride to all who order it and a joy to all who see it. The firm have applied the term, as quoted above, to an exquisitely beautiful pamphlet which illustrates in and of itself their work, the way it is done, and the place in which it is done. The engravings show the different processes actually going on, from the first to the last. The cover is a magnificent piece of embossing that will stay embossed, while the antique entablature inside printed in sepia is an art production worthy the best frame.

At the end of the brochure are a large number of well-deserved testimonials as to the work of the company.

WASHINGTON ELECTRIC CONDUIT COMPANY.

The president and general manager of this company, Mr. Wilmot Lake, reports most gratifying progress in the matter of contracts for electric conduits in different cities. Mr. Lake is at present busily engaged in laying about 10 miles of conduit in Washington, D. C., and has also just received an order for another to be laid in Albany, N. Y.; a number of other cities are rapidly falling in line, in view of the great and permanent success of all of Mr. Lake's installations thus far.

A NEW ELECTRIC WIRING COMPUTER.

We present to our readers a simple device just issued, and compiled by Mr. William Cox, by means of which the sectional area and the number of wire suitable for lighting and other purposes are at once obtained. It consists of a suitable foundation plate, with a revolving circular disc about 8 inches in diameter, both graduated in accordance with the factors of the formula whose solution it gives. This is the well-known one:

$$\text{C. M.} = \frac{l \times c \times 10.8}{V}$$

in which l = whole length of circuit in feet; c = current in amperes; v = drop of potential in volts; C. M. = sectional area of suitable wire in circular mils. The method of using this computer is shown by the following example in which we assume 76 feet as the whole length of circuit; current, 10 amperes, and loss, 2 volts. Turn the disc round until the division representing 2 volts is opposite, and coincides with, the one representing 10 amperes. We shall now find on the outer upper scale 4,100 circular mills, which corresponds to No. 14 wire, B. & S. gauge. This is, therefore, the number of wire suited to the circumstances.

Cox's Electric Wire Computer.

We understand that Mr. Cox has sold his invention to the International Okonite Company (limited) 13 Park Row, New York, to whom all inquiries concerning it should be addressed.

STILL ANOTHER—AND THIS MAKES THE SEVENTH.

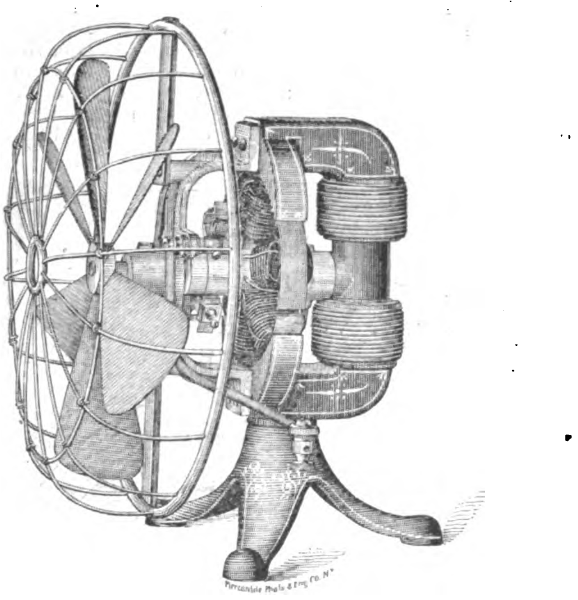
On Thursday, Aug. 4th, the "Kerite" Wire and Cable Co. placed across the Hudson another 18 conductor submarine cable. This cable, from shore to shore, is 5,300 feet in length. A small party accompanied the officers of the company to witness the laying of this cable, the ceremony, if such it may be called, occupying just five minutes from landing to landing. This was remarkable, but a beautiful and practically clear river facilitated matters so much that the record was beaten by several minutes. The cable tug "Western Union" was used in laying this cable, and has done similar service a number of times before. This cable makes the seventh 18 conductor cable furnished the Metropolitan Tel. and Tel. Co. by the Kerite Co. There is a moral here that is not hard to discover.

BALL ENGINES.

Mr. F. R. Chinnock, New York sales agent of the Ball Engine Co., of Erie, Pa., is located at 18 Cortlandt street, whence he constantly reports large sales of these well-known engines in all parts of the country.

EDISON BATTERY FAN MOTOR.

The evident demand for a fan motor operated by battery has led the Edison Manufacturing Co., of this city, to design the fan outfit shown in the accompanying engraving. This is wound to be run by four Edison-Lalande cells of the type "K" size, which are capable of furnishing current continuously for 100 hours. The cells, consisting of porcelain jars, are placed in lead-lined boxes 25 inches long, 8 inches wide and 15 inches high. The motor and fan occupy a space of 10 x 12 inches, and their workmanship is of the highest standard. The outfit can also be operated by one or two cells of storage battery.



Edison Battery Fan Motor.

THE INTERIOR CONDUIT AND INSULATION COMPANY.

The Interior Conduit and Insulation Company's business is increasing in a most interesting manner. In addition to the regular monthly increase in the manufacture of their conduit, the Lundell fan motor which they have brought out this season has met with wonderful success. Up to the first of the present month they had sold over 2,000. Their shops show remarkable activity. The recent heated term has seriously injured them, inasmuch as their mechanics were unable to stand the temperature of the building. During the first part of the week before last their superintendent, Mr. Pease, endeavored to supply every bench with a number of their Lundell fan motors. On Friday, however, the heat in the shops developed such a remarkable degree that the superintendent was obliged to shut down at noon and let the men off, as several had been overcome by the heat in the morning.

NEW YORK NOTES.

H. Ward Leonard & Co.—The position which is occupied by Messrs. H. Ward Leonard & Co. is one which is very popular with purchasers of electric railway and electric lighting plants. A "bulk" electrical contractor who undertakes the entire equipment of the plant, and turns it over to the purchaser complete in every respect, relieves the purchaser of a great deal of responsibility and annoyance, and insures the rapid execution of the work, without the division of responsibility which always is met with when various contractors are operating upon the same plant.

It is not often that an electrical contract of $800,000 is awarded. Hence there has been a very severe competition over the contract for the equipment of 17 miles of road for the Cayadutta Electric Railway Company. The contract has been finally awarded to H. Ward Leonard & Co., of New York City, who act as bulk electrical contractors for the entire equipment of the road including buildings, steam plant, electric generators, track work, bridges, overhead work, cars, etc.

The Fitch Battery and Electric Co., of Oneida, N. Y., have received notice that the Perfect battery, manufactured by them, was used with very gratifying results, in connection with the exhibition of the system of the Electric Heat Alarm Co., of Boston, recently given in St. John, N. B.

WESTERN NOTES.

Mr. Campbell Scott, of Louisville, Ky., formerly manager of the Cincinnati and Louisville offices of the Edison Company, having recently resigned his position to embark in business for himself, has opened an office in the Commerce Building, Louisville, and will hereafter represent, in Southern Indiana, Kentucky and Tennessee a number of the leading electrical manufacturers. Among them are the Detroit Electrical Works, National Electric Manufacturing Co., Card Electric Motor and Dynamo Co., John A. Roebling's Sons Co., Indiana Rubber and Insulated Wire Co., Union Electric Co., Electric Appliance Company, Buckeye Electric Co., besides a number of other manufacturers of electrical specialties and supplies, boilers, engines, etc.

Charles E. Brown, of the Central Electric Company, met with a rather painful accident last week; in adjusting a fan motor the blade of the fan struck him on the back of the hand, cutting a gash to the bone almost an inch wide. Dr. John McKinlock, the surgeon of the company, promptly dressed the wound, and there will be no occasion for serious results therefrom. Mr. Brown's hand will be in a sling, however, for some little time. In the meantime, if his friends in the trade feel slighted when they call, by not being able to grasp him by the hand, it will be due to the above circumstances.

The Gate City Electric Company, the Kansas City branch of the Central Electric Company, have sold to Armour Brothers 10 miles of Okonite and 10 to 20 miles of weatherproof wire, besides other supplies for their new buildings. The order was given on the merit of the goods, and was handled with a good deal of skill by Mr. W. D. Green, the manager at Kansas City. The Central can be congratulated upon having such a capable man in charge of their Kansas City house.

The Electric Appliance Company, Chicago, report large success in the introduction of Mica-Asbetite railway appliances. This material is receiving favorable comment from every one familiar with the requirements of electrical railway construction and a large number of Western railroads are giving the material the severest test with the best possible results; from which it would appear that the Mica-Asbetite appliances will take their place among the standard railway material on the market.

The Sioux City Electrical Supply Co., Sioux City, Ia., have added $12,000 to their paid-up capital. They are now operating a brass foundry, making a specialty of casting electrical goods, but also doing a general jobbing business in casting copper, lead, zinc, tin, aluminum and antimony, making solder, babbit, commutator bars, etc., for the trade.

The Kester Arc Lamp and Manufacturing Co., although they have only recently placed their new lamp for constant potential circuits on the market, are receiving a large number of inquiries and orders. Their lamp is handsomely finished, very reliable and economical in the use of current and a large business will no doubt be done.

Wickes Bros., manufacturers of boilers and engines, No. 510 Monadnock Building, Chicago, Ill., are doing quite a large business through Mr. A. M. Castle, manager of their Chicago office. They are handling Wood water tube boilers which are adapted for central stations, both lighting and street railway.

Electrical Engineer.

Vol. XIV. AUGUST 17, 1892. No. 224.

VACUUM LIGHTNING ARRESTERS.

BY

Lewis Searing

IT has been almost invariably the rule in devising lightning arresters to regard the arcing of the line current as a necessary evil and all invention has been directed to devices for breaking this arc, instead of preventing it. The writer having a very strong belief in the old-time adage that "Prevention is better than cure," directed his efforts to the seemingly impossible problem of discovering a means for *preventing* this arc.

Lightning, or more properly speaking, the static discharge from aerial lines, is not of a damaging character as it usually manifests itself in central station apparatus. It is the powerful heating effects of the dynamo current which follows over the static spark, a space it would be impossible to jump by virtue of its own E. M. F. It is not such a difficult matter to provide a path to the earth for the charge which may accumulate in a line, but it *is* difficult to prevent the dynamo current from following the same path. This is especially so in an electric railway circuit where one side of the line is already grounded, for connection to the ground at any one point results, virtually, in a short-circuit.

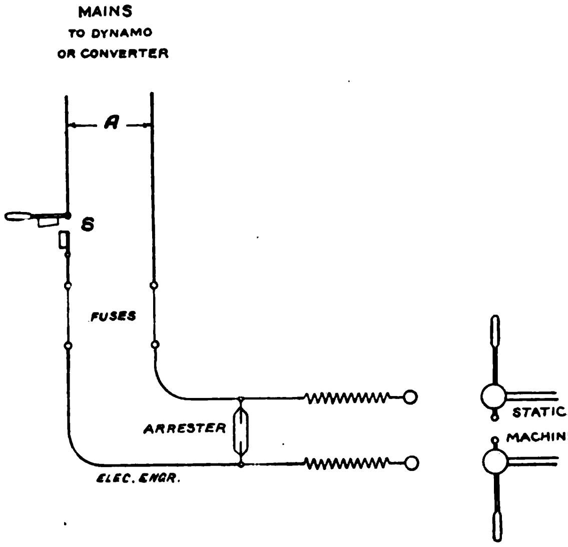
Take, for instance, the usual electric railway circuit of 500 volts, arresters formed of two carbon plates separated by a space of $\frac{1}{64}$ inch; one plate connected to the line and the other to the ground, would easily take care of all the lightning that might come on the line. But the first time a discharge took place across the arresters the dynamo current would follow, and unless interrupted by a fuse in the ground side, would completely unfit the arrester to take care of the next discharge which would be pretty sure to come immediately if the arresters are out of order. It would be a simple matter to prevent the arcing of the dynamo current by separating the carbons by a distance of six inches, but as an easy path to the ground for the lightning, in preference to a costly machine, this would be manifestly absurd.

In view of these facts one naturally seeks to find in the perfect lightning arrester, a medium of great conductivity to a static charge and a medium of great resistance to a dynamo current. A review of the various phenomena accompanying the static spark and the arc as occurring in different mediums led to the adoption of a rarefied gas as the most promising solution to the problem, and experiments were made to test the correctness of the theory and to obtain a practical form of apparatus. The arrester first experimented upon was nothing more than a glass tube three-quarters of an inch in diameter, into opposite ends of which were let platinum wires terminating in carbon points separated by a space inside the tube, the latter being exhausted by air and sealed.

The method of testing is shown in the diagram. The wires from the arrester terminated in metal balls mounted on one glass tube to enable both ends of this circuit to be connected quickly and simultaneously with the poles of the static machine, for otherwise with the arrester directly connected to the machine the leakage across the arrester and through the dynamo prevented the machine from charging itself to any degree.

The arrester being placed in position, the switch completing the circuit from the dynamo to the arrester was closed and the static machine turned by hand until fully charged. The terminating balls of the arrester circuit were then suddenly placed on the poles of the static machine, causing a disruptive discharge to take place across the arrester points.

In the first experiment the space between the carbon points of the arrester was six-tenths of an inch and the voltage at A, 1,000, alternating. The arrester being in position, the switch S was closed and before the terminating balls had approached close enough to the poles of the static machine to produce even a visible discharge, both fuses were blown.



Testing Vacuum Lightning Arresters.

The explanation is simply that the points were so close together that it required but a very slight static discharge to carry over the current from the dynamo. The arrester was not injured, although there was evidence of an arc having been formed across the carbon points.

An arrester with a separation of but one-tenth inch was next tried. The fuses blew upon closing the switch S, showing that the voltage of the dynamo was sufficient to arc across this space; with the arrester of six-tenths inch separation and the voltage at A reduced to 150, discharge after discharge from the static machine could be made across the arrester points without the dynamo current following. Raising A to 240 volts was sufficient to make the current follow over and blow the fuses.

By connecting two converters together so as to bring the primary coil to the arrester, it was found that an arrester with a separation of one and seven-eighths inch, and a voltage at the arrester of 650, the converter was completely protected, although connected to the arrester by but a few feet of wire. By raising the voltage of the converter until a luminous discharge was produced between the points and at the same time discharging from the static machine, the converter current showed no inclination to *arc* across.

It is therefore evident from these experiments that it is not impossible to obtain a medium which shall at the same time form an easy path for the lightning and resist the passage of the line current. Substitute plates for points so as to promote a brush discharge, and surround the plates by a rarefied atmosphere of a non-oxidizing gas and we obtain an arrester which is at once perfectly automatic and weather-proof, contains no moving parts to stick and get out of order, is inexpensive and effective.

VACUUM TUBE LIGHTNING ARRESTERS.

BY

Reginald A. Fessenden.

I HAVE to thank Mr. Osborne for his letter in THE ELECTRICAL ENGINEER of July 27, but must disclaim the credit of having been the first to suggest the use of vacuum tubes in this connection. The idea was suggested to me by Mr. John F. Kelly, who informed me at the time, that vacuum tubes had been used as lightning arresters on telegraphic lines a number of years ago. The fact that the experiments to determine the best vacuum to be employed were made by me and that the apparatus was put in practical shape by Mr. Nassoy and myself, is what probably gave rise to the mistake.

En passant I may speak of the reasons for designing such an arrester. It is not advisable in practice to insulate a 110-volt dynamo so that it will stand much more than 500 volts, as if this is done, the insulation takes up too much room. This corresponds to a sparking distance of less than five one-thousandths of an inch. It is therefore evident that if the potential between line and ground is more than 500 volts and the jaws of the lightning arrester are farther apart than five one-thousandths of an inch, the dynamo may be burnt out, and yet the lightning arrester fail to work. It might be thought that this is a rather problematic case, but it is by no means so; while, if a sudden difference of potential is made between line and ground, the lightning arrester is almost sure to work. It is one of the commonest things in the world for the potential on the line to creep up slowly, even on days when there is no lightning to be seen, till it gets a chance to spark across somewhere. As the charge creeps up slowly, no amount of self-induction will keep it out of the machine, and unless the air gap of the lightning arrester breaks down before the insulation of the dynamos, there is trouble.

The common statement of the engineer (one at least, which I have met with three times myself,) in such cases is, "There was no lightning to be seen and not very much rain, only a drizzle; I got a shock from the water-pipes several times during the day. When the dynamo (or dynamos) went up, the lightning arresters did not work, though we have them on all our lines. They are in good order and have worked very well on previous occasions." It was for this reason that the vacuum tubes were used as lightning arresters, as by altering the vacuum they may be made to go off with certainty at any desired potential.

I may say that I have designed another form of lightning arrester which is simple and more certain than the above, having no air gaps, but depending on the properties of a certain chemical substance. This will shortly be put on the market, but as the patents have not yet been issued, I must defer explanation for the present.

SHALL IT BE "CONTINUATOR" AND "PULSATOR"?—A SUGGESTION.

BY

L. Gutmann.

FOR some time I have been wondering why there are no short terms for a "continuous current generator" and a "pulsating current generator." Considering the great length of time that these machines have been in use, an appropriate short name, so it seems to me, would have been desirable. A great contrast seems to exist in this respect in alternating current apparatus. Not only have the dynamos of this type after having been discarded for a number of years, suddenly swept the whole globe, but also within the six years of their renewed existence a short name seemed desirable, such as proposed by Mr. Mordey, I believe. Instead of the "alternating current dynamo" the new name has become so familiar to us that we did not wait for an electrical congress to formally adopt it. We find the name "alternator" even adopted by Prof. Thompson in his latest edition of "Dynamo-Electric Machinery."

Not knowing whether other engineers think it necessary to introduce new names for the other dynamo types, or whether a subsequent discussion would not disclose more appropriate names, it would be desirable to hear the opinion of other engineers through THE ELECTRICAL ENGINEER before proposing such a name to the American Institute of Electrical Engineers, which body should be the court of last resort to finally accept or reject such propositions for the United States.

One of the main points in coining names is harmony, and it occurred to me that the new names must be of a construction similar to "alternator" to be acceptable. The name "commutator" would have been the best for a continuous current machine if it had not been adopted long ago for the mechanical device used as a portion of a continuous current machine for directing the current or changing the circuit connections of the various impulses. The next best name seems to me to be "continuator," and similarly, "pulsator," so that we would have for the alternating current dynamo, "alternator;" for the pulsatory current dynamo, "pulsator;" and for the continuous current dynamo, "continuator." I hope that electrical engineers will give expression to their views on this subject.

THE ELECTRICAL PRODUCTION OF OZONE.

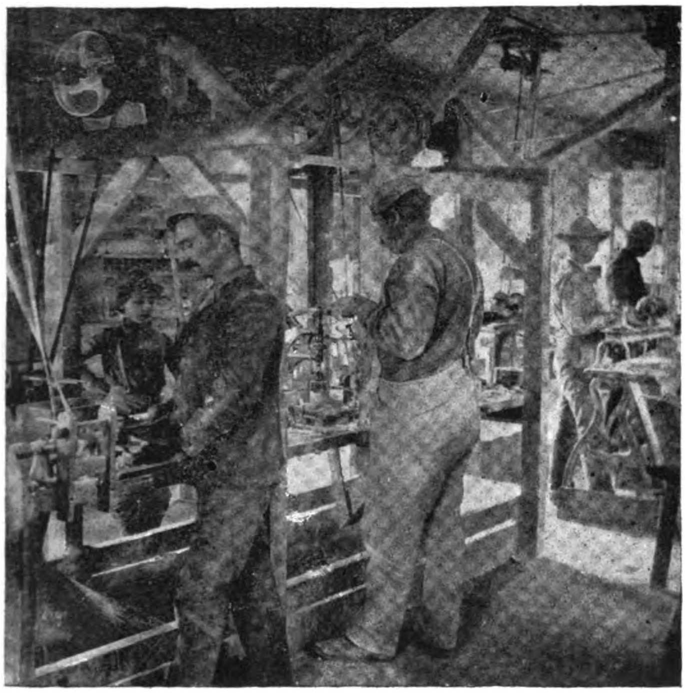
ONE use of ozone, on which Herr Frölich lays special stress in a recent lecture, is the disinfection and sterilization of water. From recent experiments in the Siemens and Halske laboratory at Berlin, it appears that good results have been attained in producing ozone on a commercial scale by means of the silent electric discharge. An apparatus now at work in the laboratory yields 2.4 mg. of ozone per second. Experiments are being made in supplying compressed ozone for technical use; and this has been accomplished with a pressure of nine atmospheres.

AN ELECTRIC WAGON.

TRIAL was made in Chicago recently of a park wagon equipped with a small 3 h. p. motor and a twenty-four-cell storage battery. With five persons in the wagon, it left the barn of the American Battery Company, on Monroe street, and traveled by the way of Winchester avenue to Jackson Boulevard, to La Salle street, to the company's office at Monroe and La Salle streets. The run was made in twenty-two minutes. After a few minutes another party made the return trip. It is calculated that the wagon can make ten miles an hour easily with the present motor, and can climb any hill in Chicago.

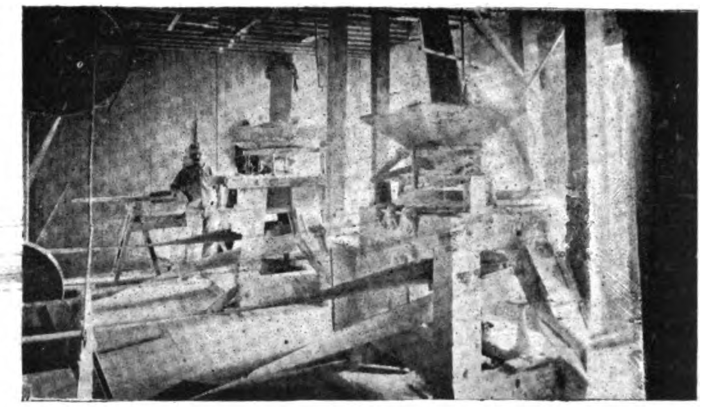
THE MAKING OF LAVA INSULATORS AT CHATTANOOGA, TENN.

LAVA insulators have won a distinct place in the electrical arts in this country, and each year sees some new application of this interesting form of insulation, wherever exacting conditions with fire and moisture have to be contended against. Lava seems to be equal to glass, porcelain and mica in its ability to withstand considerable electrical strain, while it lends itself readily to manipulation into an immense variety of shapes, especially for small parts of apparatus. It can be turned, cut or molded into any shape required, before being submitted to the hardening process, and so little susceptible is it to warping while going through the treatment for hardening that it will fit into any given place for which it was designed with the accuracy of brass or other metal. This fact offsets, or, rather, emphasizes the other quality it has of extreme hardness, as the result of which its bearing parts, or its threads, in any apparatus, remain for an indefinite time without perceptible wear; so that while other portions of the machine or instrument may need renewal, the details made in "lava" may be employed over and over again. "Lava" is not soluble in any known acid, it is waterproof and nonabsorbent, and it is absolutely resistant of heat. Any ordinary temperature that may be met with, where the parts are in contact with fire, does not hurt it in the least. The writer has seen pieces that have stood a continuous exposure of thirty hours surrounding a 2,000 c. p. arc, being part of the time practically in the arc; yet the impression, if any, made on the rings used was really undiscoverable. The insulation resistance is also extremely high. A piece of about a cubic inch tested by the Thomson-Houston Electric Co., who have used enormous quantities of lava, is reported to have shown a resistance of 50 megohms.



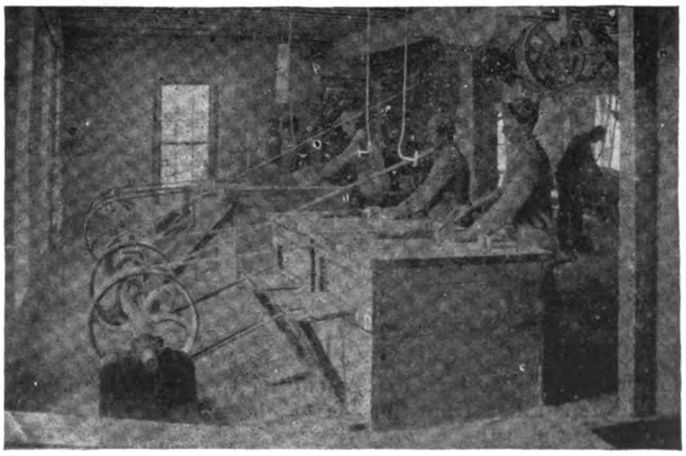
Machine Work in Insulator Department.

It is natural that with the qualities roughly outlined above, "lava insulation" should have made its way in the electrical field since its introduction a few years ago. At the present time the consumption is very large, as many as half a million pieces having been ordered in a single week. There are one or two substances that have renewed in electric lighting work a popularity already won in the domain of gas, and lava has certainly been among them. The number of lava gas tips in use now runs up into millions, and so long as gas is used there is no reason to doubt that the demand will grow.



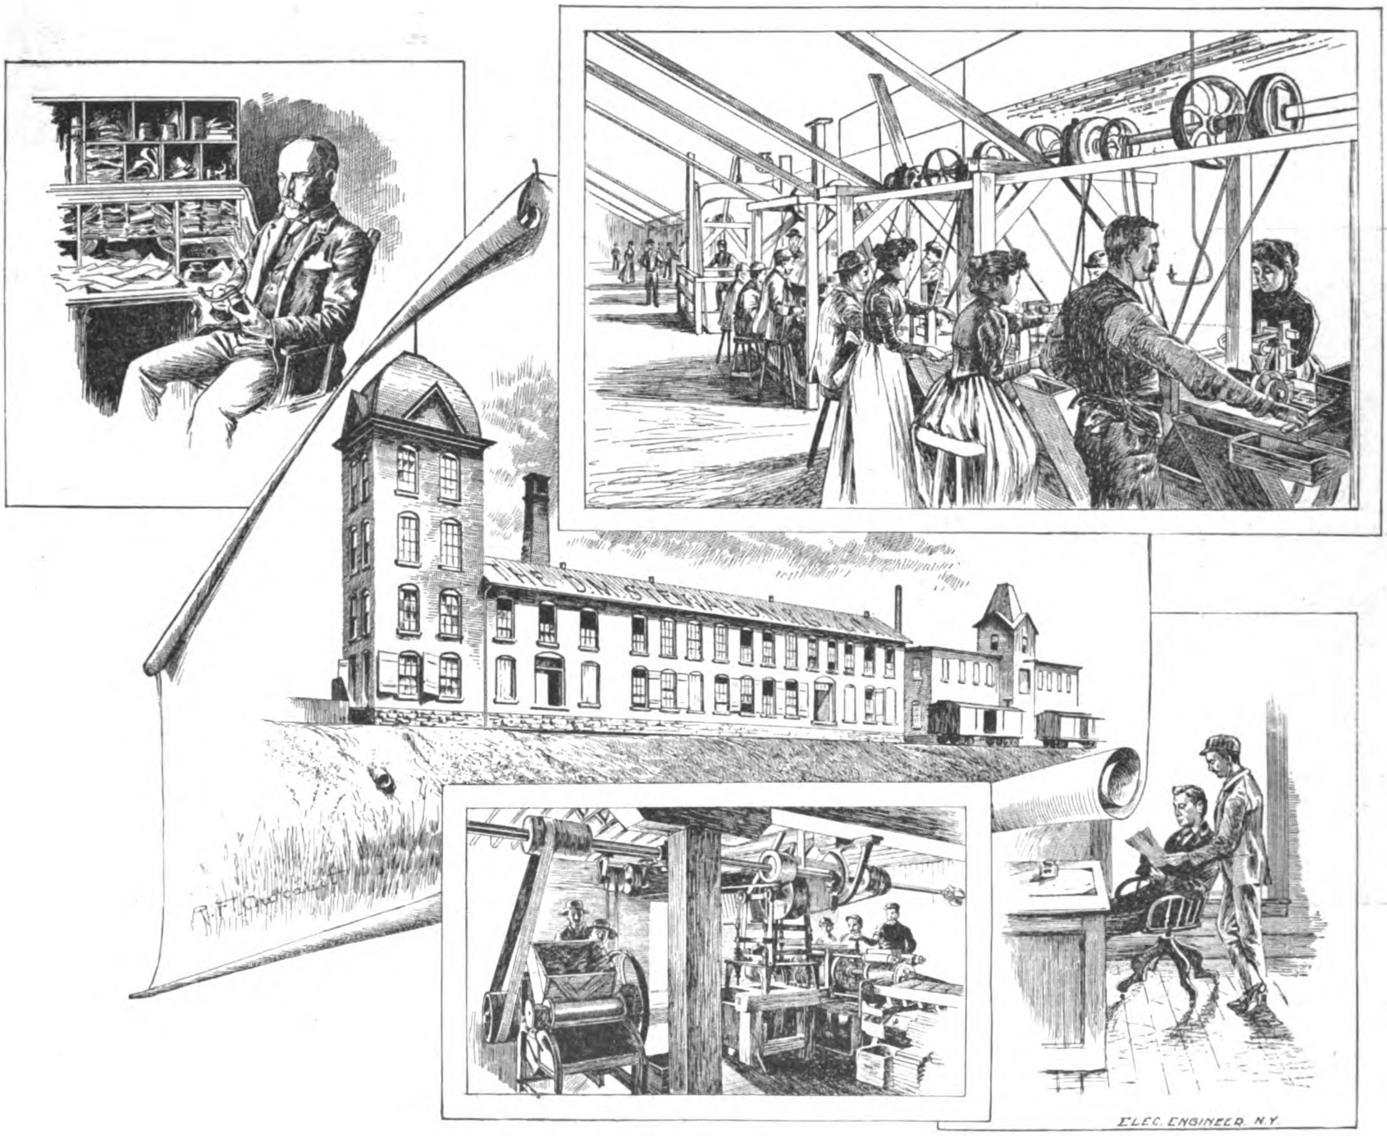
Part of the Mill Room.—Grinding Steatite.

The basis of "lava" is steatite or soapstone, of which the lava manufacturers D. M. Steward & Co., of Chattanooga, Tenn., have a remarkably fine mine. The same material is worked up into the millions of dustless crayons and slate pencils used in this country every year, and hence is a standard article of diet not only with the savages of South America, but with the gentle school children of North America. Before establishing himself in Tennessee, where he is near his source of supply of raw material, Mr. D. M. Steward carried on his industry for several years at Cincinnati. It is a singular fact, and one that tells volumes of the changed social and industrial conditions of the New South, now so warm in its welcome to manufacturing enterprise, that when he removed from Cincinnati, Mr. Steward, an old Union soldier, built his factory on the very ground where he had camped and bivouacked during the struggles of the civil war. The people with whom he had fought were not less glad to extend him the hand of comradeship than was he to settle among them as a citizen, with his energy, capital and experience. Perhaps if Mr. Steward had not gone fighting



Cutting Blanks for the Lathes.

through Tennessee he would never have known what a Land of Promise awaited in the South when the piping times of peace could come round again.



ELEC. ENGINEER N.Y.

Views at the Factory of D. M. Stewart & Co., Chattanooga, Tenn.

Taking the crude steatite as it arrives from the deposits in the mine—a pinky-white rock, soft and smooth to the touch like polished wood, or plumbago—it is first necessary to reduce it to powder. In the large factory of which a view is given in our illustrations, Mr. Steward has a complete equipment for this and all the subsequent stages of the work. The rock is ground to powder by passing it through an ordinary stamp mill, of the kind familiar in mining regions. The powder is then carried by chain conveyer to the mills proper. Here it is ground exceeding small, so that one can hardly feel it when rubbing it between the fingers. This second powder, to which the word "impalpable" might be fairly applied, is then conveyed by elevators to the bolts, where it passes through the finest silk bolting cloth. From these bolts it is deposited in large bins or settling chests, whence it falls to the lower floors again. It is taken from the receptacles and placed in revolving mixing tubs, where the mass is treated with liquid chemicals which reduce it to a condition in which it resembles bread dough, and is so little American that it is entirely and absolutely free from grit. Leaving the mixers, it is passed to the rolls, where it is repeatedly pressed, and it is again pressed in special machines, operating under great hydraulic pressure, in which the dies are placed for turning out the blanks for the lava insulators. The dies are changed in the hydraulic press from time to time, in keeping with the size or class of insulator to be made. In many instances, of course, the pieces require careful and expert cutting and working, as illustrated in our engravings, so that they may be finished. The smallness of the holes that can be made in the "lava" and the fineness of the thread, are something remarkable.

After the sawn or pressed pieces have been prepared, they are subjected to the hardening process, by being placed in a kiln into which superheated steam is introduced in pipes, the temperature being regulated by the requirements of the article subjected to its influence. On leaving the kiln, the articles are examined, finished and packed.

Where the work is of such variety as in the case of lava insulators, the details of the process are many, though they do not greatly differ, the one end being uniformity and accuracy. Some of the pieces made are extremely small, others are quite large, and the range extends all the way from rings and washers, and cores for little magnets, up to long tubes for interior and underground work, and insulators for overhead trolley wires. Mr. Steward and his two sons, G. C. Steward, assistant manager, and Clarence S. Steward, superintendent, who superintended the work, have incessant inquiries for insulators which are intended and expected to stand the severest possible tests and to come out of the fiercest ordeal as fresh and smiling as the Hebrew youths of old from their bath of fire.

In view of the conditions that prevail in the South, with its equable climate, cheap labor, and nearness to iron and coal, it is somewhat singular that so little electrical manufacturing has been done in that region. But it is cause for congratulation that Mr. Steward, as an old Northern manufacturer, has been able to transplant his important industry and carry on there with renewed and growing success his production of a very interesting and useful detail of electrical work.

The buildings have a combined frontage of 450 feet. About 25 tons of material is used every week.

HIGH VOLTAGE INCANDESCENT LAMPS.

BY

Capt A. de Khotinsky

In The Electrical Engineer of July 27, in the notes on 200-volt incandescent lamps, taken from *L'Industrie Electrique*, M. Vitte cleverly suggested making 200-volt lamps from 10 c. p. 100-volt lamps by simply doubling the length of the filament, for which suggestion lamp manufacturers should be very thankful for such an easy solution of the question of high voltage lamps. As I see from your editorial note that there is great interest manifested in electrical circles in high voltage lamps I take the opportunity of giving a short review of my work in that line.

In 1881, when I was in Paris, Mr. H. Fontaine, president of the Gramme Electrical Co., gave me a problem to solve in the construction of high voltage lamps of 250 volts and 200 c. p., limited to absorb not more than 600 watts; his idea was to replace the Jablochkoff candles on the Avenue de l'Opéra. I made several dozen of these lamps which were submitted to the committee appointed by Mr. Fontaine, consisting of Mr. Gramme, and his brother-in-law, a professor of chemistry in Brussels College; Mr. Niaudet and others.

The result of this test was favorable in all respects, as regards the efficiency and electrical part, but as the committee found it very difficult to watch the lamp during 300 hours (which was stipulated as the necessary life) they determined to test the lamp only six hours, but with 300 volts difference of potential. The highest life under this condition was 5 hours and 40 minutes, and for this reason the lamps were rejected; and that was the end of my first experiment with high voltage lamps.

During this test the lamps did not blacken on the inside surface of the globe, only a small blue flame was seen on the positive terminal of platinum near the connection of the filament, which flame, a few minutes before it ruptured, jumped many times from one terminal to the other and at last short-circuited and melted the platinum below the negative terminal of the filament, and in all cases the filaments were left intact.

The distance between the terminals was 1¼ to 1½ inch and the length of filament 18 inches in each, two filaments being employed in multiple which crossed each other at an angle of 90 degrees. The filament was punched out of bristol board, and had a section of 400 square mils; the form of the filament was zig-zag, similar to the Weston 100 c. p. filament of 1883.

In 1882 I found it possible to prepare a homogeneous material for manufacturing filaments which, after carbonizing, gave a carbon of specific gravity equal to 1.45. In 1883 I formed a company in Rotterdam, Holland, and built a factory to manufacture my high voltage and high efficiency lamp, but, I am sorry to say, the market at that time was not ready to accept my products, or, I had better say, there was no use for them, because in Europe at that time all central stations were comparatively of very limited extent, and the question of economy in copper with high voltage lamps was not appreciated; and, in addition many central station men would not bind themselves to buy from a single manufacturer. These circumstances again stopped high voltage lamps and I was obliged to manufacture ordinary lamps up to 110 volts.

In 1887 I had an opportunity to introduce my high voltage lamps in Block Station, Neue Friedrichstrasse, Berlin; this station had a capacity of 1,200 lamps 160 volts, from 10 c. p. to 150 c. p. each; this station is working at the present moment.

In 1888 I made a contract to light a part of the Brussels Exposition with 600 incandescent lamps and 18 arc lamps, all on a 155-volt circuit; and for my high voltage lamps and entire plant I received a gold medal and diploma of honor. In the same year my proposal was accepted for lighting part of the town of Reims, France, on the three-wire system at 320 volts potential, and in September, 1888, this plant of 1,200 lamps was put in operation and is working now with lamps of from 10 to 32 c. p. and 155 volts each. In 1889 Mr. Medhurst installed 2,000 lamps of 160 volts from 16 to 250 c. p. in the cotton mill at St. Petersburgh and many hundreds in South Russia, all working with Parson's turbo-electric generator.

In the summer of 1889 there was a demand for my 220-volt lamp in Marseilles, France, and Barcelona, Spain, where they were employed on the three-wire system, 420 volts being the total pressure. The drawback to the high voltage lamp was, that I was the only manufacturer of those lamps, up to the time of my leaving Europe for this country in December, 1891.

My company, in Europe, gives an absolute guarantee of 1,000 hours for the lamps of 3½ watts up to 220 volts, and the practice of five years proves that the average life is between 1,000 to 1,100 hours. Lamps of high voltage are certainly more expensive to manufacture and they cannot be sold for the same price as an ordinary 50 or 100 volt lamp, but the difference is not so great, being only about from 15 to 25 per cent.

The increase of price in manufacturing consists of platinum hooks by which I attach the filament to the globe, similar to that shown in the engraving in the Engineer of July 27, and also from the extra care with which this lamp must be manufactured.

Regarding the brush discharge between the terminals of the filament, I succeeded in reducing it to practically nothing, by special care introduced in the mode of manufacturing. I must say that the brush discharge cannot be annihilated by increasing the distance between the carbon terminals, as suggested in the editorial notes, because according to my practice the brush discharge depends mostly on the degree of vacuum, the nature of vapor in this vacuum, resistance of contact between filament and leading-in platinum wire, quality of glass from which the bulb is blown (quantity of metal oxides in the glass) and the specific resistance of the filament.

THE POLYPHASE CURRENT IN FRANCE.

According to the *Revue Internationale de l'Electricité*, MM. Guitton and Bertolus, owners of the Oerlikon patents for France, have concluded a thirty years' electric light and power contract with the municipality of Romans. They propose to use a 1,000-foot fall, 17 miles distant from the town, and to employ polyphase currents. The Edison Company of Saint-Etienne also intends to adopt the polyphase system in carrying out the large transmission and distribution of power scheme voted by the municipality. Near Montpellier a 200 h. p. fall is to drive polyphase dynamos supplying current to a group of villages.

MODERN AMERICAN TELEGRAPHIC APPARATUS.—VI.

BY

A. H. Jones

AMERICAN telegraphy being controlled and operated by private enterprise subordinates everything to speed and good service, as there are no barriers against competition, such as would exist under governmental control, at any moment the public finds the service of existing companies unreasonably dilatory or costly. Hence, in every important commercial city of the United States, branch telegraph offices are established in the offices of news associations and newspapers and in the centres of the various districts in which particular commercial transactions predominate; and such branch offices are placed in direct communication with similar offices in other cities for the purpose of minimizing the time of telegram transmission.

In each city there exists, of course, one central office in which all the principal apparatus is placed and where the electric currents are furnished for the operation of all the wires; and the branch offices, as a rule, are simply connected locally by wires called loops, or legs, to apparatus which effects the transmission of the messages. Thus, the two sending and two receiving local circuits of a quadruplex set are extended by legs to the desired branch offices, so that the four operators at the branch offices may be in direct communication with the distant city, just as if they were sitting at the apparatus in the main office. At the latter place the only attention needed is given by the chief operator, who keeps the instruments properly adjusted and the wires in working order.

In applying dynamo currents to local loops and legs between the central office and its branches economy and rapidity of operation require an automatic and compact system. The following methods, adopted by the Postal Telegraph-Cable Co. meet these conditions, placing the switches under direct control of the chief operator, and relieving the memory from every possible burden, so that the currents preserve a uniform strength at all times. Any set of quadruplex or duplex may be very quickly connected with any other set, or any single wire may be attached to work upon one side of any quad or on a duplex, or branch offices may be as quickly changed from one set to another, and in either of these changes it is necessary only to employ one dynamo, with a voltage high enough to work the loop or leg having the highest resistance, all others having their resistances graded by artificial resistance to correspond.

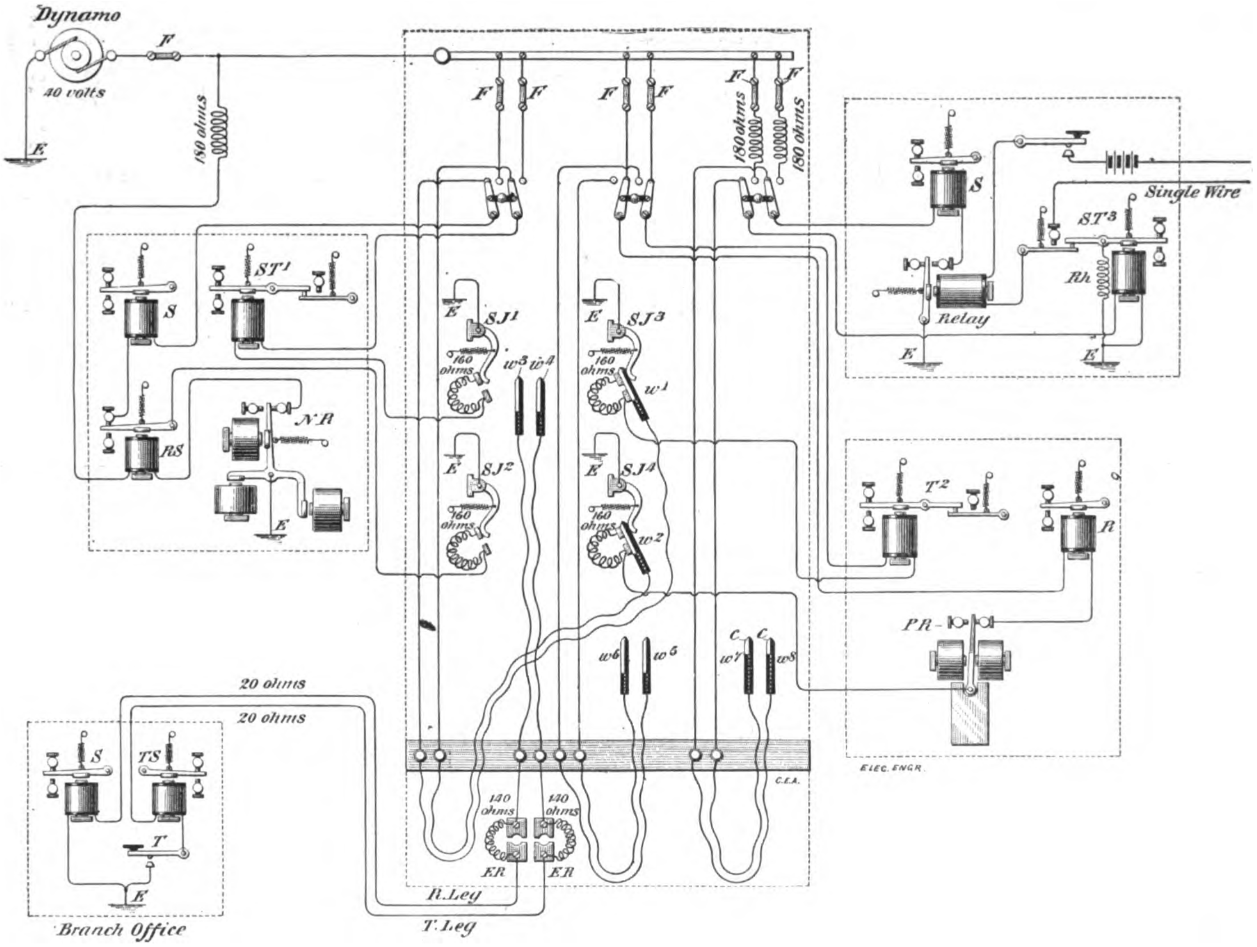


FIG. 1.

In the accompanying diagram, Fig. 1, the largest space inclosed by dotted lines represents a switchboard fitted with spring jacks, double three-point switches, flexible cords with wedges, and inductanceless resistance coils as previously described. Only two sets of jacks S J¹, S J² and S J³, S J⁴, are shown. The dynamo current is brought to a bar on the switch and the connections are made via the fuses F as will be readily understood by inspection. In the upper left-hand space inclosed by dotted lines is the No. 2 side of a quad set, and in the lower right-hand space is a duplex.

The letters represent the various instruments as follows:
F, fuses;
S T¹, single transmitter of No. 2 side of quad;
T², pole changer of duplex set;

ST^3, single transmitter of half of Toye repeater;
W R, No. 2 or neutral relay of quad;
P R, polarized relay of duplex;
S, ordinary 20-ohm sounders;
R, ordinary 20-ohm sounder of duplex set;
R S, Edison bug trap repeating sounder;
S J^1, jacks connected to the transmitter of quad set;
S J^2, jack connected to sounder of quad set;
S J^3, jack conneced to pole changing transmitter of duplex;
S J^4, jack connected to polar relay of duplex;
R H, resistance of Toye repeater;
T S, transmitting sounder of branch office;
T, sending key of branch office;
w^1 and w^2, wedges for connecting quad set;
w^3, w^4, wedges for connecting branch office;
w^5, w^6, wedges for connecting duplex set;
w^7, w^8, wedge for connecting single wire;
R leg is for reception of signals at branch office;
T leg is for transmission of signals from branch office.

The diagram shows the transmitter of the quad set connected through one of the double three-point switches with the polarized relay of the duplex, so that the signals of the latter are sent forward over the quadruplex circuit, and the transmitter of the duplex is shown connected with the repeating sounder R S of the quad, whose signals may be transmitted over the duplex. The wedges have one side insulated as indicated in black. The electromagnets of the transmitters and sounders have a resistance of 20 ohms each.

It will be seen that the branch office may be included in the local circuits by inserting wedges w^3 and w^4 in the jacks S J^1 and S J^2 so that it is possible for the distant offices to have one direct communication, and another with the repeater office or the branch office at the same time. Or a communication from one terminal office may be copied by the three other offices. By using wedges w^7 and w^8 the connections of which, C C, are shorter than those on the other wedges so that they will not cut out the equalizing resistances of 160 ohms under the jaws of the jacks, the single wire may be connected on to any duplex or one side of any quad, so that one communication may be had between an office on the single wire and the distant office on such circuits.

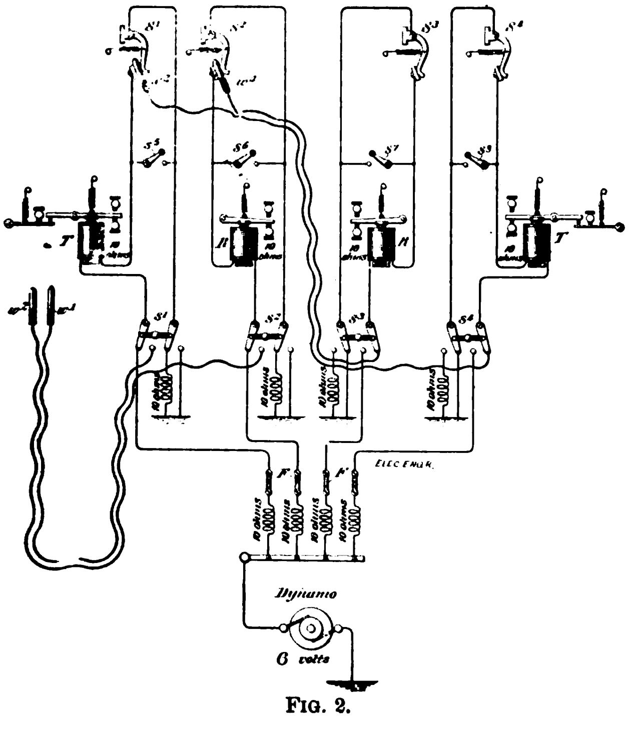

FIG. 2.

Fig. 2 is a modified arrangement more particularly adapted to repeater offices in which no business is done upon the circuits at such offices. The E. M. F. of the dynamos has been decreased from 40 volts to 6 volts and each local electromagnet has a resistance of 10 ohms; the rest of the circuit in its normal condition includes 20 ohms inductanceless resistance making a total of 30 ohms.

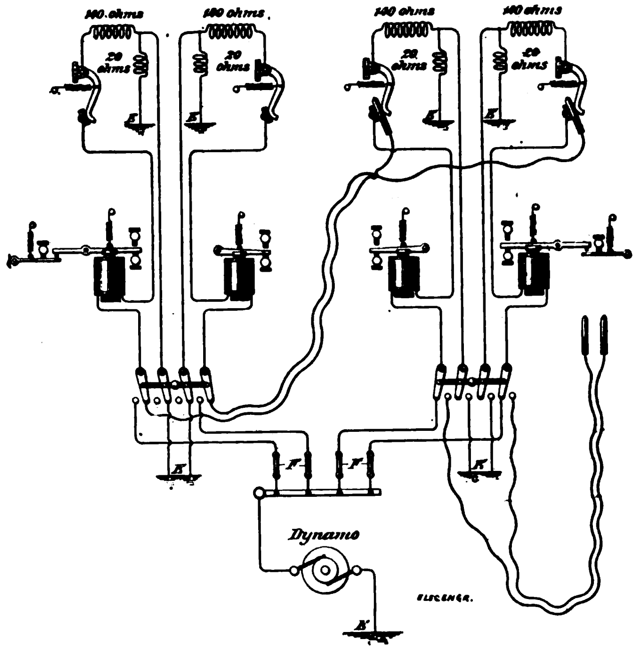

FIG. 3.

The 10 ohms resistance, inserted in the circuits between the dynamo and the fuses serves as a safeguard against a dangerous current in case of an accidental short-circuiting of the electromagnet and a failure of the fuses F^1 F^2 to act, and also to diminish the time constant of the electromagnets. By tracing the circuits it will be seen that the transmitter T and receiver R of the set on the left are locally connected through wedges w^3 and w^4 with the receiver R and transmitter T, respectively, of the set on the right. The switches are placed upon the tables near the repeaters so that if trouble occurs on either circuit the attending operator is able, by turning s^1, s^2, s^5 and s^6 to place the left-hand set independent of the right hand set, so that adjustments may be made without leaving the vicinity of the repeater apparatus, and similarly with the right-hand set by use of s^3, s^4, s^7 and s^8.

Fig. 3 is another method of accomplishing the purposes of Fig. 2 and will be understood by inspection.

GRAPHITE AND GRAPHITITE.[1]

GRAPHITE plays an important part in the manufacture of arc-light carbons, and has in the process to be first of all finely powdered. According to some researches of W. Luzi (*Deutsch. Chem. Gesellschaft*, Vol. XXIV) certain kinds of graphite, which he proposes to call *graphitite*, may be very easily reduced to powder by chemical means. It has been known for some time that graphite boiled in certain reagents, and then washed and dried, swelled in a most extraordinary fashion when baked. These reagents were concentrated sulphuric acid and a mixture of concentrated sulphuric and nitric acid. W. Luzi finds that fuming nitric acid is also a reagent. The graphite which exhibits this peculiarity of swelling comes from the following sources :—Ticonderoga, Pfafferreuth, Ceylon, Buckingham (Canada), Argenteuil (Canada), Massachusetts, Amity (N. Y.), Greenville (Ont.). The so-called graphitite comes from Passa (Siberia), New Mexico, Burkhardtswald (Saxony), Idar, Fichuelgebirge, Diedelkopf (Tyrol), Levigliani (Italy).

[1] London *Electrician*.

METALLIC vs. MERCURY PUMPS FOR EXHAUSTING INCANDESCENT LAMPS.

BY

A L Reinmann

WHEN I began to make some of the well-known Geissler tubes some twenty-five years ago, and made use of the simplest kind of mercury pump, which is now described in various catalogues of dealers in chemical glassware, such as the Doepler pump, I found it difficult, with the aid of such a pump, to exhaust tubes sufficiently well to cause a one-inch spark from a Ruhmkorff coil to disappear entirely. Later on the Sprengel pump was used for the production of high vacua, and the Geissler pump was subsequently improved by H. Geissler himself, as well as by others in this country, among them being Mr. Edward Weston, and the writer, the latter having patented the stationary reservoirs, now used exclusively, together with the floating valves, and the system of operating a series of pumps from one controlling device.

While such improvements have made it comparatively easy to exhaust incandescent lamps, it would be unwise to close our eyes to further improvements and not to look for means by which various drawbacks of the mercury pumps can be avoided. In large factories, particularly where Sprengel pumps are used, it is almost impossible to prevent the spilling of the mercury, which is carried with the dust and inhaled by the attendants. In case of breakage of a Geissler pump, 30 to 40 lbs. of mercury often run over the floor, and, in spite of all precautions, some of this mercury is lost, while the rest has to be carefully cleaned. Another item worth considering is the cleaning of the mercury pumps. Strong acids, such as nitro-muriatic, and as a second wash sulphuric acid, have to be employed to dissolve the deposits made by the oxidation and the mixing of mercury with the grease used for lubricating stopcocks and glass joints, and the fumes thus produced are most decidedly injurious to health. At the same time such cleaning means a good deal of breakage and comparatively expensive repairs are required on account of the necessary skilled labor.

It is true that with a series of Geissler pumps, as improved of late—with automatic floating valves, stationary reservoir and the improved reverser, which either turns the main stopcock to the mechanical pump to lower the mercury from the exhaust chamber, or turns it to the open air to admit the atmospheric pressure to force the mercury into the exhausting chamber and there displace the air and gases drawn from the lamps into the upper line of iron pipes, which is also connected with a metallic pump, to relieve such movement of all back pressure—these, I say, can work without interruption, and certainly do the work admirably. But it requires the aid of large mechanical pumps to keep the mercury moving, pumps of such size as would be able to do the exhausting alone, if properly constructed; and as the material for mercury pumps is rather frail in comparison with metal, the mercury, acting as a piston, cannot move up and down fast and not move them faster than once a minute; otherwise the pumps would be in danger of being smashed. On account of so slow an action (in fact the lamps are not in communication with the exhaust chamber during the time the mercury rises), the electrical treatment of the carbons has to be carefully watched, so that they are not injured beyond repair, should the current act too soon or excessively upon them in the presence of gases and the trifling amount of air remaining in the bulbs.

Among the many reasons, the few I have mentioned have made it desirable to improve mechanical pumps so far as to make use of a direct exhaustion from this source, instead of using metallic pumps to operate a series of mercury pumps. I have had occasion to witness the working of the metallic pump constructed by Messrs. Dittmar and Falkenhausen, and called in the patent papers "Electric Air Pumps," presumably because the valves are operated by the aid of solenoids, and which was described in THE ELECTRICAL ENGINEER, of June 4.

Three hundred lamps exhausted per day on a cylinder 7 x 8 showed such a good vacuum, that the spark of a 1-inch Ruhmkorff coil could not be noticed, merely creating the appearance of minute flashes due to the phosphorescence and fluorescence of the glass. A lot of twenty-four of these lamps subjected to a test showed, after 350 hours, a drop of 1 c. p., and only the faintest sign of discoloration. With the aid of first-class material, and added experience in lamp making, the leaky lamps should be so few that even a large number of lamps can be exhausted at one time. But the mechanical pump I have mentioned can be built to such size, that even 100, or more, lamps connected on to one cylinder, can be exhausted very rapidly; and as the piston makes 30 strokes per minute, the occluded gases are removed so fast that the current to the lamps can be raised in shorter periods and the whole electrical treatment can be accomplished within 15 minutes, making it possible to get along with less apparatus, such as generators, and to lessen considerably the size of a pump-room.

While I have no actual figures on hand as yet regarding the cost of exhausting by means of mechanical pumps, I know that a lamp exhausted by the Geissler system costs more than 2½ cents on an average, including all expenses for help, power, material repair, rent and superintendence, and I have no doubt that this figure can be reduced by adopting the metallic pump in factories of large capacity and output.

INSULATED ELECTRIC CONDUCTORS.—VII.

BY

James Bowstead Williams

Balata.—This substance is obtained by evaporating the milky juice of the bullet tree which grows in Guiana and elsewhere. When pure it resembles gutta-percha; and like the latter contains a small quantity of resinous matter. While it is generally considered by manufacturers to be a superior kind of gutta-percha, yet it differs from this substance in some respects, and may be considered as occupying a position midway between gutta-percha and india-rubber. For general purposes of insulation it would appear to be superior to gutta for the reason that it is more elastic, does not become so rigid at low temperatures, and does not deteriorate so rapidly when exposed to the atmosphere. But time and experience are necessary to demonstrate this.

Balata can be used for the same purposes as gutta, and can be applied to electric conductors in the same manner. Like gutta, it should not be used to insulate aerial conductors unless it can be thoroughly protected from air and light; otherwise it also degenerates into a brittle resinous mass. It can be combined with gutta, or rubber, or their compounds, both for vulcanized or unvulcanized compositions, to form useful compounds. It can also be combined with other insulating material which is added, if added, to dilute the gum and to lessen the cost of the products. Balata is said to be extensively used in this country in the manufacture of chewing-gum.

Resins.—Resins are non-crystalline bodies insoluble in pure water, but mostly soluble in alcohol, essential oils, ether, hot fatty oils, and bisulphide of carbon. They combine with alkalies to form soaps, and become soft, and finally melt, when sufficiently heated. If ignited they burn with a bright smoky flame; and if the smoke be collected it will be found to contain a large quantity of soot.

Gum resins contain gummy or mucilaginous substances in combination with the true resinous principles. These gummy and mucilaginous matters possess very slight insulating properties, as a rule, and if they are removed from the gum resin the resin which is left will be found to have a much higher specific resistance than the original substance.

If we take most of the commercial resins and gum resins and extract the pure resins from them, we will find that there is but little difference in the specific resistance of these extracts. These true resins are very brittle, however, and are not at all suitable for insulation when used alone, but must be combined with other insulating material which will impart the requisite degree of flexibility to the combinations. For this reason gum resins are sometimes more suitable for certain kinds of insulating compounds—*e. g.*, paints—than the pure resins, on account of the greater flexibility and toughness of the former.

Oleoresins are resins combined with essential oils. They possess but little value, as such, for insulating purposes, and could be dispensed with altogether.

Of the resins now used in practice the most important are colophony, shellac, copal, and amber. If these are purified and properly used they are of the greatest value, when used in suitable combinations, for use in all kinds of insulating compositions.

Colophony, or rosin, is obtained by distilling the crude turpentine (oleoresin), which exudes from various species of the pine, in copper stills at 212° to 316° F. The products of the distillation are oil of turpentine, which passes off and the rosin which remains in the still and which constitutes from 70 to 90 per cent. of the original mass.

The appearance and physical properties of common rosin are too well known to require description.

The color of rosin depends upon the care taken to distil at a low temperature and upon the purity of the oleoresin. It varies from an opaque pitchy black, through various shades of red, brown and yellow, to an almost colorless transparent mass. These different colored rosins are designated by different letters of the alphabet, A being the darkest, W, the "window glass," and W W, the "white water" varieties. The darkest colored rosins are the best for insulating material, as they contain less volatile matters than the lighter grades. The transparent varieties are obtained by distilling the turpentine with steam, or other inert gas, at a pressure of about 150 pounds per square inch and at a temperature not exceeding about 600° F.

These rosins are principally used in the manufacture of soaps and transparent varnishes, and as adulterants for the costly copal and amber varnishes.

Ordinary rosin softens at about 170° F., and melts at about 212° F., although it gets sticky when held in the hand. If all of the volatile matters be removed from the rosin, its melting point is much higher than that above given, but the rosin also becomes more brittle when cold. But the melting point of each variety should be ascertained, and the material tested electrically and chemically before it is used for insulating purposes.

Rosin is one of the most valuable insulating materials known. When pure, its specific resistance is very high, and it is capable of entering into combinations with almost all other kinds of insulating materials, whether the combinations be used while in a melted state, or in solution, or in vulcanized compounds. In the latter class of compounds it should always be combined with paraffine, shellac, or other suitable material which does not attack rubber, when heated to a vulcanizing temperature, before it is incorporated with the rubber, sulphur, etc., by means of the mixing rolls. If this be not done the rosin will almost invariably attack the rubber. Rosin will dissolve rubber in about five hours at a temperature below the boiling point of the rosin, and cause the vulcanized compound to deteriorate when exposed to the atmosphere.

No fixed rules can be given as regards the combining power of rosin with other substances, such as paraffine, ozokerite, asphaltum, etc., when the mixtures are to be used while hot to saturate fibrous material which has been applied to electric wires. This can be ascertained only by experiment, for it will be found that different samples of the substances above named are apt to vary considerably from each other. Thus, one sample of paraffine may contain less paraffine oil than the other; one sample of ozokerite contain more bituminous matter than the other, and the samples of asphaltum may vary on account of the different quantities of petroleum they may contain.

Rosin cannot be used alone to insulate wires on account of its brittleness and tendency to crack even when used with fiber and the wires remain perfectly straight. When combined with rosin oil or certain vegetable oils good flexible mixtures are produced which are well adapted for saturating fiber. But it can be stated as a general fact that all combinations of rosin and oil which possess good insulating properties absorb moisture when exposed, and that such combinations, to be of use, must be thoroughly protected from the atmosphere.

The melting point of rosin and of other resins can be raised by the addition thereto of lime or other alkali while the rosin is liquefied by heat. But no advantage is gained by this procedure, for the brittleness of the rosin is likewise increased and moisture is more readily absorbed.

Rosin is the only flux which should be used when soldering electrical connections. Mixtures containing chloride of zinc never dry of themselves, and corrode the surfaces of metals upon which they are applied. But such mixtures can be used without injury to joints, if the entire surface wetted with the solutions be covered by the solder and the joints immediately protected with a covering impervious to air.

The solvents of rosin will be given in the chapter on Insulating Paints.

THE NEW POSTAL-TELEGRAPH BUILDING.

So great has been the increase in the volume of business handled by the Postal Telegraph-Cable Company, that the necessity for more commodious and convenient quarters for the executive and operating departments has become imperative, and the officials of the company have for some time past been engaged in arranging to secure the company a building of its own. The corner of Broadway and Murray streets was selected as the best site for the purpose, it being in the centre of down-town business interests, near the newspaper offices, and convenient of access by all lines of elevated railroads, horse cars, ferries and the Brooklyn Bridge, while the frontages on City Hall Park and Murray street insure ample light and air.

Immediately upon the selection of the location, negotiations for the purchase of the necessary ground were completed, and plans for the new building prepared. Already the old buildings have been torn down and work on the foundations for the new structure is well under way and progressing rapidly.

The accompanying illustration is from the architect's drawing, and shows the building as it will be when finished. The building will be 14 stories high and will have a frontage of about 75 feet on Broadway by 150 feet on Murray street, with an L of 30 by 50 feet at the rear end. The frame will be of steel, and the walls to the fifth story will be of a fine quality of Indiana limestone; the upper stories of gray brick, with terra cotta trimmings to correspond. The interior finish will be in keeping with the handsome exterior, and no efforts are being spared to make all of the fittings and arrangements of the latest and most approved modern design.

The sub-basement will be 12 feet deep, commodious, well lighted and artificially ventilated. Here will be located the engine and dynamo rooms; the boiler-room will be in the extension of the sub-basement and will be 14 feet deep. The heating apparatus and the two dynamo plants for lighting the building and furnishing current for the circuits will be of the latest approved designs and arranged with regard to convenience and the comfort of the men in charge. The basement will be used for the supply department of the company and for storage-rooms, and will be equipped with every facility for packing and handling material. It is also intended to utilize a portion of the basement for safe deposit vaults.

The first or ground floor will be used for the receiving and delivery departments of the company, and possibly a portion of it may be leased for business purposes. The second floor will probably be occupied by a bank; and other floors, to and including the tenth, will be rented for offices. Applications for a large number of these offices have already been received.

The New Postal-Telegraph Building.

The eleventh floor will be retained by the company for its executive offices and for the executive offices of the Commercial Cable Company, which is allied to the Postal Company.

The general operating department will occupy the entire eleventh floor. And here again the arrangements will be made with a view to attaining the greatest facilities for handling the business and to provide for the comfort of the employees. The ceiling will be 18 feet high, and the exposure on the east, south, west and part of the north sides will insure perfect light and ventilation. The apparatus will be new and specially designed for this office, and it is expected that the operating department will be a model in every respect. The thirteenth floor will be used to accommodate the clerical electrical force, and also for coat rooms, lavatories, etc., for the operating and electrical departments.

It is expected that the fourteenth story will be occupied by a business men's club, and restaurant for employees, but, as these arrangements have not been concluded, we are unable to give details.

As a whole the building will be one of the best examples of modern architecture in the city and in convenience of arrangement, excellence of construction and beauty of appearance will be second to none.

The drawing of the plans and the work of construction and arrangement are under the supervision of Mr. A. B. Chandler, the president of the Postal Company, to whom, in great measure, credit is due not only for the completeness of the new buildings, but for the success of the company which has made the erection of the building possible. Mr. Chandler is assisted in the direction of the new work by a building committee, consisting of Mr. W. H. Baker, vice-president, Mr. E. C. Platt, treasurer of the Postal Company, and Mr. Geo. G. Ward, vice-president and general manager of the Commercial Cable Company. Messrs. George Edward Harding and Gooch are the architects and have charge of the details of plans and construction.

It is expected that the new quarters will be ready for occupancy in the summer of 1893, and the company's employees are to be congratulated on their prospects for improving their present fine service with the aid of the most perfect appliances and in the most comfortable and convenient quarters which could well be provided for the purpose.

CHANGES IN THE CANADIAN PATENT LAW.

Important amendments have been lately made to the patent act of Canada by the Canadian Parliament. Some new features borrowed from the United States patent laws are noticeable, such as the employment of examiners in the Patent Office to make a thorough examination of the applicant's title to his invention. The other material changes made are noted below.

Models of inventions or specimens of compositions need now only be furnished if required by the Commissioner of Patents. The duration of a patent is to be 18 years, with a fee of $60, with the option, however, of paying partial fees of $20 and $40 for terms of 6 or 12 years.

The inventor's oath or affirmation may be made before a minister plenipotentiary, *chargé d'affaires*, vice-consul or consular agent, a judge of any court, a notary public, a justice of the peace, or the mayor of any city, borough or town, or a commissioner for taking affidavits having authority or jurisdiction within the place where the oath may be administered.

Importation of the invention into Canada after 12 months from the time of granting a patent (or any extension of such period) by the patentee, his representatives or assignees for a whole or a part of his interest in the patent, renders the patent void only as to the interest of the party importing or causing to be imported.

A federal court, the Exchequer Court, is given jurisdiction not only of all questions involving the validity of a patent but also of all questions arising as to whether any interest therein is null and void.

A citizen of Canada electing to obtain a foreign patent for an invention, before obtaining a Canadian patent, shall have the right to obtain a patent in Canada, if the same be applied for within one year of the date of issue of the first foreign patent, and if, within three months after the date of the foreign patent, the inventor gives notice to the commissioner of his intention to apply for a patent in Canada, then no other person having commenced to manufacture the device in Canada during such period of one year shall be entitled to continue such manufacture after the inventor has obtained a patent in Canada, without the consent of the inventor.

Mr. Alexander L. Lineff, whose system of conduit railway traction will be recalled by our readers, has arrived in this country. It is Mr. Lineff's intention to introduce his system in the United States, where, he is confident, it will find a ready acceptance when once its advantages are understood.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, AUGUST 17, 1892. No. 224.

What is there so useful as a new idea so stated that it can be employed and lead to a useful practical result.—J. J. Storrow.

THE PROBLEMS OF COMMERCIAL ELECTROLYSIS.

ALTHOUGH one of the earliest principles of electric action applied to commercial purposes, electrolysis has, until a comparatively recent period, been confined to but a few fields of usefulness, and, with one or two exceptions, even these have been very limited in actual commercial product turned out. That there has been no lack of experimental investigations in this domain will become apparent upon even a cursory examination of the literature on the subject, which dates back over a hundred years. Of late, however, renewed interest is being manifested in electrolytic work, and in a variety of branches. Some of these have already been cultivated to some extent, and others involve original processes. In a review of the problems of commercial electrolysis, submitted in a paper read before the London Institution of Electrical Engineers, Mr. James Swinburne has outlined briefly the salient features of the most prominent electrolytic applications of the day, both actual and proposed, and has made some suggestive remarks touching their probable future. Passing over the methods whose success is already well established Mr. Swinburne, taking a broad view, asks: "Which of the oxidizing and reducing processes in use in chemical works can we advantageously replace by electrical methods?" He answers this question by stating, that "in many cases electrical methods are impossible; in others they are more expensive than those at present in use; but it is hardly too much to say that in an enormous number electrolysis is destined to play a leading part in the near future." Among the products included in the latter class, Mr. Swinburne mentions oxygen, which, he calculates, can be produced for less than one-tenth the selling price of the chemically prepared gas. In the production of caustic soda and its accompanying by-product, bleaching powder, Mr. Swinburne figures a large margin of profit by the use of the electric current; but he draws attention to the difficulty thus far invariably encountered in the gradual destruction of the positive electrodes, even carbon succumbing to the corroding action of the current, while platinum, though not entirely free from attack by chlorine, is too expensive. Mr. Swinburne also draws attention to the fact that much has still to be done in the production of aluminum, magnesium and the refining of the precious metals directly from the ores; the recovery of tin from scrap iron, the production of ozone, electric tanning, etc. The field here open to practical commercial results is indeed without limit. The refining of copper alone is well worthy all the effort and time that can be bestowed upon it, but by no means represents all that holds out promise of success. It may be well, however, to point out to beginners in electrolytic work that pitfalls may await them and that a thorough study of the literature of the subject may forestall discouraging experiences.

MECHANICAL VACUUM PUMPS FOR EXHAUSTING INCANDESCENT LAMPS.

THE tests on incandescent lamps recently conducted by Prof. B. F. Thomas and his associates and embodied in a paper read before the American Institute of Electrical Engineers, have elicited an interesting discussion in our columns between lamp makers as to the relative advantages of the mechanical vacuum pump as compared with the mercury pump now in general use. Leaving aside the question of the immunity from blackening claimed for lamps exhausted mechanically, which claim Prof. Thomas's tests seem to confirm, another question has arisen as to the economy of the mechanical method of exhaustion as compared with the mercury pump. Among those who have had opportunities for observation on the subject probably second to none is Mr. A. L. Reinman, whose views are given in a communication printed elsewhere in this issue. After years of work with the mercury pump, Mr. Reinman inclines to the opinion that the mechanical vacuum pump is capable not only of effecting an exhaustion equal to that of the mercury pump, but that it can do so at a greater economy in cost, and that further experience with the mechanical pump will serve to demonstrate its superiority.

HIGH VOLTAGE INCANDESCENT LAMPS.

THE description of high voltage incandescent lamps, which appeared in our columns recently, has served to bring out an interesting communication on this subject from Capt. A. de Khotinsky, which will be found on another page. It is well to emphasize the fact pointed out that lamps of higher voltage than those now customarily employed in incandescent lighting have been in commercial use for some time past, and that they can be successfully manufactured. It will also be remarked, however, that their cost is somewhat higher than that of the ordinary 50 or 100 volt lamps. It would be interesting to know just how far the increased cost of the lamp would outweigh the economy in distribution effected by the reduction of copper brought about by the employment of the higher potential lamp.

MEETING OF THE ASSOCIATION OF EDISON ILLUMINATING COMPANIES AT TORONTO.

The Eighth Annual Meeting (13th Convention) of the Association of Edison Illuminating Companies met in Toronto at the Rossin House, on Tuesday, August 9.

The following members were present:

W. M. Brock, general manager Edison Electric Illuminating Co., Paterson, N. J.

A. F. Walker, superintendent Grand Rapids Edison Light and Fuel Gas Co., Grand Rapids, Mich.

W. S. Barstow, general superintendent Edison Electric Illuminating Co., Brooklyn, N. Y.

Wilson S. Howell, treasurer of the Association, and honorary member.

Frederick Nicholls, president Toronto Incandescent Electric Light Co., Toronto, Canada.

C. L. Edgar, general manager Edison Electric Illuminating Co., of Boston.

J. H. Vail, assistant engineer-in-chief General Electric Co., New York.

J. A. Colby, secretary and manager Edison Light Co., Des Moines, Iowa.

F. E. Jackson, Edison Lamp Works, Harrison, N. J.

W. L. Garrison, treasurer Edison Electric Illuminating Co., Brockton, Mass.

Geo. R. Stetson, president New Bedford Gas and Edison Light Co., New Bedford, Mass.

Charles R. Price, treasurer New Bedford Gas and Edison Light Co., New Bedford, Mass.

William D. Marks, president Edison Electric Illuminating Co., Philadelphia, Pa.

J. H. McClement, president Edison Electric Light and Power Co., Amsterdam, N. Y.; also of Winston-Salem Railway and Electric Co., Winston-Salem, Va.

Arthur Williams, general inspector Edison Electric Illuminating Co., New York City.

Arthur E. Kennelly, Edison Laboratory, Orange, N. J.

A. L. Smith, president Appleton Edison Electric Co., Appleton, Wis.

Charles Wustenfeld, manager Elgin City Railway Co., Elgin, Ill.

Hoyt Post, director and attorney Edison Electric Illuminating Co., Detroit, Mich.

C. P. Gilbert, secretary and manager Edison Electric Illuminating Co., Detroit, Mich.

E. R. Weeks, general manager Edison Electric Light and Power Co., Kansas City, Mo.

S. B. Eaton, general counsel Edison Electric Light Co., New York City.

G. H. Van Etten, Edison Electric Light and Power Co., Little Rock, Ark.

J. E. Sayles, general agent Edison Electric Illuminating Co., of New York.

Charles H. Lindenberg, Columbus Edison Electric Light Co., Columbus, Ohio.

A. W. Field, secretary and manager Columbus Edison Electric Light Co., Columbus, Ohio.

Samuel Insull, president Chicago Edison Co., Chicago, Ill.

W. J. Jenks, Edison Electric Light Co., New York City.

George H. Finn, secretary, treasurer and manager St. Paul Edison Co., St. Paul, Minn.

Maurice Hoopes, superintendent Edison Electric Illuminating Co., West Chester, Pa.

W. E. Rundle, official stenographer.

John I. Beggs, director Harrisburg Electric Co., Harrisburg, Pa.

J. H. Sheddy, general manager Renovo Edison Light, Heat and Power Co., Renovo, Pa.

A. D. Page, assistant manager Edison General Electric Co. Lamp Works, Harrison, N. J.

John R. Markle, director Edison Light Co., Grand Rapids, Mich.

John Langton, Canadian Works Edison General Electric Co.

Henry W. Darling, vice-president Newport Illuminating Co., Newport, R. I.

H. J. Smith, general operating superintendent Edison Electric Illuminating Co., of New York.

M. D. Barr, district manager Edison General Electric Co., of Toronto, Ont.

Edwin W. Hammer, Edison Electric Light Co., New York City.

C. R. Van Trump, engineer and manager Wilmington City Electric Co., Wilmington, Del.

W. S. Andrews, general superintendent Canadian Works Edison General Electric Co.

FIRST SESSION.

The first session was called to order at 2.30 p. m. by Mr. John I. Beggs, who has been for the past six years president of the Association.

The standing committees of the Association were called upon for reports, and from these reports several discussions of practical subjects resulted. These included the importance of high insulation in the interior wiring of buildings and the improvement of safety fuses. On several of these questions the Association was favored with a practical talk by Capt. William Brophy, who, by vote of the meeting, was specially invited to be present and participate in the discussion.

Mr. J. H. McClement raised some interesting questions relative to the possibilities of operating electric railway systems, and during the discussion, Mr. William Lloyd Garrison, of Boston, was called upon and gave in an exceedingly interesting manner some results of his pioneer incandescent electric light experience at Brockton, Mass. Instructive remarks were made by Messrs. Barstow, of Brooklyn, and Mr. Stetson, of New Bedford. By invitation of the Association Mr. M. J. Sullivan, for several years official stenographer of the Association, read a paper entitled "The Central Station and Street Railways," which commanded the close attention of the delegates and occasioned further discussion on the questions suggested.

An interesting and valuable paper, illustrated by statistical tables and diagrams, was read by Mr. J. H. Vail on "The Application of New Apparatus and High Economy Engines in Central Stations to secure Greater Commercial Efficiency and Economy of Coal."

On Tuesday evening the delegates were treated to a very pleasant sail on Lake Ontario by the Toronto Incandescent Electric Light Co., of which Mr. Frederick Nicholls is president, and who had neglected nothing that might in any way add to the comfort or pleasure of their guests. Carriages were furnished to and from the wharf, and music and refreshments were provided on the boat for the entertainment of those present. The excursion was thoroughly enjoyed by all, the cool lake breezes being very refreshing after the heat of the day and the long afternoon session.

SECOND SESSION.

Returning from a delightful drive through the suburbs of the city, in open carriages provided by the Edison Company of Toronto, the Association convened at eleven o'clock a. m., August 10.

The courtesy of the Edison Company in arranging for this early morning drive and the moonlight sail of the previous evening was suitably acknowledged by vote of the Association.

The Canadian Department of the General Electric Company offered to the delegates an excursion to the Peterborough factories, but as the business engagements of the majority of the members of the Association prevented any general attendance upon such an excursion, the invitation had to be declined. The principal feature of the day's programme was a discussion of important questions of business policy.

In the afternoon the discussions of the morning were continued; Mr. C. A. Coffin, president of the General Electric Company, and Major S. B. Eaton, general counsel of the Edison Company, being present and participating.

The following officers were chosen for the year to come: President, John I. Beggs; vice-president, Frederick Nicholls; secretary, W. J. Jenks; treasurer, Wilson S. Howell. Executive committee, C. P. Gilbert, C. L. Edgar, E. R. Weeks, W. D. Marks, Samuel Insull. The question of the place of holding the next annual meeting was left to be decided by the executive committee.

A statement regarding the work which had been done during the year by the fuel gas committee was made by J. R. Markle. The committee was continued for another year, as were also the committees on lightning protection, dangers from systems of high pressure and grounding the neutral wire.

Besides the delegates in attendance there were quite a large number of visitors and representatives of supply houses, several of whom made exhibits of their apparatus.

STORAGE BATTERIES IN THE COOPERSTOWN, N. Y., CENTRAL STATION.

In reply to an inquiry as to the employment of storage batteries in the station of the Cooperstown, N. Y., Illuminating Co., we have received the following information from the superintendent, Mr. John F. Corbin: We have in use from midnight until morning 56 cells of The Accumulator Co's. type "A" battery, which will stand a discharge of 35 amperes. As we maintain 110 volts upon our circuits and each lamp requires ½ ampere we can feed 70 night lamps if occasion requires. Our ammeters indicate 22 amperes (44 lamps) in use when we bank fire and stop engine and dynamos at midnight. At daylight we find a draught of 10 amperes upon the battery; at 6 a. m., 6 to 8 amperes; at 7 a. m., 3½ to 5 amperes. We charge the battery from four to five hours with 25 amperes. From Nov. 1 to April 1 we relieve the battery at 5 a. m., and run the engine and dynamos until after sunrise. This is necessary because the morning lighting requires more than 35 amperes.

RATIONAL AND EMPIRICAL FORMULÆ SHOWING THE RELATION BETWEEN THE MAGNETO-MOTIVE FORCE (*H*) AND THE RESULTING MAGNETIZATION (*B*)[1].

BY CHARLES E. EMERY, PH. D.

THIS paper is in three parts, with sections numbered consecutively. It will not be possible to preserve the section numbers in this abstract, but the references thereto, in the original, remain in many cases. The author states that in Part I the theory that magnetization is the circulation of an ether is examined by the law of the flow of fluids, with the gratifying result that a rational fluid function has been developed which corresponds very well with the observed curves of magnetization, and which, moreover, shows decidedly a phenomenon equivalent to that of magnetic saturation. The observed results indicate a more intense action during the earlier stages of magnetization than is provided by the fluid function, but the discussion shows that the theory of molecular magnets appears quite sufficient to account for such intensified action. Following the discussion on this subject there are presented in Part II, Sec. 23, empirical formulæ for practical use, corresponding satisfactorily with typical *H-B* curves derived from experiments,[2] and in the "*Conclusion*," Sec. 36, a general formula is derived, embodying the fluid function first discussed, and a linear function, which together satisfactorily represent, on a rational basis, the observed conditions throughout the entire range of observation, including Ewing's experiments with very high magnetizations.

The human mind must found its impressions of unseen phenomena on analogy, so it is natural to suppose that all "action at a distance" is due to the motion of something extending through that distance. The rational discussion is based on a theory which has heretofore been proposed in substance, though generally with hesitation, shown by the fact that other plausible theories were advanced in the same connection. It will be considered that the magnetic field results from the circulation along definite lines of an ethereal atmosphere of such extreme tenuity that it moves readily through all bodies, fluid or solid, of which our senses are cognizant, though, like other fluids, capable of being moved and directed by other forces and of being concentrated in certain paths by particular materials. If this theory be true the etheric fluid should respond to the same laws as govern the flow of other fluids, air and water for instance, and we will first examine the formulæ relating to fluids tangible directly to our senses, and see if the flow of a fluid of such extreme tenuity that we cannot feel, see or hear it, but only judge of its presence and its circulation by the results produced, will show in such formula a substantial agreement with the observed results. Starting with well-known formulæ derived from the law of falling bodies, the author first develops the equation of the flow of an incompressible fluid and states that it indicates the general form of a differential equation of the flow of an elastic fluid which will show the momentary rate of flow of its elementary masses. With an elastic fluid the density practically varies with the pressure. If p be the total pressure, a certain portion, rp, is required to overcome resistances, and the remaining portion, $(1-r)p$, is the part available for density. By combining these quantities in a differential equation, integrating and substituting in quantities referring to etheric magnetic flow, the author deduces

$$I = A\,(3r^2-2r^3)^{\frac{1}{2}}\,(fH)\,H_s \qquad (10)$$

in which H is the exciting force, H_s the exciting force at saturation, r the proportion of the exciting force required to overcome resistances, A the product of the several constants developed, and I the portion of the magnetization due to what the author calls "the concentrating influence of the iron," and which according to the experiments of Ewing is to be added to lines proportioned to the exciting force H, which the author described as "lines which flow through the space occupied by the iron as though no iron were present." The total magnetization, B, is then equal to $H + I$. In Eq. 10, the function $(3\,r^2 - 2\,r^3)^{\frac{1}{2}}$ develops a factor of the variable coefficient of H_s, depending upon the law of the flow of fluids, and all influences on the value of I, due to external causes, are provided for by the other factor, $A\,(f\,H)$. In the above expression if $r = 0$, so that no part of the pressure is expended to produce motion, the whole equation reduces to 0 and there is no flow. If $r = 1$ the expression containing r reduces to unity. The ordinates of the fluid function are shown proportionally in Fig. 1. A direct linear function is shown by the diagonal. The modification due to $3\,r^2 - 2\,r^3$ is represented by the reversed curve in dotted lines crossing the diagonal at the centre of the figure, and the complete function including the square root of the above is shown by the heavy line curve. The latter is in general similar to a curve showing the relation of the exciting force H to Ewing's intensity of magnetization I, and also resembles an *H-B* curve of magnetization, with a less intense initial action which is yet to be provided for by substituting in Eq. (10a.) the value of $(f\,H)$. If we adopt the theory of etheric flow, we must conceive that the magnetization expressed at present as a definite number of magnetic lines is represented by the flow of a definite weight of etheric fluid. Recalling the signification of r and $1 - r$, it will be seen that the fluid function simply shows that when r is small, but little of the exciting force is expended in forcing forward the electric fluid and the larger portion of such force is utilized in increasing the density of the etheric fluid circulated, so that the weight circulated, and therefore utilized, is large compared to the exciting force expended to produce circulation, a higher percentage of the total exciting force is utilized and a higher efficiency of transmission obtained. When, however, the flow in a given area is increased, a larger proportion of the exciting force is required to produce the circulation, and a smaller quantity available to increase the density; so the weight moved approaches a limiting or constant value which evidently will be reached when the volume is infinite and the density zero, a condition typified when $r = 1$ in Eq. (10) and Fig. 1, and by the magnetic condition that the permeability μ and induction I, due to the iron, each reach a maximum. *The author therefore calls especial attention to the fact that the simple laws relating to the flow of tangible fluids show a limiting condition analogous to that of magnetic saturation.*

The author then discusses at considerable length Weber's theory of molecular magnets as amplified by Maxwell and Ewing, submitting in connection therewith a sheet of curves showing Kirkaldy's experiments on the compression of steel, such curves bearing a remarkable resemblance to *H-B* curves of magnetization, and concludes that this theory "offers an interesting and somewhat plausible explanation of the whole phenomena without necessarily involving the theory of etheric flow. The author, however, contends that *etheric motion of some kind necessarily follows from the phenomena of magnetic action at a distance* (Sec. 2); that magnetic phenomena rather indicate a flow than a transfer of vibrations; that the fluid function plotted in a curve shows a general similarity to an *H-B* curve and a limiting condition analogous to magnetic saturation (Sec. 9); that such fluid function therefore confirms the theory of translatory rather than vibratory movements of the ether to explain magnetic phenomena, and that, therefore, such function is of the highest importance as evidence to connect magnetism with ethereal flow On the contrary, the theory of molecular magnets does not aid in the explanation of action at a distance, but is still of value to intensify the effects shown by the fluid function."

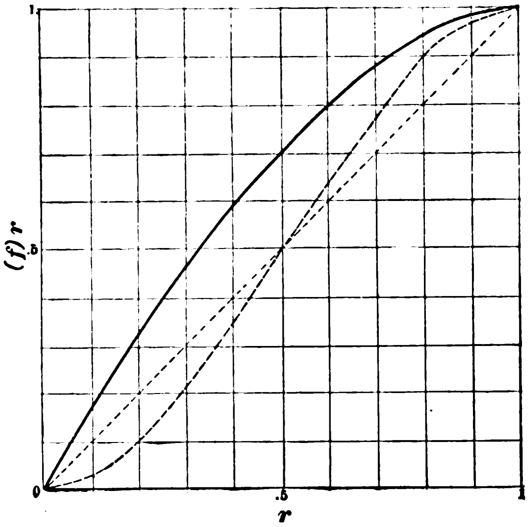

FIG. 1.

The author finally deduces a rational equation, embodying the fluid function, on the basis that the results shown thereby are intensified by the action of the molecular magnets. In such equation the influence which causes the initial delayed action of the iron, shown by the reversed curve at the origin of an *H-B* curve, is measured by the number of lines necessary to expand the core, disengage the molecular magnets from their accidental positions and arrange them substantially parallel. This number of lines is represented by k, and it is explained that $H-k$ is to be used instead of H in the final equation, thus practically causing the curve to intersect the axis of abscissa at a distance k from the origin. The value of r is stated as equal to the actual number of lines available for excitation, viz.: $H - k$, divided by the exciting force at saturation, viz., H_s.

In the form given above the fluid function is, as stated in Section 11, of insufficient intensity. If we consider, as is probable, that the molecular magnets act to change the intensity in accordance with the same laws as the fluid function acts, we can change the intensity shown by the fluid function by simply changing its exponent. As r is fractional, the intensity will be increased by *decreasing* the exponent. On this basis the following general equation is developed for $H = 0$ to H_s,

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, Ill., June 6, 1892.

[2] We expect to present the substance of Part II in a subsequent article.—EDS.

$$B = (H - k) + K\left(3\left(\frac{H-k}{H_s}\right)^2 - 2\left(\frac{H-k}{H_s}\right)^3\right)^n \qquad (26)$$

For H greater than H_s.

$$B = (H - k) + K.$$

That is, above the point of saturation the iron ceases to act to concentrate magnetic lines, so the fluid function must be caused to disappear as r reaches its limiting value, unity.

In connection with the proposed change of the exponent, the author calls attention to the curious fact that with $n = 1$ the equation is that of a straight line and plots in the diagonal of Fig. 1, while if $n = 0$, or rather when it has a very small finite value, the curve develops a right angle, so that "for values of n intermediate between 0 and 1 the whole area of the triangle would be filled with similar curves, gradually changing in shape from a right angle to the hypothenuse of a right angled triangle." It is stated that, therefore, by changing the exponent, the bend in the curve may be made as sharp as desirable. The curve shown in Fig. 3 was developed by making $k = 2.3$, $H_s = 500$, $K = 21{,}800$, and $n = 0.08$. Such curve corresponds closely to other curves within the limits usually stated. The author discusses the experiments of Ewing at some length, and in connecting Ewing's work with high magnetizations with that done by others within customary limits, concludes that, at the higher limits, the magnetization increases directly with the exciting force and is numerically equal to the saturation value of I, plus the exciting force H, and indicates that this law extends from these high values back to the origin where the exciting force and magnetizations are zero. If in Fig. 2 we let the ordinates of the triangle R T S represent the lines of magnetization due to the solenoid, or substantially in the language used in Section 17, to the number of lines circulated through the space occupied by the iron as if no iron were present, the base and altitude of this triangle will each equal H, and on the principle above stated, this triangle must be superimposed upon a rectangle of which the base $= H$ and the altitude equals the saturation limit of the iron or I maximum which we will call K. The figure has purposely been drawn to scale to include the highest values given by Ewing (Table 3), viz.: for $H = 19880$, $B = 41140$.

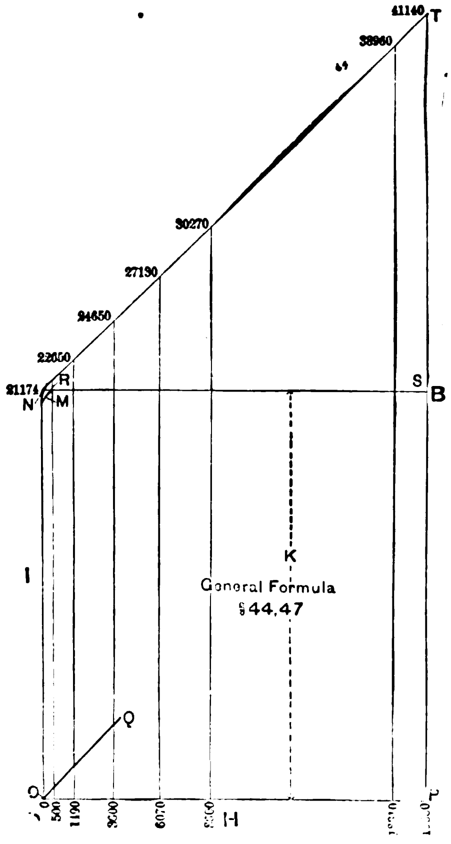

FIG. 2.

Further investigations appear to show that the iron which produces a concentration, $K = 21174$ lines per square centimetre reaches saturation with an exciting force H_s between 500 and 2,000 lines, whereas less than 100 lines are generally used, so the only part of the trapezoidal Fig. 2 which we refer to in practice is about $\frac{1}{100}$ of its length, or about $\frac{1}{5}$ of the portion included between the ordinates at the origin and the parallel line close thereto marked 500. In order to ascertain how the ordinary H-B curve of magnetization applies within this limit, it is necessary to make another view, Fig. 3, extending from $H = 0$ to 500, the range included between the first two ordinates in Fig. 2, but with the horizontal scale magnified. In this view $R\ T^1\ S^1$ represents the initial portions of the triangle $R\ S\ T$ in Fig. 2, and $O\ R\ S^1\ P^1$ represents similarly a portion of the rectangle below the same. M represents a modified curve of magnetization in which the ordinates of an ordinary H-B curve are shortened by the corresponding values of H when measured from the base $O\ P^1$, and N represents the same curve of reduced height when the ordinates are measured from an inclined line $O\ Q^1$ parallel to $R\ T_1^1$. The curved gore between M and N has the same area as the portion of the triangle from the ordinate at the origin to the point of tangency of the curve, so the upper curve N represents the entire H-B curve of magnetization if its ordinates be measured from the base $O\ P^1$.

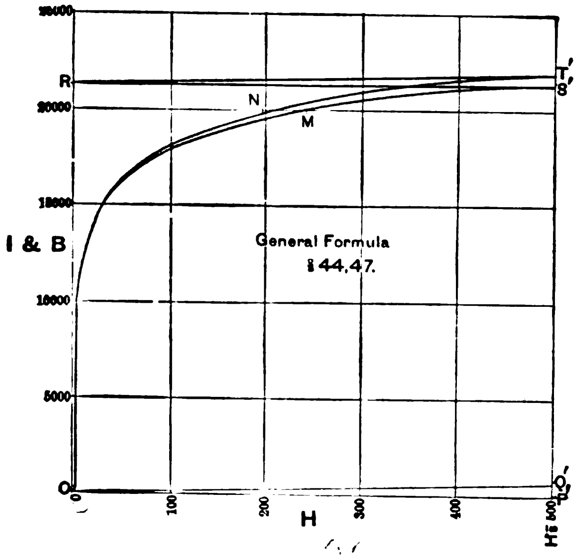

FIG. 3.

In closing this branch of the subject, the author considers how other physical phenomena can be explained if it be finally settled that magnetism is due to the circulation of an ethereal atmosphere. In such case we must imagine that the ether pervades all space, and we may suppose it susceptible to vibrations, and therefore capable of transmitting vibratory forms of force, such as light, without interference with the phenomena of magnetism due to the circulation of its ultimate particles. This atmosphere need not necessarily be the luminiferous ether, though there is no reason why it should not be so. The etheric fluid itself may pass freely through all substances, gaseous, liquid or solid, and yet its vibration known as light be damped and checked by some of such liquids and solids, but flow freely in others known as transparent. It will be more difficult to consider one mode of motion of the same ether as light and another as electricity, for both modes of motion should be damped by the same substances that dampen light, whereas we know that light is readily transmitted through glass and electricity is not, and that electricity is readily transmitted through copper and a similar class of substances known as conductors, which do not transmit light. If magnetism be the circulation, and electricity a form of vibration, of the same ether, there would be a more direct transformation of electric into magnetic force, whereas we know that no direct transfer takes place. A magnetic flow and an electric current may be moving at the same time in the same piece of metal, an iron magnet for instance, without one modifying the other in any way.

Any explanation founded on the anology of the polarization of light should be proved from some direct transformations of electricity into light without heat. Tesla appears to be doing this, but it is believed that his results can be explained on the basis that the passage of a high potential and high frequency alternating current through a low conducting medium actually puts the ether in vibration, thus producing light as above indicated. It is

---

1. This is the I-B curve of Ewing.

believed also that the apparent transmission of high tension discharges through the dielectric instead of the conductor will eventually be traced to a magnetic phenomenon, leaving us free to consider substantially as in the past that electrical phenomena are due to a form of motion of the molecules of solids which are susceptible to this kind of motion, like metals of the copper class, though the molecules of all substances, even of gases, and possibly of ether, are conductors in a limited sense or under peculiar circumstances.

THE ELECTRIC PERCUSSION DRILL IN THEORY AND PRACTICE.[1]

BY HARRY N. MARVIN.

THE general requirements of an electric percussion drill for mining work are that it shall be light enough to be quickly handled by two or three men; powerful enough to compete with an air drill that absorbs eight or ten horse power; so simple in its design that it can readily be repaired by an ordinary mechanic without electrical experience; so constructed that the complete machine and its several parts can be soaked in mud and water without injury; be incapable of burning out; able to endure the roughest handling without injury, and the materials employed should be as little subject to crystallization as possible. My experience suggests the following elements of construction to be avoided: Traveling conductors; commutating or current shifting devices; sliding contacts; spring contacts; cotton insulated wire, and all insulating material capable of carbonization; switches; lamination of the moving parts; close fittings and joints liable to be impaired by considerable wear, and all constructions that may be injured by careless or unskilled attention. For the benefit of those unfamiliar with the actions of the air drill I will state that the general practice at present is to give the machine a stroke of from five to seven inches, to strike as nearly as possible an uncushioned blow upon the rock, and to make as many blows per minute as the power applied will develop, usually from two to four hundred per minute. It is found that a stroke of about five inches is necessary to properly free the hole from mud.

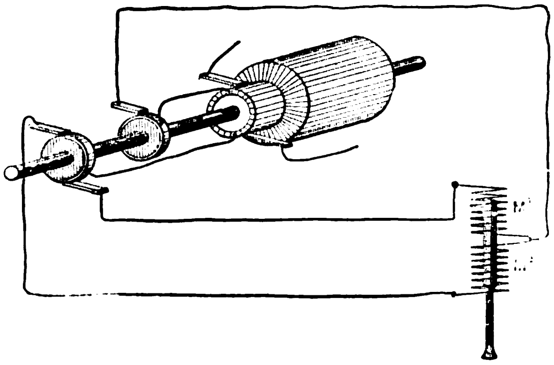

FIG. 1.

In the electrical solution of the problem the solenoid and plunger afford the simplest method of developing this action, and most of the work in this field has been confined to this line. After much experimental work with divided solenoids and commutating devices mounted upon the drill I abandoned these methods and in 1888 devised the system of operation that is at present rather well known, but for clearness may be illustrated.

Fig. 1 shows an ordinary continuous dynamo having two opposite points of its armature connected to a solid collecting ring and a half ring, respectively. The outer terminals of the drill coils M^1 and M^2 are connected by line wires to the two brushes alternately bearing upon the half ring. The inner terminals of the coil are joined and led to the solid ring. It appears that as the armature revolves current impulses are directed into the drill coils in alternation, causing a reciprocation of the plunger in synchronism with the dynamo armature. It will be noticed that the action here closely resembles the action of a steam engine, force being exerted first in one direction and then in the other, one end of the cylinder being idle while the other end is active. Of course connections are such that the polarity of the plunger is never reversed. This system simplifies to the utmost the construction of the drill and enables it to be so designed as to satisfy all of the conditions before mentioned. The complications of this system are more apparent in theory than in practice. Three wires are required, but once placed they give no further trouble. The generator can be used to develop continuous current and pulsating currents at the same time if desired, but I believe that it is better practice to use a separately excited drill generator without regular commutator. I have found it desirable to run these drills at a speed of about 400 per minute, a rather slow speed for small dynamos. By one method the regulator commutator of a continuous current armature is equipped with a pair of revolving brushes one of which connects to the solid ring of the drill circuit commutator and the other to the half ring. In this manner pulsations are developed in the drill circuit as the brushes are rotated and with a frequency entirely independent of the armature speed. With this arrangement we are also able to take off 100-volt alternating currents from a commutator that is also supplying a 500-volt continuous current circuit, by spacing the revolving brushes an amount less than 180°.

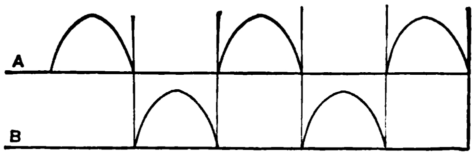

FIG. 2.

Another method of reducing the frequency of the pulsations is by gearing the drill commutator to the dynamo shaft, reducing the frequency to one-half the speed of the generator.

The general character of the impressed E. M. F. in the two drill circuits in the above systems is shown in Fig. 2, curve A showing the voltage over the upper coil and curve B showing the voltage over the lower coil.

A method of operation by which a somewhat different curve is obtained is shown in Fig. 3. It will be noticed that here current is admitted to the drill circuits when the voltage is at a maximum, the curve of impressed E. M. F. being generally as shown. The general plan of admitting the current alternately to the two drill circuits, one circuit being idle while the other is active, characterize all the above methods. This may be called plan "A."

I have also devised a method for effecting this without commutation, by leading one wire from a simple alternator to the drill while the other wire passes through the secondaries of two converters. The cores of these converters are continuously saturated by continuous currents in the primary coils, the windings of the converters being opposite. When current endeavors to pass through these it is checked considerably in the converter whose magnetism it tends to reduce and to a much less degree by the converter whose magnetism it tends to increase. A reverse current is opposed by the other converter and thus pulsations of one polarity are strong in one coil while those of the reverse polarity are strong in the other drill coil. This would not probably be a very efficient method.

Another general plan of drill operation, which I will call plan "B," has been developed to some extent by the late Mr. Van Depoele. This plan is based on a difference of phase of current in the two coils. The two outer drill wires are connected to the two regular brushes of the armature, and the middle wire connects with a solid ring connected to one point of the armature. As the armature revolves, current rises in one drill coil and falls in the other, producing the reciprocation of the plunger. The voltage curves for this type of machine are shown by Fig. 4. An armature giving two alternating currents of 90° difference of phase may also be used, but with the disadvantage of reversing the polarity of the drill plunger. The above appears to be less efficient than plan "A" for the reason that the drill coils are constantly working against each other, and being heated up by current opposing the action of the drill.

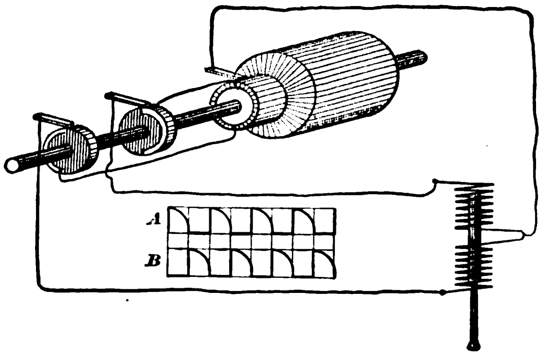

FIG. 3.

A third plan of operation, which we may call plan "C," is that devised by Messrs. Siemens & Halske. Three coils are used in the drill, the middle coil being excited by a continuous current and the two end coils by an alternating current of proper frequency. The function of the middle coil is to maintain a constant polarity in the bar, and the motion is effected by the effort of the two end coils. In this system both motor coils are continuously excited as in plan "B," but there appears to be less waste of energy.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago, June 7.

Aside from the extra complication of drill construction it is questionable if as much power can be obtained from a given weight of wire with this arrangement as can be realized on plan "A." It must be borne in mind that in these machines it is necessary to get the utmost power possible out of a given weight of copper and iron, and the heating limit is the only practical consideration. The efficiency of the machine is secondary.

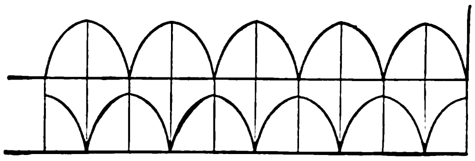

FIG. 4.

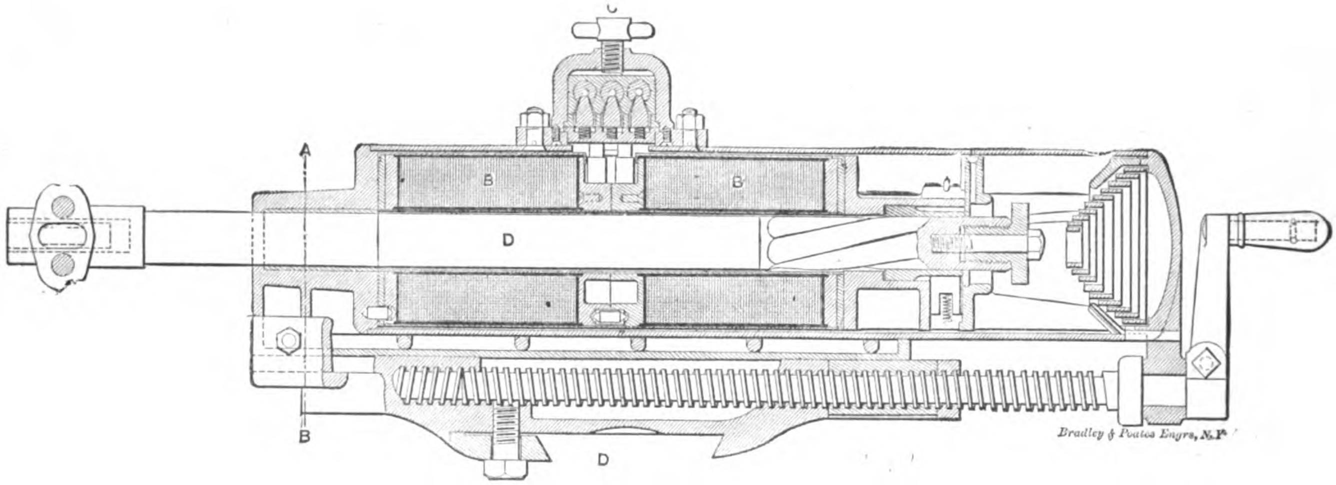

FIG. 6.

Plan "C" has been reduced to practice in this country by the late Mr. Van Depoele, who avoided the use of a fourth wire in the system by an ingenious method shown in Fig. 5. The regular commutator is supplied with rotating brushes B^2 B^3 in addition to the regular brushes B, B^1. It appears that as the rotating brushes revolve a simple alternating current flows through the end coils of the drill, while a unidirection pulsating current of one-half the frequency circulates in the middle coil.

The requirements of construction and service have thus far induced me to employ a rather low voltage in the operation of drills, our present practice being to use about 100 volts alternating upon the drill. I have employed several methods of operating drills from high voltage circuits.

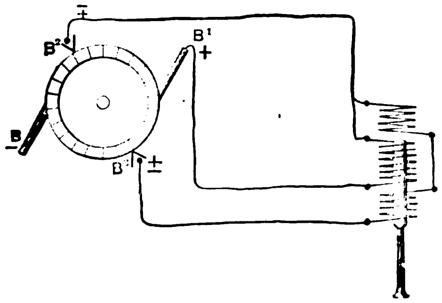

FIG. 5.

Another method is where a 1,000-volt alternating circuit is led from the prime generator to the vicinity of the mine, where it passes through the primary of a converter in which the voltage is reduced to 100 volts. A small motor running in synchronism with the generator directs the alternate pulsations into the drill circuits.

Turning now to the drill construction, Fig. 6 shows the first form in which the percussion drill was put upon the market. This I call a type "A" machine. As appears in the engraving, the machine consists of a seven-inch boiler tube provided with a suitable mounting. Within the tube are two solenoids, B, B, a rotating device and a cushion spring. Traveling through the coils is a two-inch plunger, D, the middle portion of which is of iron; the upper end is of brass and is rifled as shown to fit the rotating device; the lower end is also of brass, and is enlarged at the end into a chuck to hold the bit. The three sections of the plunger are welded together. The weight of this plunger was 38 lbs. This machine was designed to make 600 blows per minute with a three-inch to four-inch stroke. The first of these machines to be put into a mine was that started in May, 1891, in the Black Bear mine at Gem, Idaho. This was, I believe, the first commercial electric percussion drill plant ever operated. During the next few months several other mines and quarries were equipped with these drills, with the general result that where the rock was not excessively hard the work was fairly satisfactory, but in extremely hard rock several defects developed. The brass portion of the plunger would crystallize and break a short distance above the chuck. Under the severe strain of continuous work in hard rock the coils would become so heated as to ground, and the spring connections between the cable and the coils would give out. The construction of these drill coils deserves special description. The coil is constructed as follows: Upon a brass spool, the body and heads of which are insulated with mica, is wound a bare copper wire of square section; this wire is insulated, as it is wound, with mica. The complete coil is wrapped with mica and a metal tube slipped over the whole and soldered to the coil-heads, making the completed coil waterproof and heat-proof, as it is insulated with mica alone, nothing but mica and metal being used in its construction.

The design of the machine was then altered. The plunger was then enlarged to two and three-fourths inches, and is what I call the double-magnet type. The forward part is now made of steel, the rifle part is also of steel, and the connecting piece is of brass. This design gives a solid steel chuck and brings the brass part of the plunger within the drill body. The coils are now encased in boiler-tube jackets brazed up with hard spelter and are heated to a bright red in process of manufacture. The spring connections have been abandoned and solid set screw connections now connect the cable to the drill. A switch is inserted in the cable near the drill. This machine seems to overcome the defects of the old

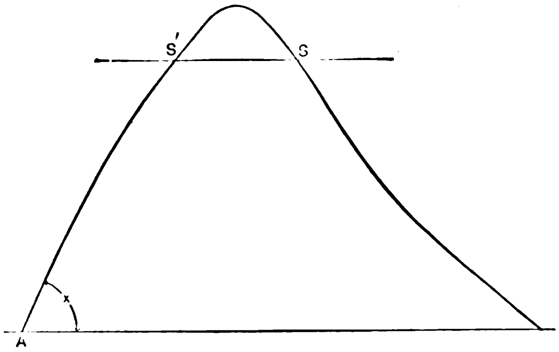

FIG. 7.

drill, and has thus far proved very satisfactory. This machine takes a stroke of about five inches and runs about 380 blows per minute. This longer stroke is found more effective in keeping the hole free from mud.

A still later type of drill that I have recently built, and which promises to be much better than the others, has a plunger of a solid steel forging four inches in diameter. No brass is used in the plunger, the metal being reduced in section where it passes through the front head. The ratchet device is similar to that used in air drills, and, in fact, the whole design of the machine quite closely follows the air drill construction. This machine takes a stroke of from six and one-half to seven and one-half inches, and makes about 380 blows per minute; the plunger weighs 80 lbs.

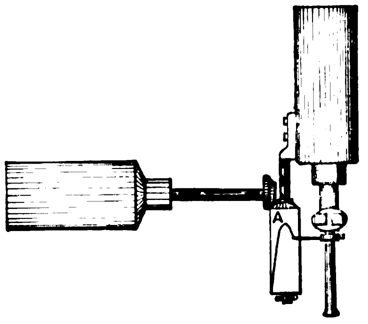

FIG. 8.

Fig. 6 shows the cable connection and switch, A, and the cable fuse-box, B, through which connection is made from the mains to the cable. A study of the operations of these machines presents many interesting features. In Fig. 7 is shown what I term an energy curve of the machine. This curve is obtained in a manner similar to an indicator card of a steam engine, as run in Fig 8. A is a cylinder mounted parallel to the drill-rod. This cylinder is geared to the armature shaft in such a manner that it rotates in synchronism with it. A pencil carried by the drill-rod rests upon the cylinder, A; it follows that as the drill-rod reciprocates, and the cylinder A rotates, a curve will be traced by the pencil.

The direction of motion of the paper being from left to right, it appears that the angle of the curve at any point indicates the velocity of the plunger at the instant. A is the point where the plunger strikes the rock and the sharp rebound is shown by the angle. The buffing spring is encountered at S and S', and the curve shows little loss in the spring. A simple calculation gives the energy of the blow in foot pounds. This affords a good method of comparison between different machines and conditions. The general character of the curve reveals the general action of the forces during the stroke.

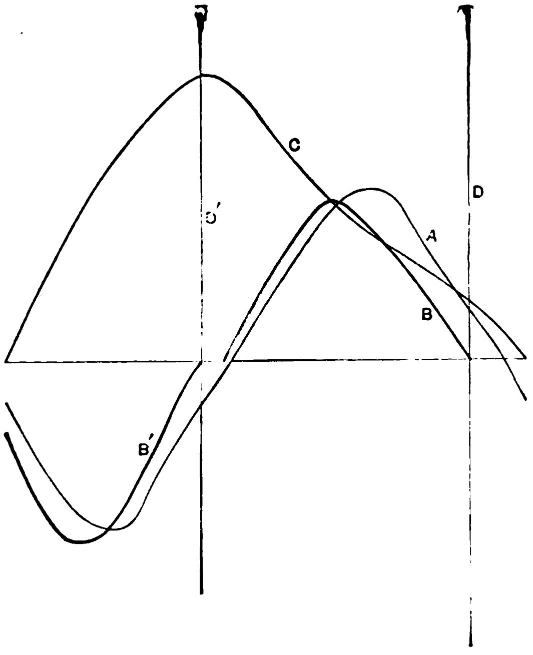

FIG. 9.

Some interesting curves are shown in Fig. 9. Curve A shows the voltage on the drill circuit; curves B and B', the current in the two coils. Curve C is the energy curve. The lines D, D', indicate where the brushes make contact with the half ring.

The efficiency of the above machines, compared with other forms of electric motors, is, of course, low, but this factor is of comparitively little moment in percussion drill work. It is far more important that the machine should be able to endure the development of a large amount of power with a small weight than that it should be highly efficient. It would seem that the general mechanical designs of these machines admit of greater durability and simplicity of construction than air drills, as there are no steam-tight joints required, and a very great wear upon the moving parts does not reduce the effectiveness of the drill. The general flexibility of the electrical system and its peculiar adaptation to mining work are well recognized, but it has been urged that for drill work compressed air is a necessary factor for ventilation. A careful investigation of this matter reveals the fact that there is little or no weight in this objection. The instances are extremely rare where compressed air is relied upon for ventilation and I have found few miners who considered this matter of importance.

Although the introduction of the percussion drill has been attended with many difficulties, I believe that the obstacles have been so far overcome that the machine is to-day in thoroughly practical shape.

ELECTRIC LAUNCHES AT THE CHICAGO EXHIBITION.

THE announcement that the contract for supplying launches to convey passengers on the lagoon at the Columbian Exhibition will be awarded to an electric company is interesting as confirming faith in the feasibility and utility of electric navigation under the conditions to be met at Chicago.

The various craft submitted for test were ten in number, as follows:

Steam	launch	"America,"	submitted by	Willard & Co., Chicago.
"	"	"Isabella,"	"	Meeker & Co., Jersey City.
Naphtha	"	"Chicago,"	"	Gas Engine and Power Co., New York.
Oil	"	——	"	Columbia Launch Co., Chicago.
Electric	"	"Electra,"	"	Electric Launch and Navigation Co., New York.
"	"	"Volta."	"	Columbia Launch Co., Chicago.
"	"	"Ferdinand,"	"	Meeker & Co., Jersey City.
"	cab boat,	——	"	Columbia Launch Co., Chicago.
Hydrocarbon	cab boat,	——	"	Columbia Launch Co., Chicago.
Pneumatic	launch	"Pneumatic,"	"	Willard & Co., Chicago.

Of the above boats only the "America," "Isabella," "Electra" and "Volta" were generally considered to be in the contest for the franchise, some of the others having been submitted as suggestions, especially the "cab boats" (small boats intended not for schedule trips, but for small parties engaging them by the hour.)

The "America" was larger than called for in the specifications, and, although a very creditable boat, the general impression was that this boat was too large for lagoon service. The "Isabella," "Electra" and "Volta," were of about the dimensions called for.

Each boat was tested on a 10 hours' run and each had a special day for the test. They were loaded partly with passengers and partly with sandbags, so as to make full load according to the capacity claimed in each case. The boats were run around the part of the lagoons called the "Basin" and the "Harbor," the length of the circuit being 4,200 feet, of which only a few hundred feet were straight course, the rest being circuitous. On each round trip two landings were made, including a stop of one and a half minutes at each landing by way of exemplifying the conditions under which the boats are to run during the fair. The several boats mentioned made the following records: "America," 53 trips; "Isabella," 48 trips; "Electra," 45 trips; "Volta," 33 trips in 10 hours, including stops. The electric launch "Electra" carried 62 cells on board weighing about 2,400 lbs., and the "Volta" 104 cells, weighing about 4,160 lbs.

While both steamboats named were excellent boats of their class, the performance of the "Electra," together with her attractive appearance and other advantages as compared with steam, gained for this boat a recognition which gradually crystallized into preference, and it effectually demonstrated that electric launches are not merely a possibility but an achievement which the steamboat men were forced to recognize notwithstanding their confident predictions that electricity would fail to come up to the mark. The fact that the performance of other electric boats present failed to equal that of the "Electra" supported the steamboat mens' predictions to some extent, but, thanks to the presence of the "Electra," only to the extent of proving the necessity of proper engineering in electric boats, as in other electrical work, to secure the best results, and that the mere putting of a battery and a motor into a hull does not make a satisfactory boat. The only electric boat approved by steamboat men was the "Ferdinand," which would not go at all and was therefore withdrawn.

The "Electra" performed better in Chicago with 62 cells than in Newark (before shipment to Chicago) with 78, owing to the

---

1. For a full description and illustration of the "Electra" see THE ELECTRICAL ENGINEER, June 15, 1892.

fact that all the "kinks" due to warping and swelling of the timbers when the boat was still "green" had been removed and everything brought to a settled and normal condition.

THE ELECTRIC FOUNTAINS AT THE COLUMBIAN EXPOSITION.

AMONG the features of the Columbian Exposition early decided upon was the operation of electric fountains, which have proved to be such attractive features at previous expositions. It was not until recently, however, that active measures were taken with this end in view and the work of designing the fountains undertaken. The Exposition authorities very wisely placed the entire matter in the hands of their consulting electrical engineer, Mr. Luther Stieringer, whose plans were at once adopted and when carried out will result in a display which will far exceed in magnitude and beauty anything of the kind thus far attempted.

The fountains will be located east of the Administration Building, one on each side of the larger fountain at the west end of the basin. They will be much larger and much more beautiful than those at the recent Paris Exposition. To supply them with water there will be a twenty-four-inch main for each, and a pressure of 100 pounds to the square inch will be supplied. This will force the water 175 feet into the air. The jets will be in three rows and will number several hundred.

A bid for the construction of these fountains was last week offered the Grounds and Buildings Committee by Lieutenant Spencer, of the General Electric Company. This bid, which was about $48,000 for the electrical portion and operating during the entire exposition, was referred to Chief of Construction Burnham and will undoubtedly be accepted.

Personal.

MR. A. J. ARNOT.

AMONG the passengers on the "City of Paris" from New York, on Wednesday, August 3, were Mr. and Mrs. A. J. Arnot. Mr. Arnot is the electrical engineer of the corporation of the city of Melbourne, and has been in America for some two months for the purpose of testing electrical apparatus to be supplied by the Thomson-Houston International Electric Company for the public lighting of Melbourne. In addition to this, Mr. Arnot has investigated thoroughly the underground wire practice as it is exemplified in the States, having visited the principal cities where lighting is done by underground service. In England Mr. Arnot will inspect the boilers which are being manufactured for the Melbourne lighting, and in London and on the Continent will visit the principal centres to pursue his investigations in underground work. During his stay in this country Mr. Arnot impressed those who met him with his careful, painstaking methods and thorough knowledge of the subject in hand. The evening before his departure from Boston he was tendered by the board of directors of the Thomson-Houston International Electric Company a dinner at the Algonquin Club, at which President Coffin of the General Electric Company presided. The gentlemen present, besides Mr. Coffin, were Professor Thomson, President Newhall of the International Company, Vice-President Bartlett, Manager J. R. McKee of the Mining Department, General Counsel F. P. Fish and Associate Counsel R. P. Clapp and General Manager Davenport of the International Company.

MR. HENRY W. FISHER, electrician of the Standard Underground Cable Co., has recently been appointed electrician to the Central District and Printing Telegraph Co., of Pittsburgh. This company operates the telephone system of Pittsburgh and the increasing amount of underground wires has made it necessary to employ an expert to superintend the cable work. Mr. Fisher, however, retains his position with the Standard Underground Cable Co., as heretofore.

DR. S. S. WHEELER, president of the Crocker-Wheeler Electric Company, sailed August 3 on the "Germania" for a much-needed vacation. He has taken with him letters of introduction to the leading electricians of Europe, and will also visit the principal central stations abroad.

PROF. F. B. CROCKER, vice-president of the Crocker-Wheeler Electric Co., arrived on the "Teutonic" on August 3 after a six weeks' sojourn abroad. He has seen in this short time nearly every electrical engineer of note, has visited the principal central stations and works of Europe, and has taken a general survey of the electrical field.

THE TROY AND NEW ENGLAND RAILROAD which was supposed to be defunct, has been resurrected, and a meeting of the directors has been called, to broach (it is said) the question of equipping the road with electric power instead of steam.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED JULY 26, 1892.

Accumulators:—

Secondary Battery, A. E. Colgate, 479,753. Filed Apr. 26, 1892.

Employs a plate consisting of an assemblage of strands composed of flat strips or ribbons of lead twisted together.

Alarms and Signals:—

Electric Signaling Device for Fire Hose, J. G. Wharton and J. W. Braid, 479,540. Filed Nov. 11, 1891.

Employs a conductor running through each section of the hose and electrically connected with the brass joints and contact pieces for insuring good connection at the joints.

Switch and Signal Apparatus, J. G. L. Schreuder, 479,666. Filed June 10, 1891.

Employs a fluid pressure motor connected with the track and having an electrically controlled valve mechanism and lock.

Key Controller and Signal Transmitter, M. Martin, 479,715. Filed July 16, 1889.

Employs a detachable key for operating the signal transmitter, combined with a detent that engages the key when introduced into the box, an electromagnet to operate the detent and a circuit changer at the central office for operating the electromagnet.

Conductors, Conduits, and Insulators:—

Electric Conductor, F. A. C. Perrine, 479,525. Filed Sept. 23, 1891.

Employs a single strand conductor twisted to a helical form and having a covering of paper supported on the exterior lines of the helix, so as to form air spaces between the conductor and the covering.

Dynamos and Motors:—

Motor-Frame for Electric Locomotives, S. H. Short; 479,469. Filed Oct. 29, 1889.

Has for its object to insulate the motor from the ground by insulating it from the metallic portions of the truck.

Alternating Current Motor, W. Stanley, Jr., and J. F. Kelly, 479,675. Filed Nov. 14, 1891.

Employs a stationary coil closed upon itself and having its convolutions substantially parallel to those of the armature coil so as to neutralize the self-induction of the armature.

Alternating Current Motor, W. Stanley, Jr., and J. F. Kelly, 479,676. Filed March, 5, 1892.

Claim 2 follows:

The combination with an alternating current motor and in series with the circuit or circuits of the same of a polarization cell adapted to yield an electromotive force opposite to that of the self-induction of the motor.

Alternating Current Motor, W. Stanley, Jr., and J. F. Kelly, 479,727. Filed March 8, 1892.

Claim 1 follows:

The combination with an alternating current motor having independent energizing circuits of a polarization cell included in one circuit and a self-induction device in the other.

Electromagnetic Motor, J. F. Kelly, and W. Stanley, Jr., 479,746. Filed May 29, 1891.

Employs a condenser in series with an alternating current motor to neutralize the self-induction.

Galvanic and Thermo-Electric Batteries:—

Sealed Battery Cell or Similar Articles, C. Willms, 479,541. Filed Apr. 30 1892.

A battery cell of glass, having an end sealing plug of plastic material, which expands while setting so as to prevent leakage.

Thermo-Electric Element, C. W. Iden, 479,596. Filed Nov. 11, 1889.

Consists of an iron box with a compound of zinc and antimony cast within it, and pole pieces of some different metal cast in the ends of the zinc and antimony.

Lamps and Appurtenances:—

Cord Adjuster for Electric Lamps, J. W. Heaphy, 479,509. Filed Nov. 11, 1891.

Electric Arc Lamp, W. E. Irish, 479,510. Filed May 4, 1892.

Relates to the combination of a thermo-expansive electric conductor, a clutch, an operating lever and a spring for communicating the motions of the conductor to the clutch, and carbon electrodes engaged with the clutch.

Electric Arc Lamp, J. A. Pierce, 479,659. Filed Oct. 15, 1891.

Employs a bracket attached to the frame of the lamp and to which are pivotally attached swinging arms carrying rollers which embrace the electrode for the purpose of rendering steady the feed of the carbons.

Apparatus for Producing Variegated Lights, F. L. M. Smith and W. J. Bryan, 479,673. Filed Jan. 5, 1892.

An apparatus for advertising signs, etc.

Miscellaneous:—

Cord Carrier for Underground Conduits, S. R. Bradley, 479,397. Filed Jan. 27, 1892.

Consists of a magnet, the armature whereof actuates devices which engage with the interior wall of the conduit so as to propel the carrier forward.

Electric Bell, A. M. Eklund, 479,410. Filed May 2, 1892.

Electric Self-Winding Clock, M. Mackellar and G. D. Weaver, 479,520. Filed Aug. 12, 1891.

Electroplating Toy Apparatus, E. A Clark, 479,557. Filed Mar. 16, 1892.

Temperature Regulator, W. H. Kilbourne, 479,761. Filed May 13, 1891.

Employs a thermostat bar connected with a hot water radiator, electrical devices connected with the thermostat, and rods connected with the electrical devices for operating valves or dampers.

Matrix-Making Machine, G. A. Goodson and A. C. Capehart, 479,772. Filed May 31, 1887.

Employs an electromagnetic feed mechanism and electrical contacts corresponding with each group of dies and connections from the same to the feed mechanism.

Matrix-Making Machine, G. A. Goodson, 479,773. Filed Mar. 20, 1888.

Similar to No. 479,772.

Railways and Appliances:—

Electric Railway, M. W. Dewey, 479,493. Filed July 24, 1891.

Employs a condensing plate upon the vehicle carried in inductive proximity to the line conductor.

Trolley, F. F. Poole, 479,608. Filed May 11, 1892.

Employs spring plates adjustably secured to the sides of a support and fulcrumed on the axle and metal blocks, so arranged on the springs as to touch the wire beyond, but in the centre line of the trolley wheel.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED AUGUST 2, 1892.

Accumulators:—

Storage Battery Plate, H. G. Osburn, 479,835. Filed Nov. 21, 1891.

Consists of longitudinal webs and transverse bars deflected alternately in opposite directions.

Alarms and Signals:—

Electric Signal Apparatus, A. J. Wilson, 479,928. Filed Nov. 9, 1891.

Has for its object to permit the presence of more than one train at a time on the guarded block without the passage of one train from the block clearing the signal behind another following train or trains that may still remain.

Fire-Alarm Telegraph Indicator, F. F. Loomis, 479,950. Filed Dec. 1, 1891.

A fire-alarm circuit provided with boxes, which shall automatically indicate by figures the number of the box from which the alarm is given.

Train Order Annunciator, L. T. Crabtree, 480,078. Filed Oct. 15, 1891.

Automatic Device for Electric Block Signals, J. B. Stewart, 480,147. Filed Jan. 26, 1892.

An electric locking device comprising a circuit, including magnets at each station and batteries opposed to each other on the line.

Conductors, Conduits and Insulators:—

Insulator, J. J. Green, 480,011. Filed Mar. 24, 1892.

Provides means whereby the conductor, having been first introduced into a transverse groove in the insulator, is fixed in place by simply turning the insulator upon the screw supporting it.

Distribution:—

System of Distributing Electric Currents. C. J. Van Depoele, deceased; C. A. Coffin and A. Wahl, executors, 479,964. Filed May 20, 1891.

Has for its object to supply currents capable of operating a number of different types of machines with the use of the smallest possible quantity of copper in the conductors.

Dynamos and Motors:—

Commutator, W. H. Elkins, 479,793. Filed Jan. 26, 1892.

Employs a number of individually insulated segments and alternate segments having contact portions in different planes of rotation.

Brush Holder, F. J. Haeseler, 479,802. Filed Nov. 5, 1891.

Employs a copper and carbon brush in contact with one another.

Electromagnet Bobbin, E. B. Hatch and C. A. Colton, 479,804. Filed Jan. 13, 1892.

Employs projecting flanges of partially vulcanized india-rubber and asbestos composition in a single piece and helices of wire wound about the bobbin between the flanges.

Influence Generator of Electricity, W. Henry, 479,941. Filed May 29, 1891.

Employs two groups of insulated metallic sectors placed in relatively different inductive proximity to one another so that polarization shall take place in the induced sectors at different moments.

Pulsating Current Generator, H. N. Marvin, 479,951. Filed Dec, 3, 1891.

Employs brushes capable of being rotated about the commutator and means for establishing connection alternately between the brushes and the circuits of a drill.

Controling Mechanism for Reciprocating Electric Engines, C. J. Van Depoele, deceased; C. A. Coffin and A. Wahl, executors, 479,960. Filed Dec. 31, 1889.

Employs a circuit supplying alternating currents to the motor coils and means for regulating and controling the current strength and also the number of alternations or phases in the motor coils.

Feed Mechanism for Electric Reciprocating Engines, C. J. Van Depoele, deceased; C. A. Coffin and A. Wahl, executors, 479,961. Filed May 22, 1890.

Reciprocating Electric Engine, C. J. Van Depoele, deceased, C. A. Coffin and A. Wahl, executors, 479,962. Filed Sept. 19, 1890.

Comprises a plurality of motor coils, a magnet plunger therein, a generator having an armature of the continuous current type and means for dividing the current of the generator.

System of Supplying Currents to Reciprocating Electric Engines, C. J. Van Depoele, deceased; C. A. Coffin and A. Wahl, executors, 479,963. Filed April 11, 1891.

Dispenses with moving parts upon the commutator and substitutes additional contact surfaces provided with insulated portion and from which the current is collected by stationary brushes.

Field Magnet Frame for Dynamo-Electric Machines, E. P. Warner, 480,049. Filed Feb. 10, 1890.

Galvanic and Thermo-Electric Batteries:—

Galvanic Battery, M. M. Clark, 479,786. Filed Jan. 9, 1892.

A dry battery employing a porous cup immersed in the electrolyte, a negative element within said porous cup and surrounded by a depolarizing substance, a packing of fibrous material above the electrolyte and a tube secured to the positive element and extending through the sealing material and having a closing cap.

Galvanic Battery, F. de Lalande, 479,887. Filed June 27, 1891.

Employs an electrode consisting of an agglomerated mass of copper oxide having its surface reduced to a metallic state.

Heating:—

Electrical Water Heater, R. Kennedy, 479,814. Filed April 1, 1891.

Lamps and Appurtenances:—

Incandescent Lamp Guard, G. W. Demmick, 479,791. Filed June 22, 1889.

Spark Arrester for Electric Arc Lamps, C. Smallwood, 479,994. Filed Dec. 26, 1891.

Duplex Arc Lamp, E. P. Warner, 480,050. Filed Feb. 21, 1891.

Employs two pairs of carbons placed in derived circuit, a unitary electromagnetic device for controling them and a polarized commutator to transfer the arc from one pair of carbons to the other.

Reflector, C. A. Meadows, 480,201. Filed Dec. 31, 1891.

Measurement:—

Electric Meter, L. V. Brillié, 479,932. Filed Oct. 2, 1891.

A "motor-meter" in which the current passes through an electro dynamometer, the speed of the motor being regulated by a current-regulator controler.

Device for Measuring Electrical Currents, C. H. Rudd, 480,089. Filed Nov. 6, 1891.

Employs a measuring coil concentric with and in the field of a field coil and movable with respect to the latter and a telephone in the circuit of the measuring coil.

Miscellaneous:—

Process of Purifying Liquors, C. W. Brunson, 479,781. Filed Nov. 9, 1891.

Claim 5 follows:

The process of purifying spirituous liquor or other liquid by means of the application thereto of electrolysis, while said liquor or liquid is kept in a state of frigidity approximating its freezing point.

Valve Controler, C. L. Fortier, 479,795. Filed March 5, 1892.

Electric Steering Gear, E. H. Mumford, 479,828. Filed Aug. 20, 1891.

Employs a curved arm of magnetic material attached to the tiller and a solenoid fixed to the body of the vessel and receiving within its coils a portion of the curved arm

Device for Indicating Washouts in Railroad Beds, J. Ortega y Espinosa. 479,834. Filed Oct. 23, 1891.

An arrangement for electrically indicating at railway stations any washouts of the roadbeds or bridges as may occur along the line.

Electric Current Regulator, A. S. Krotz, 479,886. Filed March 26, 1891.

Employs a solenoid included in shunt circuit, an electromagnetic device included in the main circuit and maintaining the shunt circuit normally open, devices connecting the core of the solenoid with the generator and means for automatically controling the number of solenoid coils included in the shunt circuit.

Mold for the Manufacture of Electrical Switchboards, J. B. Lyon, 479,891. Filed Jan. 19, 1891.

Elevator, L. M. Hosea, 479,913. Filed Aug. 21, 1891.

An electric elevator having fixed suspension ropes secured at the top of the runway and wound over sheaves actuated by a motor carried upon the car.

Reciprocating Electric Drill, F. F. Loomis, 479,948. Filed April 11, 1891.

Has for its object to increase the force of the stroke and insure a quick return by alternately increasing and reducing the attraction of the solenoid.

Reciprocating Electric Pile-Driver, C. J. Van Depoele, deceased; C. A. Coffin and A. Wahl, executors, 479,965. Filed May 23, 1891.

Electrical Transmission of Power, C. J. Van Depoele, deceased; C. A. Coffin and A. Wahl, executors, 479,966. Filed May 6, 1891.

Relates to means for the distributing of pulsating currents for reciprocating engines, rock drills, etc.

Testing Apparatus for Electric Lighting Circuits, C. H. Rudd, 480,088 Filed Dec. 10, 1888.

Has for its object the localization of the first accidental ground that may be formed in order that the damage may be repaired.

Electric Jail-Plate, W. S. Hull, 480,099. Filed Dec. 8, 1891.

Electric Screens for Doors or Windows, W. S. Hull, 480,100. Filed Feb. 3, 1892.

Rheostat, C. W. Tobey, 480,151. Filed July 11, 1891.

Consists of powdered graphite and asbestos compressed into a compact body.

Electric Cord Tip, C. W. Tobey, 480,152. Filed Nov. 24, 1891.

Railways and Appliances:—

Closed Conduit for Electric Railways, E. H. Johnson, 479,809. Filed Feb. 10, 1887.

Employs two separate conduits carrying working conductors and two contact carriers connected with the car and moving in said conduit.

Electric Railway, C. H. Baker, 480,004. Filed Sept. 1, 1891.

Has for its object to thoroughly protect the conducting wires in the conduit and at the same time provides efficient means for conducting the current from them to the motor.

Trolley for Electric Cars, G. E. & C. W. Purple, 480,240. Filed Sept. 8, 1891.

Employs dogs upon the supporting yoke of the trolley wheel having inclined upper surfaces and projecting over the wheel.

Switches and Cut-Outs:—

Electric Switch, A. P. Lundberg, 479,821. Filed Dec. 29, 1891.

A rotary switch having angular contacts and contact springs, and in which the base and cover form bearings for the spindle.

Electric Switch. F. F. Loomis, 479,949. Filed July 31, 1891.

Employs a tank containing an acid metallic solution, and a revolving nonconducting cylinder mounted therein and partially covered with a conducting plate and brushes resting on the cylinder.

Safety Cut-Out, R. Furgang, 480,009. Filed Oct. 14, 1891.

Telegraphs:—

Mechanical Telegraph Instrument, B. F. Butler, 479,782. Filed May 16, 1892.

A device by which students may learn the art of telegraphy without the employment of magnets, batteries, etc.

Telegraph Key, A. F. Tucker, 479,859. Filed Mar. 24, 1892.

A telegraph key provided with an automatic switch, whereby the circuit is normally closed when the instrument is not in use.

THE COST OF MAGNETIC CONCENTRATION.

IN a recent paper on magnetic concentration, at the Tilly Foster Mine, F. H. McDowell, of this city, reports the results of work as follows:

From the time the plant was put in operation, in 1890, to January 1, 1892, there have been 78,915 tons sent to the mill, of which 60,827 tons came from the dump and 18,088 from the mine, and the total concentrates shipped to January 1, 1892, were 27,462 tons. The cost of making one ton of concentrates has been reduced from $2.10 in 1890 to $1.99, and this has been accomplished in the face of an abnormal increase of expenses, due to the shortened season brought about by the drought, the laying of drains for the new reservoir system, the building of walls for the increased storage of the tailings and the purchase of several new cars.

THE ELECTRICAL ENGINEER ABROAD.

THE following letter speaks for itself:

ISMAY, IMRIE & CO., WHITE STAR WORKS,
STRAND ROAD, BOOTLE, July 7th, 1892.

TO MR. T. W. SEWELL,
Chief Engineer S. S. "Majestic."

You will please purchase when next in New York six of the Ries regulating lamp sockets, mentioned in accompanying article from THE ELECTRICAL ENGINEER, sending same to this address upon your return.

Yours very truly,
ISMAY, IMRIE & CO.,
Per S. GORDON HOSBURGH.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

An "ad" reaches the mountains as well as the seashore.

THE HAMMER ELECTRIC CLOCK.

Correct time is so essential to the conduct of modern business and social life that the efforts to place the public in possession of reliable time-pieces ought to be encouraged in every way. For the distribution of standard time, electricity is eminently adopted and among the recent applications in this domain is the electric clock system of Messrs. E. G. Hammer & Co., of Brooklyn, N. Y.

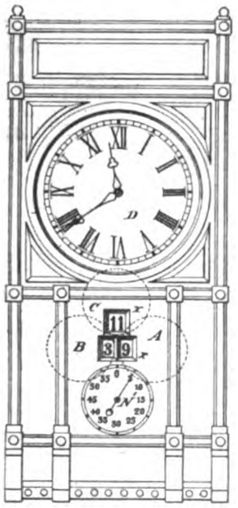

Fig. 1.

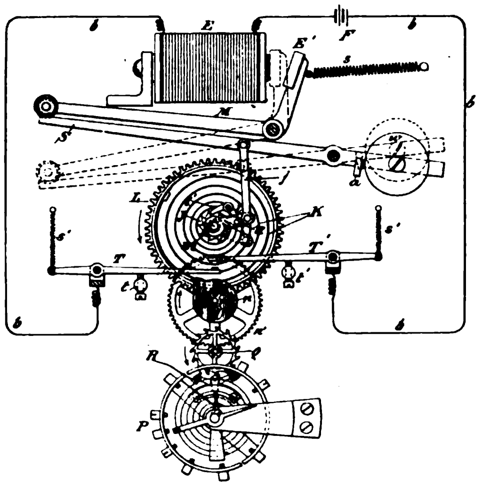

Fig. 3.

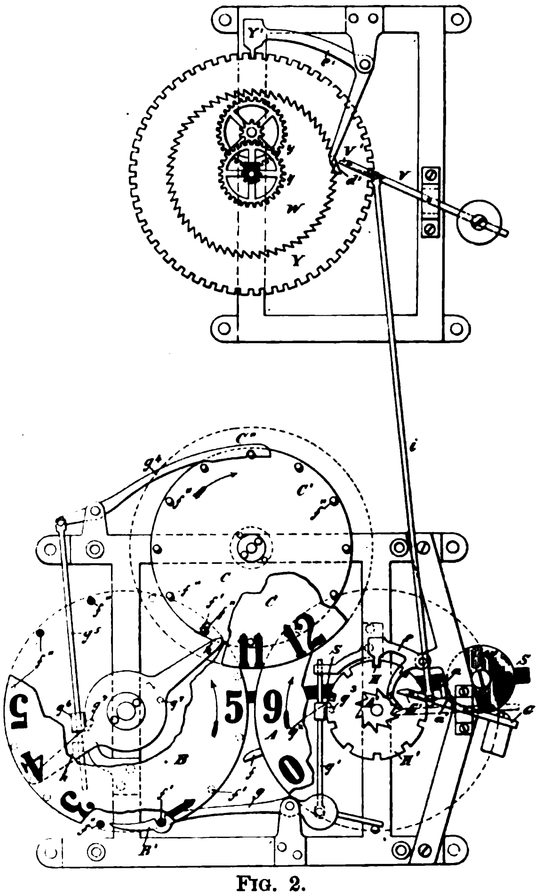

Fig. 2.

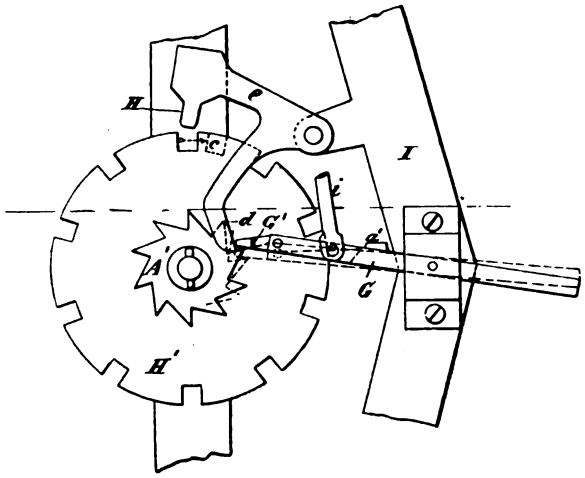

Fig. 4.

Hammer Electric Clock.

In the accompanying engravings, Fig. 1, represents an independent electric clock complete, showing time in two ways, by hands and dial D, and by figures showing railroad time painted on discs, A, B, C. Fig. 2 shows the interior of this arrangement from which it will be seen that this duplex system may be separated so that it leaves a secondary hand clock as well as a secondary figure clock. Fig. 3 shows the simplicity of the turning construction, which is easily explained. It consists of a notched wheel H′ and a ratchet wheel A′ a lever *e* with a bolt H and the other end S on which acts a reciprocating tooth G′, which turns loosely in lever G. It is shown as lifting bolt H out of a notch and is ready to turn ratchet wheel A′; at the same time it leaves point J and thereby allows bolt H to fall in the succeeding notch. This simple device can also be applied to an ordinary hand clock as the upper portion of Fig. 2 shows.

Fig. 4 shows an escapement which may be attached to this secondary clock whereby it becomes an independent clock, spring K which drives the escapement being wound once every minute by a counter-weighted lever S, which also sets the time-indicating service. Contact points T T excite magnet E, and thereby lift through intermediate lever M weight W which, after the breaking of the contact becomes free to act. One of the principal points in this construction, besides its simplicity, is the fact, that the electric current itself does not do any special work except to lift a weight, which weight does the actual work; and as weights do not vary it becomes evident that this mechanism must work very steadily. This secondary hand clock would be eminently fitted to be run in connection with electric railroads or electric light stations as they are simple, durable and precise.

THE WILDER DUPLEX FIRE-ALARM AND MESSENGER COMPANY.

Mention has been made from time to time regarding the incorporation of the Wilder Duplex Fire Alarm and Messenger Company, but as to the nature and extent of the business being done nothing has really been said. It will be of interest to persons contemplating any system of protection for vaults, messenger service, etc., to know that the system of this company is now in use in Kansas City, there being at present about 500 district messenger boxes as well as a complete system of burglar alarms. Mr. E. F. Mullay is secretary and manager.

At Little Rock, Ark., there are at present in use over 300 No. 10 call boxes, and the city of Wichita, Kan., has purchased the system and will use it for fire-alarm and messenger calls. The office of the company is at 167 Broadway, New York, where they have in operation a complete system showing the many advantages claimed for their particular apparatus. Mr. A. M. Sloss, the genial manager, is pleased at all times to explain the workings of the machines.

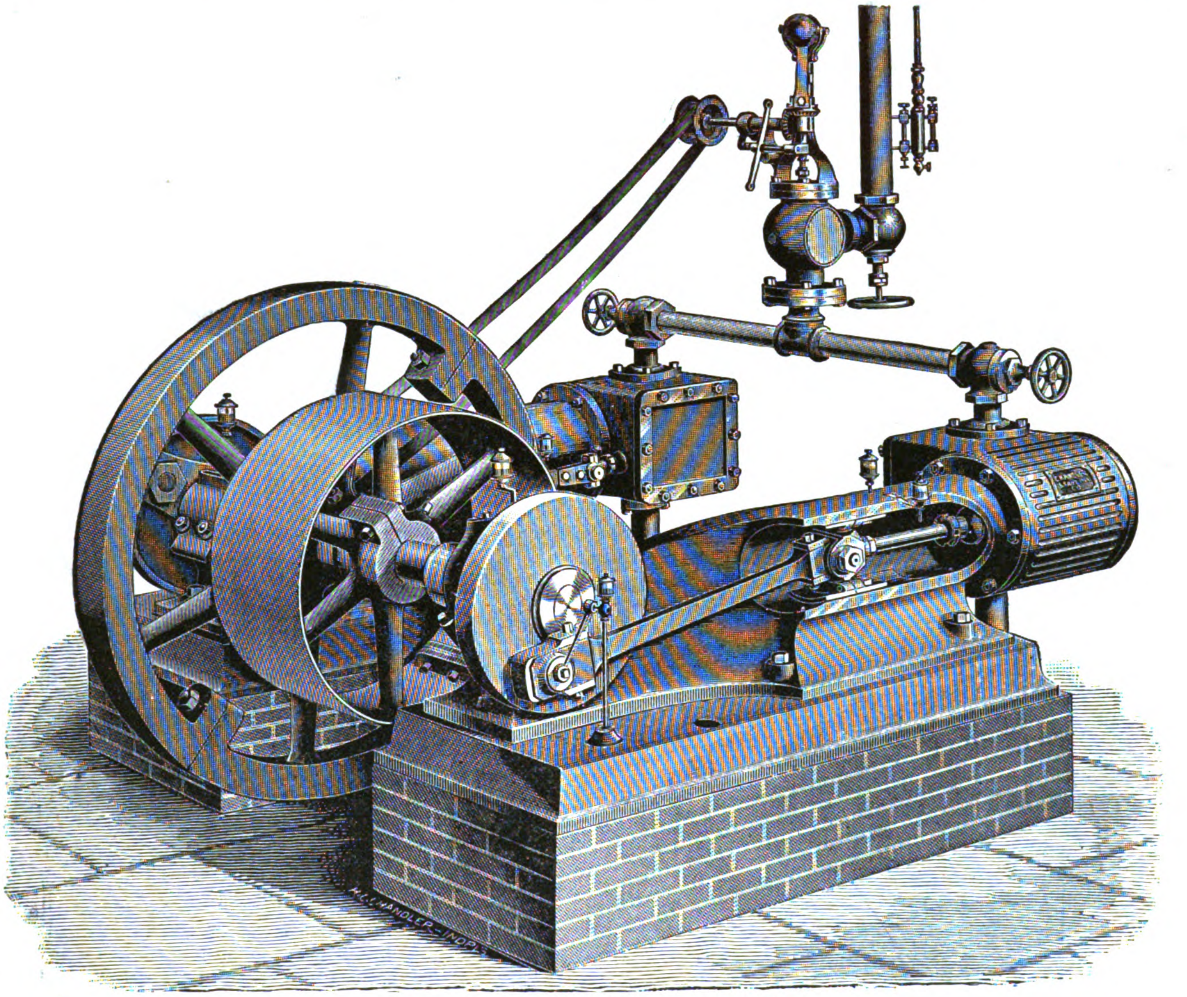
The Enterprise Electric Co., of Chicago, have opened a St. Louis branch house at No. 15 North 9th street. They will carry an assortment of staple electrical supply goods. This will enable them to handle their large trade to the very best advantage in that section.

THE CHANDLER & TAYLOR TWIN ENGINE.

THE accompanying illustration shows a new form of engine lately introduced by the Chandler & Taylor Co., of Indianapolis, Ind. As will be seen, the arrangement consists of a right and a left-hand engine coupled quartering, with crank discs on the ends of shafts, and dispensing with outboard pillow blocks. A comparatively small fly-wheel is required for this type of engine, and where great regularity is not necessary, this may be dispensed with and the turning still be sufficiently uniform for the purpose. The working strains are also more equally distributed than with a single-cylinder engine. The engine is so constructed as to admit of high rotative speed when desired, as in electric light plants, etc.

To render unnecessary the removal of crank discs, which are both permanently fixed, the band wheels and eccentrics are made in halves, which saves work and avoids the possibility of throwing out a crank while removing and replacing a disc.

The governor is at the centre of the connecting pipe, and by means of valves either engine may be shut off without affecting the other. These engines are also fitted with a link motion.



CHANDLER & TAYLOR TWIN ENGINE.

BALL ENGINES.

THE BALL ENGINE Co., of Erie, Pa., have shipped during the past three weeks the following: Compania Mexicana y Luz Electrica, City of Mexico, two 60 h. p. engines, two 60 h. p. heaters, etc.; Hot Springs Electric Co., Hot Springs, Va., one 100 h. p. engine, two 80 h. p. boilers, one 200 h. p. heater, one 200 h. p. pump; Ames-Bonner Co., Toledo, O., one 80 h. p. engine; Brooklyn Navy Yard, Brooklyn, N. Y., one 80 h. p. engine; Arnold Ore Mines, Ferrona, N. Y., one 35 h. p. engine; Northwestern Supply Co., Tacoma, Wash., one 25 h. p. engine; Carbon Iron Co., Pittsburgh, Pa., one 130 h. p. engine; Diamond Light and Power Co., Sheldon, Ia, one 80 h. p. engine; North Hudson County Railroad Co., Hoboken, N. J., one 250 h. p. engine; Puget Sound Pulp and Paper Co., Everett, Wash., one 25 h. p. engine; Pittsburgh Iron and Steel Engineering Co., Pittsburgh, Pa., one 130 h. p. engine; Whitman & Barnes Mfg. Co., Akron, Ohio, one 80 h. p. engine; Fort Clark Street Railway Co., Peoria, Ill., one 130 h. p. engine; Boulder Electric Light Co., Boulder, Col., one 100 h. p. engine, one 100 h. p. boiler, one 150 h. p. pump, two 100 h. p. heaters; Shamokin Electric Railway Co., Shamokin, Pa., one 130 h. p. engine; North Avenue Street Railway Co., Baltimore, Md., two 130 h. p. engines; Mt. Vernon Electric Light Co., Mt. Vernon, Ohio, one 150 h. p. engine; H. F. Watson & Co., Erie, Pa., one 350 h. p. cross-compound engine; Rock Cut Clay Co., Lim., Alfred Centre, N. Y., one 60 h. p. engine; Metropolitan Telephone Building, New York City, one 60 h. p. engine; La Gran Fundicion Nacional Mexicana, Monterey, Mexico, one 60 h. p. engine.

PACKARD ARC LAMPS.

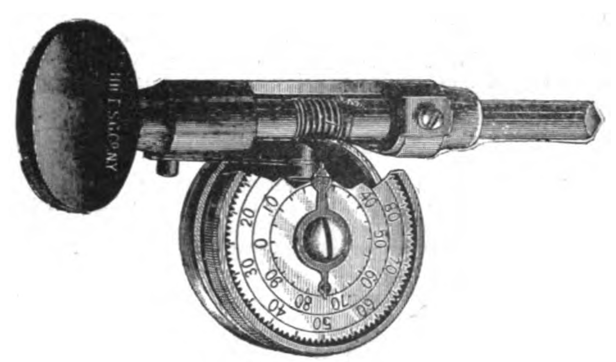
THE ELECTRIC APPLIANCE COMPANY report having secured the general Western agency for the Packard lamp and will hereafter handle the Western trade from Chicago. The Electric Appliance Co. are certainly to be congratulated on their success in adding the Packard lamp to their large line of very desirable specialties. They have been controlling the sale of the Packard lamp in Indiana and Southern Michigan for some time and have met with such large success in that territory that the New York & Ohio Co. have decided to give them control of the Western territory. Arrangements are being made to carry a large stock of lamps in Chicago for the accommodation of the trade.

There is probably not another lamp on the market which has enjoyed such a reputation from the first day it was put on the market. There may be other good lamps to-day but they have gradually worked up to that point through failures and imperfections, whereas the Packard lamp was a perfect lamp from its inception and its brilliant record has been continuous.

ONE of the handsomest isolated plants being put in at present is that in the power station of the Broadway Cable Road. The plant will comprise between 3,000 and 4,000 lamps, and quite a number of electric motors. Slow-speed dynamos, coupled directly upon the engine shaft, will be used. H. Ward Leonard & Co. are acting as the bulk contractors for the entire electrical equipment.

THE GEM ALARM BELL INDICATOR.

THE accompanying illustration shows one of the neatest and most useful pocket tools for electricians and others that have been lately put on the market, known as the "Gem" double-speed alarm bell indicator. It is a combination of a speed indicator and alarm bell. It is nickel-plated, and in size is only 3⅝ x 1¼ x ⅞ inches, and may be easily carried in the vest pocket. In use the engaging point is applied to the shaft of the machine being tested, and the operator, watch in hand, waits until the bell rings. Upon the ringing of the bell, he begins to observe the time and continues as long as may be desired, it being simply necessary to count the strokes of the bell thereafter, each stroke indicating 100 revolutions. Upon the expiration of time limit the indicator is removed and any fraction of 100 that may be shown upon the dial is added to the full hundreds previously counted by bell strokes.



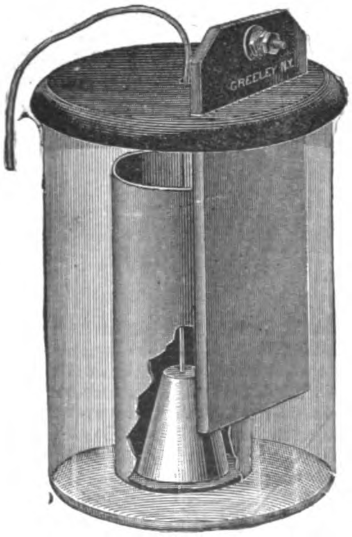
GEM ALARM BELL INDICATOR.

This instrument will be readily appreciated by all who have to do with machinery and engines of any kind.

The E. S. Greeley & Co., 5 and 7 Dey street, New York, who are introducing these instruments, anticipate a very large sale for them.

THE FULLER BATTERY.

THE accompanying illustration shows a telephone batttery especially adapted for use in cities where telephones are almost constantly in use, and on long-distance lines, over which extended conversations are held. Much attention has been given to this form of battery by some of the largest telephone companies in this country and after many trials and exhaustive tests has won their expressed approval.



IMPROVED FULLER BATTERY.

The main features claimed for this type of Fuller battery are high efficiency, durability and uniformity of strength. This battery is sold by The E. S. Greeley & Co., 5 and 7 Dey street, New York City.

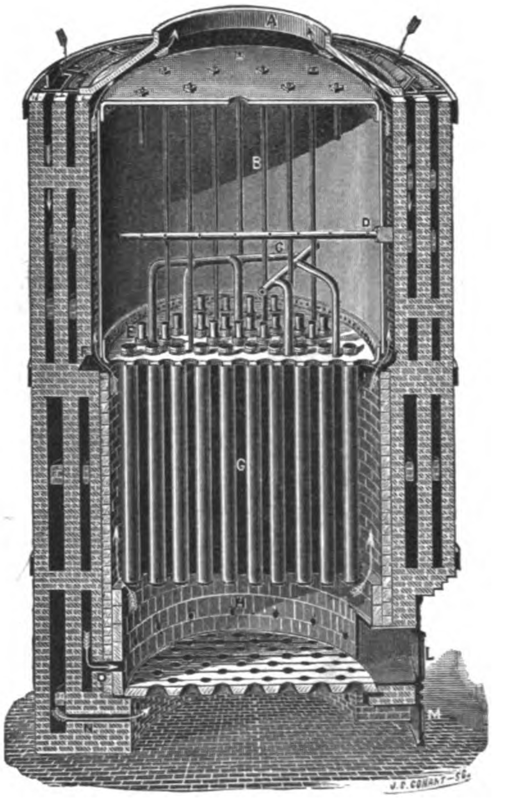
MR. JOHN R. MARKLE, the pioneer electrical expert of Detroit, Mich., called at the Western office of THE ELECTRICAL ENGINEER last week.

THE McLAUTHLIN SAFETY BOILERS.

Two 125 h. p. drop tube safety steam boilers, manufactured by Messrs. George T. McLauthlin & Co., of 120 Fulton street, Boston, were recently installed in the new station of the Atlanta Traction Co., Atlanta, Ga., where they are giving the utmost satisfaction. The results of a test in comparison with tubular boilers, we are informed, showed a saving of nearly 600 pounds of coal per day for three days in favor of the McLauthlin boilers with the same power and conditions.

The accompanying illustration shows a sectional view of one of these boilers, as now manufactured. Here H is the furnace with firebrick lining, which extends up to the supporting ring F, and is set flush with its lower edge. The ring F rests upon the brick-work, and supports the boiler by lugs extending underneath the cylinder; above it the brick-work is laid flush with its upper edge. B is the steam and water cylinder. The two heads are stayed by the vertical braces B, a part of which are broken away to better show other parts. At A is the smoke bonnet, which has its aperture over the centre of the boiler.

The feed-pipe, D, extends across the boiler inside, far above the tube-sheet; it is closed at the end, and perforated so as to secure extended distribution of the feed water in minute upward jets. C is the blow-off pipe, having several branches which dip down to within a quarter of an inch of the tube-sheet; so that all the water blown off is sucked up from the spaces between the tubes, thus securing a clean boiler. The tubes, G, extend through the tube-sheet, and the circulating tubes, E, extend above them. The latter are not shown in the front row.



McLAUTHLIN SAFETY BOILER.

The company claim great safety for their boilers through the following features: The tubes can expand without affecting the cylinder, which, being enveloped by the passing gases, has equal heat throughout every horizontal section; so that no undue strain or change of texture can take place by any possibility of irregular expansion. The manifold blow-off, in connection with the enforced circulation, keeps the boiler throughly clean throughout. The boiler is suspended entirely within the fire-chamber, and free from contact with the brick-work. It has a central fire beneath, an annular draught-space around, and a central draught-flue above, securing a systematic distribution of heat upon all portions of the boiler, and avoiding contact with corroding and heat-conducting surfaces. The distributive feed, in fine upward jets, secures instant vaporization, avoiding the possibility of water coming in contact with overheated surfaces.

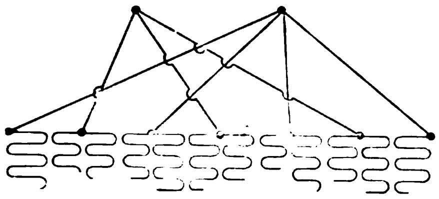
These boilers are carefully built, and are tested at a pressure of 200 pounds.

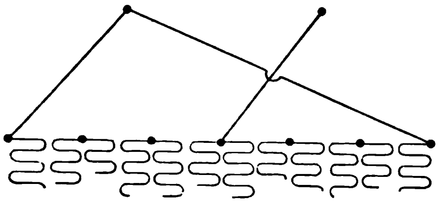
W. E. READ & Co., No. 339 "The Rookery," are the agents for the McEwen engines and boilers, especially built for electric lighting and street railway work.

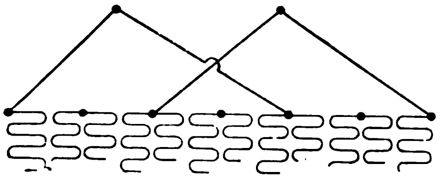
THE CARPENTER ENAMEL RHEOSTAT.

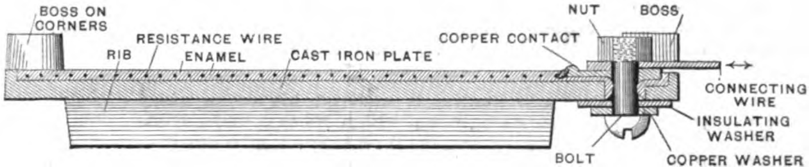
The accompanying illustrations show an exceedingly simple and compact form of rheostat manufactured by the Carpenter Enamel Rheostat Company, of Bridgeport, Conn.

The principle of this rheostat is the conduction and dissipation of heat by holding a resistance wire in close relation to a metal plate so that the heat generated in it by the passage of a current is rapidly conducted to the plate, which becomes the radiating surface. This is accomplished by the use of an enamel which permanently attaches the wire to, but insulates it from, the radiating surface plate, and which also completely surrounds and protects the wires from chemical action. In practice it is found that a wire that will carry a certain current when exposed to the air, will carry ten times that amount of current safely in this rheostat. On this principle, since the cross-section of the conductor can be greatly reduced, it follows that its length can be also proportionately shortened for any required resistance, and no consideration of mechanical strength of the wire enters into this construction since it is so perfectly confined and supported on all sides. For example: A 24 B. and S. German silver wire will, in this rheostat, carry 25 amperes and 80 feet of the wire coiled upon the surface of a plate 10x10 inches, will absorb and dissipate five kilowatts of energy in starting a five-kilowatt motor of 220 volts under full load.

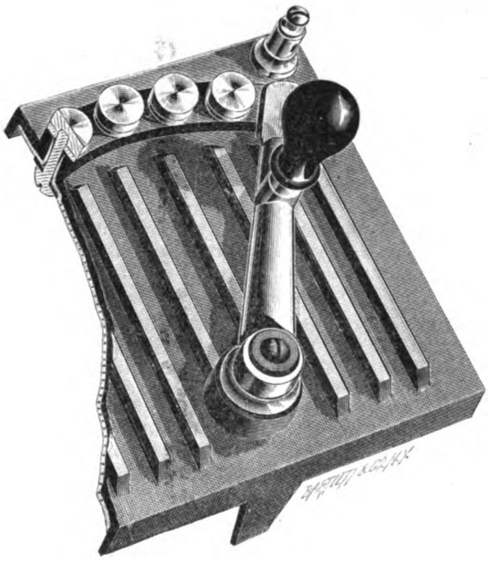








Section of Standard Rheostat Plate



Figs. 1, 2, 3, 4 and 5.—Carpenter Enamel Rheostat.

To increase the radiating surface, the back of the plate is provided with ribs shown in Fig. 4. The plates will dissipate continuously 8 watts per square inch of one surface, *i. e.*, a 10x10 inch plate, or 100 square inches, will dissipate 800 watts, and the temperature will be entirely safe. These plates will carry for a few seconds a current two and a half times as large as that for which they are rated, for continuous service. Standard plates are rated for continuous duty on the basis of 4 amperes per kilowatt when used as a starting rheostat for a 220-volt motor.

The standard plates have always an even number of steps, and, by connecting in various ways, various resistance and current capacity may be obtained. For example, plate No. 1, having 40 ohms with capacity for 5 amperes, and 6 steps, has 6.6 ohms per step. By connecting as indicated in Fig. 1, a plate is secured having a capacity of 30 amperes and 1.1 ohm. The second arrangement shown in Fig. 2, gives for plate No. 1 a capacity of 10 amperes and resistance of 10 ohms; the third arrangement (Fig. 3) of plate No. 1 gives 15 amperes capacity, with 4.4 ohms.

Figs. 4 and 5 shows a standard Carpenter rheostat. It will be noticed that the same iron plate which carries the switch contacts and lever has the coating of enamel on its under side, with the wires embedded in the enamel, so that the rheostat occupies an extremely small space.

The fireproof and waterproof qualities will be evident from the illustration, as will also its compactness, mechanical strength and simplicity.

Some of the other advantages claimed for this valuable instrument are great compactness, simplicity, durability and cheapness.

INSULATING MATERIAL AND INSULATING PAINT.

The effect of intelligent effort, directed by successful business ability, has seldom been better illustrated than by the proportions which the department for insulating materials of the Roessler & Hasslacher Chemical Co., of New York City, has assumed in the last two years. Their contracts for the "Isolatine" insulating material for delivery during this year aggregate three times the amount they were a year ago, while the sales of insulating paint since January are more than four times as large as those of the whole preceding year. Their largest business, however, was done in their protecting paint used by electric railways and steam railroads for poles, bridges, etc., in which field they successfully battled against asphalt and mineral paints.

Its high electric resistance being readily admitted by every user, the permanent pliability of Isolatine, or of the dry coat of Isolatine paint, appears to have rendered unnecessary the usual time tests, and progress in the introduction has on that account been rapid.

The latter point, permanent pliability, also holds good for the paint for protecting iron and wood against weather and soil, while the fact of its great insulation resistance is *prima facie* evidence that it will absolutely exclude moisture.

The firm count among their steady customers electric roads in New Jersey, Philadelphia, Washington, Pittsburgh, Baltimore, etc., who not only employ Isolatine paint for all their insulation work, but also for painting iron and wooden poles, etc., while, after exhaustive experiments, a number of large railroads have sent in their trial orders.

The present outlook augurs well for a still larger business during the last half of the year in this deservedly popular product.

CENTRAL ELECTRIC COMPANY.

The Central Electric Company have got in a large stock of wheatherproof wire, in double and triple braid, and are making prices to suit the customer. The success with the Lundell Fan Motor is very encouraging, and they are selling a large number. Orders for Interior Conduit are still rolling in, and the Central Electric Company can be congratulated upon the maintenance of their large business during the warm weather.

"AMERICA'S GREATEST RAILROAD."

The New York Central has once more given undoubted evidence of its desire and intention of giving its patrons the best possible protection. The company have but recently given, in connection with their block system, which is well nigh completed, an order for some 800 miles of Kerite aerial conductor wire. This is the largest single order for wire ever placed in the country. Kerite is old and tried. The father of the telegraph used it, and was always pleased with it, and there is no reason to believe it will fail now when called upon to do its duties in preventing accidents and loss of life on the lines of the "only four-track railroad in the world."

WESTERN NOTES.

Mr. Chas. E. Gregory, of 313–317 South Canal street, Chicago, is doing a good business at his trading store. Some of his sales during the past month were as follows: Lighting plant for a dredge at the World's Fair grounds; a 30 arc light plant to the Berlin Mantello Granite Co., Mantello, Wis.; 25 arc light plant to Archer Electric Co., Chicago; 60 arc light plant to O. V. Bachelle, Chicago; 15 arc light dynamo to Henne & Co., Chicago; 150-light incandescent to Saratoga Hotel, Chicago; 110-light incandescent to H. Ingraham, Co., Chicago; and 256 cells of storage battery to Patton Motor Co. and other Chicago parties; ten arc lamps to Charlotte, Mich., and 13 Ellis oil filters; one 25 light Sperry dynamo to Holt & Follett, West Plains, Mo.; 1 h. p. Mayo motor to Hiller & Wohl, Chicago.

Mr. Albert Blanchard has lately severed his connection with the Pond Engineering Co., with which he has been connected for more than five years, and is now located at room No. 427 "The Rookery," as an engineer and contractor in steam specialties. Mr. Blanchard is prepared to submit plans and estimates for plants of any desired capacity. His long experience in building car plants for electric lighting and street railway central stations, and as a contracting engineer and superintendent of the construction of numerous steam plants enables him to give the best of references and guarantee satisfaction.

The Electric Appliance Company announces the securing of the agency for the celebrated Elkhart transformer, and will handle the Western trade. The Elkhart transformer has had a record remarkable in a great many respects. It began its career in a quiet way about a year ago, and the manufacturers claim that they have never yet sent out a sample machine that has not resulted in securing them the transformer business of the customer. It is now being used exclusively by a number of the largest plants in the country who could not be induced to make a change at any price.

The Enterprise Electric Co., of 313–315 Dearborn street, Chicago, have found their St. Louis trade increasing so rapidly that it has become necessary for them to open a branch house there, and Mr. Walter C. McKinlock is now in St. Louis looking after the interests of the branch house. Mr. W. F. Richardson reports business as excellent. The new National india-rubber wire, for which they are general Western agents, is taking remarkably well with the trade and they have already secured some very nice orders.

Mr. Wm. Hood, No. 239 La Salle street, Chicago, has closed a contract with the Electrical Manufacturing Co. for the exclusive right to sell their incandescent lamps in the States of Illinois, Indiana, Iowa, and Nebraska with the privilege of selling also in the States of Wisconsin, Minnesota, Michigan, Ohio and other Western States. He will carry a large stock of not less than 10,000 lamps always on hand, thus enabling him to fill orders with the greatest promptitude. The name of the lamp is the "Brilliant."

George Cutter is organizing a company for the manufacture of rheostats and electric heaters with the wires imbedded in enamel. The new company expects to build factories both at Chicago and in the East, and will start with a capital of $250,000.

Mr. L. K. Comstock, electrical engineer and contractor, No. 1419 Monadnock Building, is doing a good business in electrical construction work. Mr. Comstock makes plans and specifications for the installation of electrical plants.

Mr. George B. Merrill, manager of the Western department of the Falls Rivet & Machine Co., reports business as excellent in his line and has numerous large contracts for power transmission machinery on hand.

Mr. W. R. Mason, general manager of the Railway Equipment Co., of Chicago, has just returned from a short trip East. He is full of business as usual and consignments are going out to street railroads everwhere.

Mr. Thomas Dillon of Indianapolis was in Chicago last week and a caller at the Western office of the Engineer. He is doing an extensive business in his mast-arms and other specialties.

Clark & Marshall, No. 418 Rookery, Chicago, have received the Western agency for the Premier Electric Co., of Brooklyn. N. Y., for their battery fan motors and other specialties.

T. C. Rafferty, secretary of the Great Western Electric Supply Co., Chicago, Ill., has just returned from a three weeks' trip to the Maine summer resorts, where he had a glorious time.

Mr. R. Humffreys-Roberts, secretary and manager of the Fontaine Crossing Co., Detroit, Mich., spent a few days in Chicago last week on railroad and electrical business.

The Standard Battery Co. are very busy manufacturing the Willoughby iron gravity battery, which was recently described in The Electrical Engineer.

The Central Electric Co. are very busy and are making some exceedingly heavy shipments in Okonite wire and general electrical supplies.

PHILADELPHIA NOTE.

After a very severe contest, the entire electric contract for the Betz Office Building, in Philadelphia, has been awarded to H. Ward Leonard & Co. In this handsome office building there will be between 3,000 and 4,000 lamps, and the plant will be a most modern one in every respect. Dr. W. A. Drysdale is the consulting electrical engineer for the work, and Mr. Alfred Wolff, of New York City, the consulting engineer on the steam work. The plant is to have slow-speed dynamos, directly coupled on the shaft of the engine. The plant, when completed, will be one of the handsomest in the United States.

NEW ENGLAND NOTES.

The Northern Electrical Supply Company, of Concord, N. H., has been organized with the purpose of doing a general electrical supply and construction business in that section of the country. They have to start on a paid-up capital of $5,000; but the directors have already voted to increase that amount to $20,000, and further increase will be made as the business demands. They have at present the agency for Eddy motors in their territory, and are using the Bernstein incandescent lamps. They will also carry a complete line of telegraph instruments, and will form other agencies as soon as they can be arranged. The officers of the company at present are as follows: T. L. Hoitt, president; N. E. Martin, vice-president and treasurer; H. J. Lowell, general agent; W. B. Ross, general manager, and Geo. P. Warde, superintendent.

The Barney Ventilating Fan Company, of Boston, have just installed two 60-inch fans in the dynamo-room of the Congress street station of the Boston Electric Company, for the removal of hot air; one 48-inch fan for the same use in the station of the Fall River Electric Light Company, at Fall River, Mass.; one fan in the station of the Walworth Light and Power Company, Boston, and another in the electric light department of the J. Montgomery Sears estate, in Boston. It is a common thing to find dynamo-rooms extremely hot, and these fans are well calculated to reduce the temperature and keep a cool draught circulating all the time by the removal of hot air.

MONTREAL NOTES.

The Merchants' Telephone Co., of Montreal, has applied for incorporation with a capital of $100,000, to do a general telephone and electric business. The object of this company is to furnish a telephone service at the lowest possible rates by having a co-operative company, with the telephone users as stockholders. The experience in Canada as to other opposition companies is that they are sooner or later absorbed or bought out by the Bell Telephone Company, and in order to prevent this, in the case of the new company, each subscriber for a telephone must also subscribe for $100 of its stock and also agree to take his telephone for a period of five years. The rental of a telephone has been fixed at $25 per annum, and the stock of the company having been fully subscribed, will be increased largely. The incorporators are F. X. Moisan, L. E. Beauchamp, O. Vanier, J. E. MacDougall, J. Archambault and C. F. Beauchemin.

Canadian General Electric Co.—A meeting of the Canadian General Electric Company will be held in Montreal shortly with the object of making arrangements for the consolidation of the Edison and Thomson-Houston interests in Canada. This company was incorporated at the last session of the Canadian Parliament with a capital of $1,000,000, the incorporators being Samuel Insull, M. D. Barr, H. W. Darling, John Langton and H. M. Francis.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

Electrical Engineer.

Vol. XIV. AUGUST 24, 1892. No. 225.

DIVING FOR TREASURE AT HELL GATE.

BY

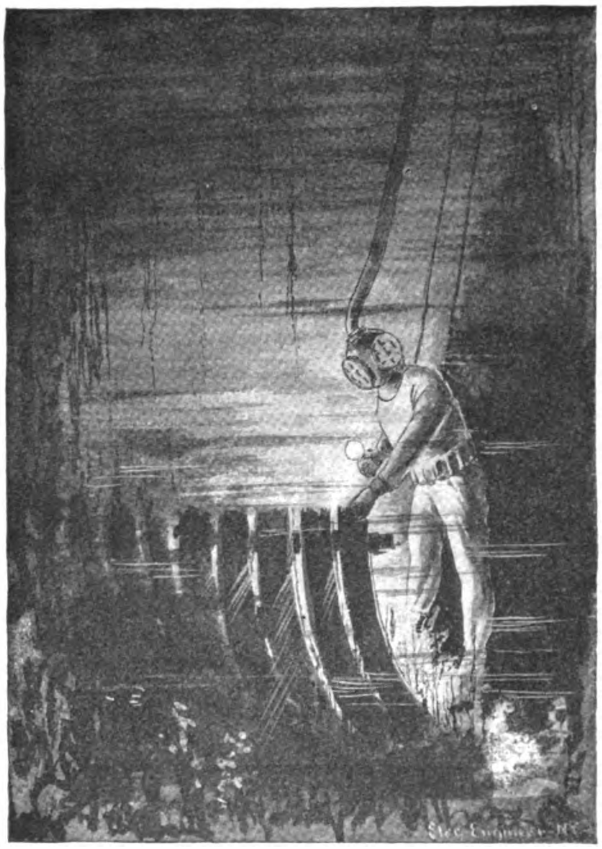
George Barton Muldaur

“*Found!*”

AT THE bottom of Hell Gate, nearly opposite Port Morris, lies all that is left of the British man-of-war, “Hussar,” together with her cargo of $4,800,000 worth of British guineas. The chains that bound seventy American prisoners to the gun deck and dragged them under when the good ship sank one hundred and twelve years ago, are probably there too, but they are empty by this time, and not being made of gold, are of no further interest. The “Hussar,” carrying the pay for the King's troops then massed in the vicinity of New London, failed in an attempt to make the Hell Gate passage, at that time infinitely worse than at present, and went down in deep water near the western, New York shore. She lies at the foot of a sheer precipice, with her hull extending diagonally into the stream, at a point where the water is now 72 feet deep at low tide; and is covered with the accumulated sand, mud, and barnacles of a century.

Several futile attempts have been made to recover the hidden treasure, the most important being that of the Worcester Hussar Wrecking Co., in 1866. By that time the wreck had become so caked with sand and barnacles that explosives were used, and numbers of historic relics, quantities of guns, balls, bullets, and flints, some jewelry and a little money were recovered. The tides and darkness proved too great a handicap, however, and the enterprise was abandoned like the rest.

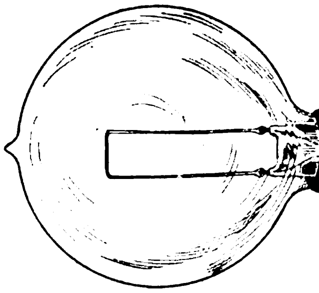
It is more than human nature can readily stand to allow so much wealth to remain long undisturbed only a few rods away. That the distance is vertical, and is more properly measured in fathoms is a mere detail, so that the advent of the Little Giant Hussar Wrecking Company prepared to make another attempt is not surprising. The company was formed by Capt. Thomas Simonds, of Leominster, Mass., whose dredging outfit has already done good service, in New England waters, and contains some points of especial interest. The dredging scow is fully equipped with the machinery usual in such cases. The engine and hoist for the dredge, and the pump operating the hydraulic cylinder which closes and opens it, take up most of the space, but the interest of an electrician is immediately attracted to the opposite end of the scow, where, on a little shelf about 12 x 18 inches in area, stands the dynamo which, more than any other piece of apparatus, gives to the present undertaking an air of novelty. The former attempts at raising the treasure were given up mainly on account of the pitchy darkness at the bottom of the river, even during the strongest daylight above, compelling the divers to work entirely by the sense of touch. But now all this has been changed.



The Electric Light at Twelve Fathoms.

At the opposite end of the scow referred to is stationed the pump used to supply air to the diver when at work. This is run by a small vertical 5 x 7 inch Atlas engine, to the fly-wheel of which is belted the dynamo, a 50-volt machine built by the Colburn Electric Company of Fitchburg, Mass., and having a capacity of eight 25 c. p. lamps. Only one Thomson-Houston 35-volt lamp of 65 c. p. is employed. This has a spherical bulb of especially heavy glass to withstand the pressure of the water, for it is used without the protection of a box, shield or cover of any kind.

When the diver is ready to descend, the small engine is set in motion, starting the air pump and dynamo, and the flexible conductor leading to the lamp is paid out with the air tube as it is needed. The conductor is fastened to the side of the helmet some three feet from the lamp, so that when not in use, or when the diver needs both hands for his work, the lamp is simply let go and floats out of the way above his head like a miniature fire balloon. When he wants it again, it is drawn down by the conductor. The socket is carefully wrapped with rubber tape to protect it from the water. The men are delighted with the simplicity and effectiveness of the arrangement, which enables them to do so much better, quicker and safer work; and it would seem that such an outfit would find general application in comparatively shallow waters, or for wrecking operations of like nature.



Lamp Without Shield or Case Used in Twelve Fathoms of Water.

UNITS AT THE BRITISH ASSOCIATION MEETING AT EDINBURGH, SCOTLAND. AUGUST, 1892.

BY

H. S. Carhart.

The committee of the British Association on electrical standards have had two long meetings at their session, and to these meetings were invited Prof. von Helmholtz, Drs. Lindeck and Kahle, of Berlin; Dr. Guilleaume, of the French Bureau at Sevre, and myself as foreign visitors. The result of these discussions was the following report:

"1. That the resistance of a specified column of mercury be adopted as the practical unit of resistance."

"2. That 14.4521 grammes of mercury in the form of a column of uniform cross-section, 106.3 cm. in height, at 0 degrees C., be the specified column."

"3. That standards in mercury or solid metals, having the same resistance as this column, be made and deposited as standards of resistance for industrial purposes."

"4. That such standards be periodically compared with each other, and also that their values be redetermined at intervals in terms of a freshly set-up mercurial column."

It was further agreed that these resolutions be communicated to the electrical standards committee of the Board of Trade.

With regard to the unit of current and of electromotive force, it was agreed that the number 0.001118 should be adopted as the number of grammes of silver deposited per second from a neutral solution of nitrate of silver by a current of one ampere, and that the value 1.434 should be the electromotive force of Clark cells at 15° C. Prof. von Helmholtz expressed his concurrence in these decisions.

The reason for not expressing the dimensions of the mercurial column in cross-section was the discrepancy between the standard kilogramme and the cubic decimetre of water at 4° C. The investigations in France and Germany show the mercurial standard to be exceedingly reliable as now constructed.

Regarding the Clark cell, the value of the E. M. F. assigned agrees with the value 0.001118 grammes of silver deposited by an ampere per second, when the cell is set up with a saturated solution in a particular specified manner. No recommendations were made as to the form of the Clark cell which is best for practical industrial purposes.

I may add that the comparisons of my own cells made with the standards kept at the Board of Trade electrical bureau by Major Cardew and Mr. Rennie agree with my own assigned value to a very gratifying degree of precision.

THE AURORA BOREALIS.

At Godthaab, in South Greenland, says the London *Electrical Review*, auroræ boreales are, of course, frequently observed phenomena, and from a lengthy series of observations which have been made on them there and elsewhere, A. W. Paulson has recently come to certain important conclusions. In temperate countries the auroræ take place in the higher regions of the air, whilst in the south of Greenland, the region in which they are produced, probably extends from high altitudes to the surface of the ground. Hypothecating, therefore, the electrical origin of the phenomena, it appears that an electric current circulates in low latitudes in the higher regions of the atmosphere, whilst in the zone proper of auroræ boreales, it descends to the surface. Doubtless, too, they are connected with the rarefaction of the air; a great difference in this property being observed in the atmosphere of arctic and temperate regions. At Godthaab, the greatest daily activity of the auroræ is at 9 p. m., and the annual maximum is about the winter solstice; there is a maximum frequency at those periods when the number of sunspots is *smallest*, and conversely. The observations which have been made appear to contradict Trombolt's law, according to which the auroral zone moves in the course of 24 hours, so that it is directed to the north.

A GREAT ELECTRIC BOULEVARD BETWEEN WASHINGTON AND BALTIMORE.

Admiral Ammen's scheme to turn the old turnpike between Washington and Baltimore into a great boulevard and to construct an electric line connecting the two cities has been revived, and there are prospects of its success. The company has its franchises and is organized with $150,000 capital, with authority to increase it to $300,000.

Widener & Elkins, the Philadelphia street car magnates, and their associates, have a controlling interest in the enterprise. The distance is about forty miles, and the expectation is that it will be a succession of suburban towns. The electric road would come into competition with the Baltimore and Ohio.

THE CHICAGO-ST. LOUIS ELECTRIC ROAD.

Work has begun on the construction of the Chicago and St. Louis Electric Railroad at Edinburgh, Christian county, Ill., and the president of the proposed new road says that the building of the road will be pushed, and that it will be in operation in a few months, as most of the right of way has been secured and much preliminary work done. The road, as surveyed, makes a bee line between St. Louis and Chicago. It will be remembered that this is the scheme of Dr. Wellington Adams as recently described by him before the New York Electric Club.

THE MODERN ELECTRIC SEARCH LIGHT.

BY

E. R. Knowles. C. E.

In a former article[1] I have given a general history of the electrical projector or search light from its earliest inception up to the present time, together with a general description of its various form and uses. In the present article I shall endeavor to give a general description of the latest and most improved form of electrical projector.

As with age comes experience and with experience comes a knowledge of the exact fitness of things, so with the electric projector. At first a very simple and crude piece of mechanism, limited in its capacity and application, it has, as time has passed, been more and more perfected and improved, its capacity has been enlarged and expanded, and its applications have become more numerous and widespread until, at the present time, it has passed the experimental stage and has become an instrument of exactness and precision, with vastly enlarged capacities, while its commercial applications have become almost innumerable.

With the experience due to this evolution from the simple to the complex has come the knowledge of the requirements of such an instrument. In general terms the modern electric projector must be capable, among other things, of filling the following conditions: It must be entirely automatic in its operation; controllably operated from a distance or operated by hand if so desired; it must give a parallel beam of light or a variable divergent beam at will as may be desired; it must be capable of revolving the beam of light horizontally in either direction or automatically back and forth over any specified arc of the horizon and also vertically up or down. In addition to this, it must be capable of varying the speed of its movements fast or slow in any direction, or of being moved by small increments of distance step by step in any direction; its lamp or source of light must be either automatic in its operation or hand controlled and capable of quick and easy adjustment; it must be light-tight, that is, no light must escape from the apparatus other than the projected beam, while at the same time it must be well ventilated so that the heat generated by the lamp may not injure the reflecting mirror. Finally, it must be arranged so that the projected beam may be alternately extinguished and made visible or "flashed," for the purpose of signaling.

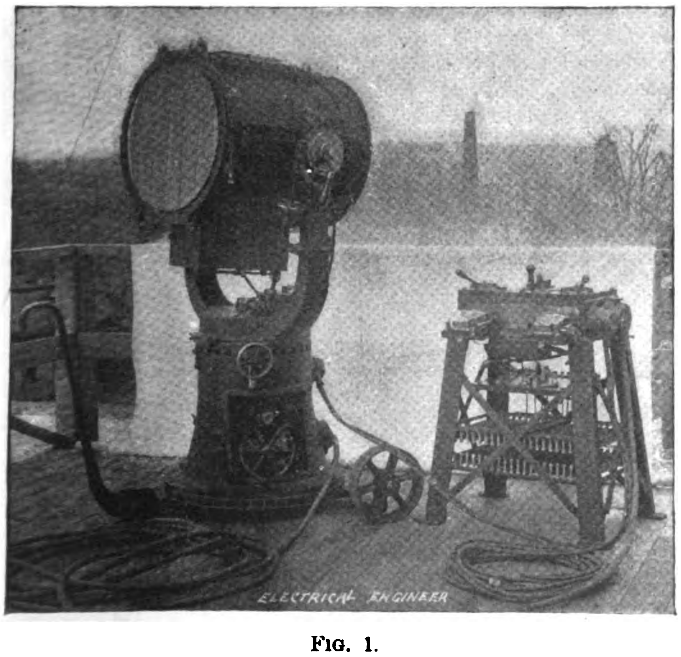


Fig. 1.

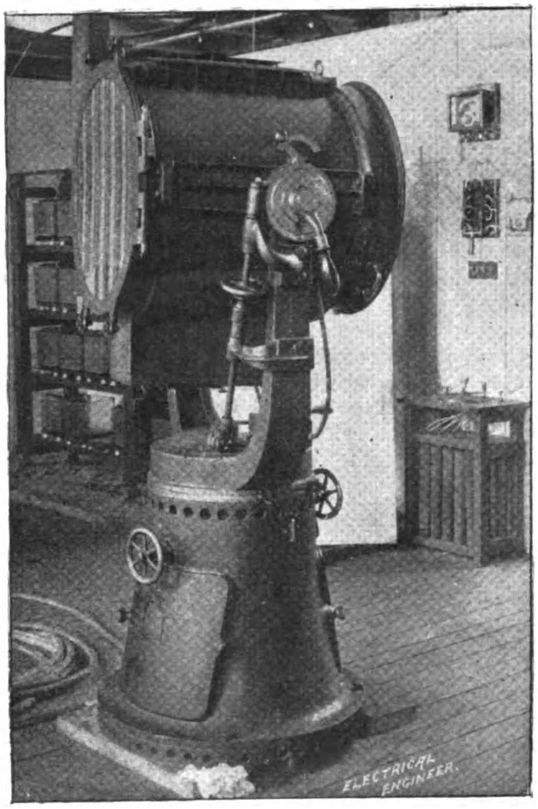

Fig. 2.

The electrical projector to be described, and illustrated in the accompanying engravings, was designed to meet these varied requirements. In Fig. 1 is shown the complete instrument, together with its control stand and electrical connections. The projector is also shown enlarged in Fig. 2, and the control stand in Fig. 3. It will be seen from the illustration, Fig. 2, that the projector is composed of three principal parts, viz., a drum suspended on trunnions at the top of a fork, which is in turn supported by a base or pedestal. The drum is made of sheet metal reinforced at each end by metal rings and strengthened along the side by girders which carry the supporting trunnions; this drum carries at one end the reflecting mirror, which in these instruments is of glass of the Mangin type, and at the other end a pair of doors, one hinged to the drum and the other capable of moving back and forth horizontally across the face of the fixed door. These two doors are each provided with a set of strip lenses, so arranged that when the movable door is at one end of its path the two sets of lenses act together to render the emergent beam of light sensibly parallel, and when at the other end the two sets of lenses act together to cause the beam of light to be spread out at a maximum angle of divergence, the angle of divergence of the beam being any desired amount between these two limits according to the relative positions of the two sets of lenses.

The top and bottom of the drum are perforated and covered by shields so arranged as to permit the entrance and egress of air but preventing the escape of light from the interior of the drum. At the bottom of the drum is provided a box in which the mechanism of the electric lamp is placed when it is in operation; this box is provided with suitable mechanism for adjusting the position of the lamp along the axis of the drum in order to bring the luminous arc into the focus of the reflecting mirror. Inside the drum a movable shield is placed in such a position that by means of a lever on the outside of the drum it can be lowered when desired, so as to cover up the luminous arc of the lamp and so shut off all light from the reflecting mirror. By giving this shield a back-and-forth movement, the light can be alternately shown and extinguished or flashed according to any set of preconcerted signals.

---

[1] See The Electrical Engineer, July 27 and August 3.

The drum is arranged to revolve vertically in bearings at the top of a fork which is pivoted to, and is capable of revolving horizontally upon, a supporting base or pedestal. Attached to one of the trunnions of the drum is suitable gearing, which passes down the side of the fork and through its base into the interior of the supporting pedestal, where it is connected to an electric motor and controlling device situated therein, which is shown in Fig. 5. This gearing is so arranged that it can either be operated by this electric control, or can be operated by hand independently, by means of suitably arranged hand wheels.

On the outer surface of the base of the fork are placed two adjustable stops, which, by the horizontal rotation of the fork, are brought into contact with and move a switch lever upon the outside of the pedestal, which acts to automatically reverse the operating of the electric control motor, and so automatically reverses the direction of the horizontal motion of the fork. These stops can be placed in any desired position so that the fork, and with it the drum, can be caused to move horizontally back and forth through any desired angle. The motor and electrical control is so arranged that it may be revolved in either direction and by means of the gearing provided, it can move the drum up or down in a vertical direction and the fork carrying the drum horizontally in either direction. The electric lamp is shown in Fig. 4, and is so arranged that it is perfectly automatic in its operation, feeding both carbons together as they consume a proportionate amount so as to maintain the luminous arc at a fixed point, or is so arranged that it may be operated and the carbons moved by hand.

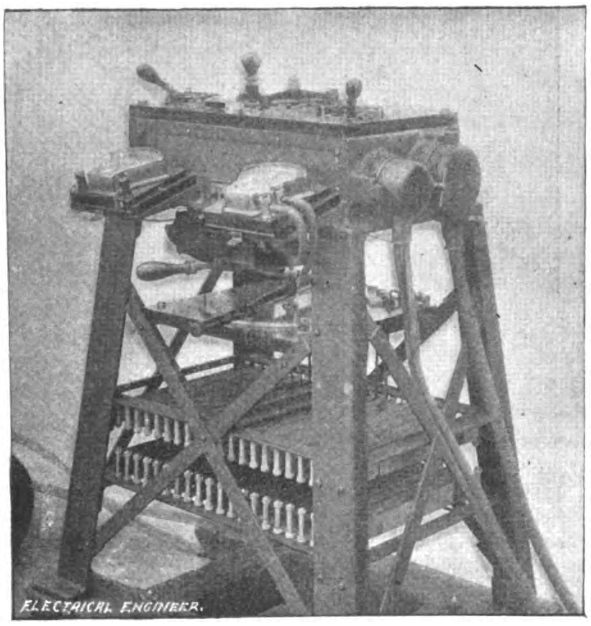

Fig. 3.

In Fig. 3 is shown the control stand, which is connected to the source of supply of the electric current and to the projector by suitable wires, and which may be situated at any distance desired from the projector. It is provided with a switch and adjustable rheostat for controlling the electric lamp, with a switch and adjustable rheostat for controlling the electric control motor, and with switches for controlling the vertical movements of the drum and the horizontal movements of the fork, and also with a switch for giving a step-by-step or slow movment in any desired direction, It is also provided with a voltmeter and ammeter for indicating the pressure of the circuit and at the terminals of the electric lamp and the current which is flowing through the apparatus. By means of this control stand, all of the required movements described may be accomplished and the electrical projector be always under control, no matter how far away it may be placed.

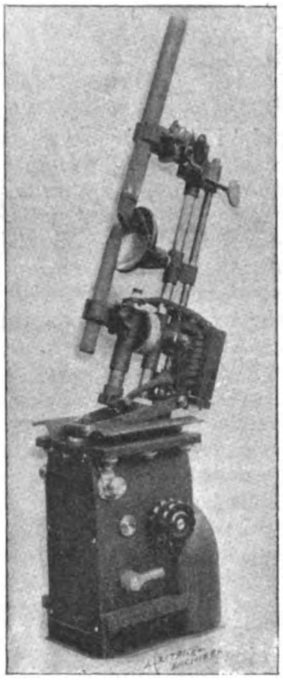

Fig 4.

These projectors are now built in various sizes, according to the diameters of the reflecting mirrors, either electrically or hand controlled, singly or together, and are provided with fixed or variable divergence to the beam or with only the non-divergent beam, as may be desired. They are solidly and durably built, of compact yet graceful form and design, and are believed to embody all the most recent improvements and as being the most powerful instruments now in use. From recent tests it is found that the 24-inch instrument is capable, on a dark night,

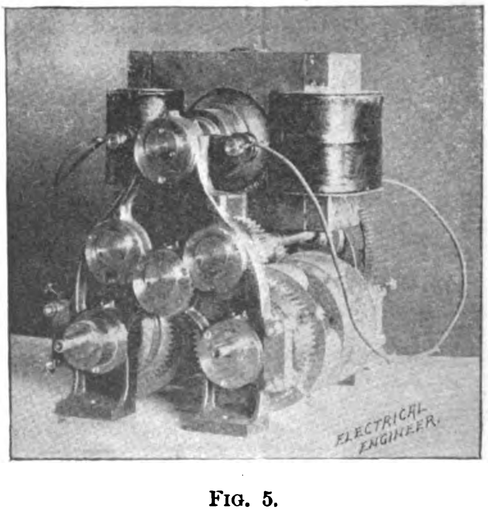

Fig. 5.

of picking up a light-colored target at a distance of 15,000 feet, the other instruments being in like proportion. Fig. 6 shows the appearance of one of these projectors when in operation. The illustration is from a photograph taken at night, and graphically depicts the appearance of the projector and its beam of light and an object in the distance which is illuminated by the projected beam.

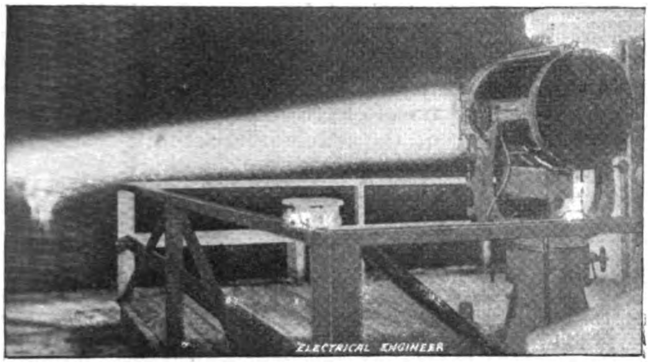

FIG. 6.

THE CENTRAL STATION OF THE CONCORD GAS LIGHT COMPANY AT CONCORD, N. H.

BY

A. C. Shaw.

MUCH interest has of late been shown in the new station of the Concord Gaslight Company, at Concord, N. H., owing to the fact of its being the first central station in this vicinity in which all the dynamos are driven by the "L. P. and D.," transmitters manufactured by Perry and Demeritt, of Montpelier, Vt. The Concord Gaslight Company commenced business about six years ago with about 15 Thomson-Houston arc lights in a small basement, and increased by gradual stages, in much the same way as other New England central stations that I have described in these columns, until they had about a year ago four Thomson-Houston 50-light arc dynamos in full service. As the business kept increasing, and the demand for incandescent light became pressing, a new station was rendered necessary, where economical power could be procured, and where the capacity could be increased when required.

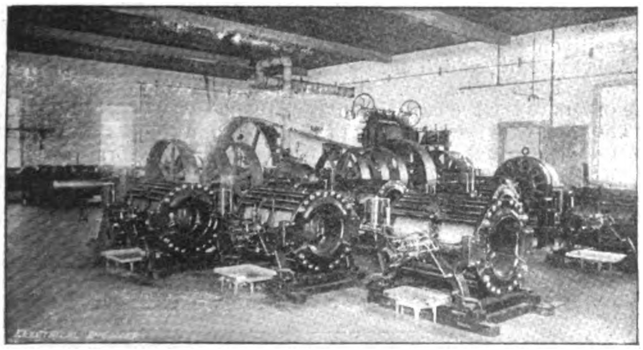

FIG. 1.—CONCORD CENTRAL STATION.

The site of the station is about 500 feet from the Merrimac River, though, unfortunately, owing to the water being impregnated with a fine sand, it is impossible to pump it for condensing purposes. The boiler-room is 45 feet by 32 feet, one story high, and contains two three-sheet steel boilers 72 inches diameter by 16 feet long, manufactured by the Bigelow Company of New Haven, and fitted with Sydney Smith setting. In the boiler-room also are a 300 h. p. Jacobs feed-water heater and a Spencer damper regulator. The engine-room is 45 feet by 65 feet, and is one story and a half high, the upper room being used as a storeroom. The engine is of the Reynolds-Corliss high pressure type, built by E. P. Allis & Co. of Milwaukee, Wis., with single cylinder 18x42 inches, making 84 revolutions per minute, and working at 100 pounds pressure. The fly-wheel is 12 feet in diameter, with a 27-inch face, and belts direct onto the countershaft, which runs across the entire length of the room, the belt running under a belt tightener manufactured by the Holyoke Machine Company, of Worcester. The shafting is 5 inches in diameter, with a 54-inch driving pulley on the engine end, and having one Hunter friction clutch in the middle of the shaft. The whole was supplied by H. N. Bates & Company, of Boston. The section of the shaft nearest to the engine carries three 54-inch pulleys with 9-inch face, which drive three 50-light Thomson-Houston arc dynamos used for the city lighting. On this section also is a 72-inch pulley with a 13-inch face driving a 1,350 light Thomson-Houston alternating incandescent dynamo at a speed of 1,070 revolutions per minute. The other section of the shaft also carries three 54-inch pulleys which drive three 50-light Thomson-Houston arc dynamos for commercial lighting.

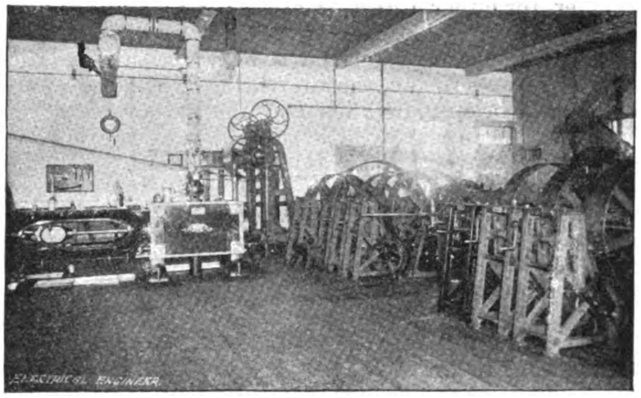

FIG. 2.—CONCORD CENTRAL STATION.

As the "L. P. and D." system is quite novel for central station work, and one of the strongest claims which can be made for it is the saving in floor space, a few details as to the dimensions of the area occupied by the shafting, dynamos and transmitters will be found interesting. The three pulleys are set on the shaft 22 inches apart, measuring from the centres of the face. The dynamos are arranged one behind the other, as shown in Fig. 1, their centre lines being also 22 inches from each other. The distance from the centre of the shaft to the centre of the pulley of the nearest dynamo is 4 feet 8 inches, and the one dynamo stands 5 feet 6 inches behind the other, measuring between the pulley centres.

Leaving out of consideration the incandescent dynamo, as it is an odd feature in the arrangement, the six arc machines are thus arranged in two groups of three, each group being driven from different sections of the shaft. Each group of three dynamos stands in an area measuring 15 feet by 7 feet, and the six dynamos occupy an area of 15 feet by 21 feet 3 inches. The six dynamos, together with the shafting, clutches, floor stands, and six "L. P. & D." transmitters, the details of which have already been described in THE ELECTRICAL ENGINEER, occupy a space of only

22 feet 4 inches, by 21 feet 3 inches. Each dynamo is driven by a separate transmitter so that it can be started or stopped at will, not interfering in the least with the action of the others. The station has been running since March of this year, and this system of driving has given perfect satisfaction, and is greatly appreciated by the electrician and engineer, there being perfect regularity in the speed and no slip. When the alternator is started and the potential determined, the speed is so steady that it is unnecessary to touch the rheostat again for the rest of the evening. An 8½ inch belt is used for transmitting the power to the arc dynamos, and a 12½ inch belt for the alternating dynamo.

The arc light switchboard, built by the Wright Electical Engineering Company, of Boston, is made of slate and iron, divided into two horizontal sections. The top section is fitted with lightning arresters, below which is a row of spring jacks on each side of the circuit, so arranged that the lightest circuit can be arranged for lighting the station. On the lower section are the machine terminals, the wires to which are all carried on porcelain insulators below the floor. The station is wired throughout with Okonite, as much as three miles of wire being used. The alternating switchboard is of the skeleton type, made of ash, filled and varnished, and fitted with four double-pole double-throw switches, for use when two dynamos are in service, to prevent the current from the one entering the other. The board is long enough for two machines and is fitted with the usual Thomson-Houston current indicators and voltmeters, in addition to which a standard Weston voltmeter for either direct or alternating circuits is used.

The building is of brick with Concord granite foundations. The engine stands on a heavy brick foundation with granite underneath, the alternating dynamo being also situated on a brick foundation and the anchor bolts held down by cast iron plates. The shafting runs on brick piers with iron plates resting on granite foundations. The floor is of Georgia pine oiled, resting on hard pine stringers. The roof is of wood covered with tin and slate, and is of the same construction both in the engine and boiler rooms. On the roof of the boiler-room is a steam whistle, with an eight-inch gong attached to a two-inch steam pipe, for calling the attention of the lamp trimmers when required, who respond by going to the nearest telephone. The trimmer who attends to the lamps is provided with a safety bicycle, fitted with a leather bag for carrying the carbons. All carbons taken from the lamps are taken back to the station and the short lengths jointed together by the M. P. Stevens patented process and used again in the lamps.

The Concord Gas Light Company was incororporated in 1852, and has now a capital of $125,000. The Hon. John Kimball is president and treasurer of the company and W. A. Richmond, superintendent and electrician, all of the electrical work having been designed by him and carried out under his instructions.

SENSITIVE WATERFALLS.

BY

Edwin J. Houston

I HAVE been much interested in a note by Prof. W. B. Croft in *Nature*, quoted in the issue of THE ELECTRICAL ENGINEER of July 27. In this note reference is made to the phenomenon of a water jet that responded to the running of a small Wimshurst electrostatic induction machine at a distance of some 13 feet.

Unfortunately I am out of the city at present and having no access to Prof. Croft's note, cannot intelligently discuss the conditions of the problem. Timed electrostatic discharges could readily cause the disturbances referred to and so also could a musical note of a definite pitch. I do not exactly understand the reference to similar phenomena being produced by the presence of the electrified rod, unless it is a phase of Faraday's experiment with a liquid jet.

I make this brief communication, however, for the purpose of referring to some observation made by me in 1872, and published in the *Journal of the Franklin Institute* for October, 1872. These experiments would appear to show that the phenomena referred to by Prof. Croft might have been caused by sympathetic sound-waves; or, as I have already hinted, by timed electrostatic discharges.

Below is a copy of the article referred to:

A SENSITIVE WATERFALL.

By Prof. Edwin J. Houston.

The recent developments of acoustics have been rich in their revelation of the wide-spread influence exerted by sound-waves, in shaping and moulding matter when in a condition to easily allow the movement of its particles. The eye as well as the ear can now be appealed to to detect the presence of these invisible waves. At their touch, light sand strewn over tense membranes is heaped up in miniature hills, with even greater precision and regularity than by the grosser waves by the seashore, the number and order of the hills, together with the relative size of their interlying valleys, not only witnessing the work of the sound-waves, but also indicating their exact nature and number. Water jets, gas jets, smoke jets and flames of most all gases are also, under favorable circumstances, likewise affected, changing their shape, size, duration and general appearance in the most curious manner. So delicate, indeed, are some of these methods, that waves too feeble to allow of translation by the ear into sound are instantly appreciated by the eye as motion.

There are many different ways in which sound-waves can thus reveal their presence to the eye; we have sensitive flames, both covered and naked, smoky and clear, silent and noisy; we have sensitive jets of gas, water and smoke, and many other instances of this kind of sensitiveness that will recur to the student of physics. I propose to add another, of quite a novel character to the already lengthened list.

While spending a summer's vacation in Pike County, Pa., I had the good fortune to discover the sensitiveness of water to sound-waves on a large scale. Among the many beautiful waterfalls in this portion of our State I visited one in which a scanty supply of water was dripping from the moss-covered walls of a precipice. Each stream poured from the end of a pendant of moss, formed generally of one or two tiny leaflets. The air was unusually still, and the streams presented for some distance a vein remarkably free from ventral segments. Struck by this circumstance, it occurred to me to try the sensitiveness of these streams to the notes of the voice, and after several attempts I found a tone, a shrill falsetto, to which they would respond. On sounding this note the grouping of the drops and the positions of the ventral segments were instantly changed. As the streams were of different diameter, they were not all sensitive to the same note; but at one portion of the falls, from which about one hundred of these thin, delicate streams were dripping, a very large number of them responded. A friend who was with me, a gentleman of nice powers of observation, witnessed the same phenomenon.

I was unable to determine the exact conditions of success, but am satisfied that they are not easily obtained, as at several other falls, where the streams appeared nearly of the same character, none were found that would respond to the voice, although a variety of different tones were tried. At one falls, however, a number of streams were found that were almost equal to the first in sensitiveness.

A heavy rain, which flooded the stream, prevented me from renewing the observation. The publication of the facts will enable others to try the experiments for themselves.

The change in the grouping of the drops and the position of the ventral segments is, no doubt, to be ascribed to a vibration communicated by the sound-waves to the delicate filaments of moss from which the water flows. These act somewhat in the manner of reeds, and simulate the orifice of the ordinary sensitive jet, by whose vibrations the appearance of the issuing stream is altered.

The falls at which the observation was first made are situated on Adams' Brook, near Dingman's Ferry, about two and one-half miles up stream from the stage road leading to Milford, Pa.

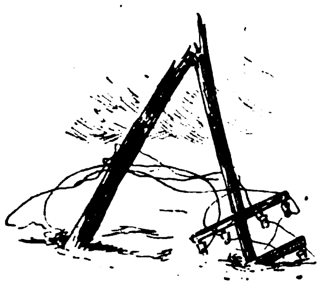
ELECTRICITY AND PROGRESS.

OUR CORRESPONDENT at Troy, N. Y., writes us: "It is constantly impressed upon every one here that the motor cars passing through a neighborhood, have the peculiar affect of brightening up the surrounding property by causing houses to be repainted, sidewalks relaid, and what might be called putting a new face on the whole matter. Great is progress; and electricity is at the bottom of it."

PERMANENCY AN IMPORTANT FACTOR IN ELECTRICAL WORK.

BY

Geo. Harris



A WORD that the writer would strike out of the language forever, so far as it relates to electrical work, is that often-used one, "Temporary." Where is there among the vast army of electrical workers one who has not heard this and kindred expressions, "Never mind, its only temporary" and "We can't afford to spend much time or money as it is only temporary" and who is there that has not seen the resultant disastrous effects of such blindness to the real truth? The synonym of "temporary" should be carelessness, incompetency and consequent loss, as they are the causes that lead to such a careless disregard of all the well-established rules of good workmanship.

It has been my good fortune to visit three-fourths of the various countries on this globe always taking an active interest in the many fields of applied electricity. I have been a close observer, but I am not alone in it; others have noticed it like myself and have commented on the only too general lack, chiefly in America, of the stability and the permanency which should be *the* important factors in electrical installations of whatever character. True, there is a gradual awakening on these lines and with the advent of the electrical engineer comes safe, permanent work in every department.

Up to within a short time, no class of electrical workers were more prone to substitute temporary work for that which should be permanent than telephone employees. This was caused in part by the ever-shifting character of the work, and the army of men that was necessarily employed, who happily have been weeded out until only the bright members of the flock remain. Troubles were of a consequence in the ascendency and the sole object of every man was to remove them, no matter if they did come in again a few days afterwards. The ways for clearing trouble were many and varied. If the line was grounded and the trouble was found to be caused by the wire dropping down on an awning or iron front, how easy it was to tighten it by taking a few turns around the insulator, or worse still by crimping it zigzag fashion with your pliers. Of course if the manager discovered it (and he rarely did so) your excuse was, "That it was only temporary," or that you had fogotten your vise and strap or that the line would have to be changed. The next man that came along knocked the wire off the insulator or else the strain gradually straightened out the kinks until the same old "ground" came in again, only to be repaired in the same manner. If your line was found open, how much easier (!) it was to cut in a new line and change it in the exchange than it was to trace out the trouble and fix it. Of course you didn't intend to leave it that way. As soon as you got the chance you would hunt it. *The time never came.* If the gas meter was taken away from the building leaving the line open, the quickest way to close it was to connect the pipes together temporarily until you could run a new "ground" to the street pipe. The new ground was never run unless the thing got tired of working through red lead joints and kicked; and then it had to be put in good shape. If you found that the transmitter battery had given out in disgust and actually eaten itself up through want of attention, you were dismayed to find that you had forgotten to bring an extra zinc with you, but by filling the jar full and pushing the zinc farther down you would be able to talk and be satisfied in your own mind that it was all right. You would come by there "to-morrow" and put in a new zinc. The "to-morrow" is still coming. If the cord was broken it was *so* easy to use a couple of pieces of office wire until a new cord could be procured—generally several days afterwards, and not perhaps even then, unless the subscriber "kicked" or the wires broke off. Then you would remember your former visit and go loaded.

These are not exaggerated cases, as any man that has been any length of time in the telephone business knows. You fully intended to go back and fix things up as they should be, but somehow or other you never got the chance to go.

Though I have not been actively engaged in telephone work in some time, except at intervals, I have kept myself familiar with its progress and I am glad to note a general tendency towards permanent work both inside and out. The advent of the Long-Distance Telephone and the splendid construction of that company has done much to stimulate matters in this direction, together with the fact that the companies themselves have begun to see the necessity of keeping the "Maintenance Account" within the rental account at least. With many companies it exceeded the receipts. The multitude of inventions in this direction has done away with many troubles, and their consequent removals have been reduced to a minimum.

With something like the ardor of the moth attracted to the candle, the army of employees of the electric lighting companies were recruited from the telephone companies, and the same methods were carried out until the height of bad workmanship was reached.

In electric lighting the necessity for *permanency* is even a greater factor than in telephony. With valuable property at the mercy of every installation contained therein, permanency and safety go hand in hand. Electrical engineering has made wonderful strides in this direction as well as in every other, as safe and permanent work is good engineering, no matter in what direction it tends; but there is yet an immense amount of progress to be made before perfection will be reached, if ever. How many stations we find that are actually a disgrace to the profession, if the persons in charge can be classed as being members of the profession. The sole object of such stations, or more properly speaking of those in charge, seems to be the grinding out of current and the collection of the bills, and the manner in which the former is accomplished would cause a good station manager to hold up his hands in holy horror. Every element of safety, permanency and good workmanship is cast to the four winds. Wires run in all directions, switchboards and their expensive apparatus are exposed to leaking sky lights or roofs; no other flooring but Mother Earth, no protection to employees, etc. I have in my mind one station not far from Dallas, Tex., that was operated under just such conditions as these until as a natural result it depreciated itself and was sold out under a deed of trust bringing scarcely the original price of any one of the dynamos. No fault could be found with the apparatus. It was simply the manner in which it was installed and afterwards maintained. The plant consisted of six arc and one incandescent dynamo, with two street arc circuits, two commercial arc circuits and the incandescent circuit. At first each circuit had its particular dynamo, but as the plant grew and changes became necessary, some one conceived the brilliant idea that all of the arc dynamos could be run in series—a very wise plan but one needing perfect insulation throughout the entire installation. A switchboard of wood was constructed and equipped with a number of single-strap arc switches, so connected that various portions of the circuits could be cut off as lights were turned off. This worked surprisingly well, but with this current of about 4,000 volts and 20 amperes there was fun. Was everything perfectly insulated and carefully handled? By no means. The switchboard was placed directly beneath a skylight, which was always left open for ventilation, and, as a result, the board was drenched every rainstorm. It was built of white pine. It soon became thoroughly soaked. It was wired up with Underwriters' wire, insulated with *soft-rubber tubing!* A pleasing combination. Did any accidents occur therefrom the reader will ask? No, none serious, but they were only prevented by enclosing the board with a railing and throwing all of the responsibility upon one man, the engineer, who was also dynamo man, and fireman as well, at times. But he was one of those rare beings whom an all-wise Providence watches over. After receiving several doses of the *fluid*, he, forever afterwards, threw those switches with about 18 inches of good insulation between them, composed of a water gauge glass, *well dried.* But there were displays of the electric arc in its native state that were beautiful to behold. There were 12 switches to throw, and, consequently, more combinations than a bank vault lock ever dared have. If he forgot the combinations or broke his glass before all the switches were over it was all right. Flying belts, arcs running up or down the switchboard, burning armatures, etc., had no terrors for him. He smiled, Nero like, through it all, and straightened things out as soon as he got around to them. That he was not killed was because he was reserved for a better or worse fate, as he has since become an inmate of one of the State penitentiaries.

The same state of things was prevalent throughout the whole system with its Underwriter's wire, poor porcelain knobs, soft-rubber tubing, and the various other elements of danger. The result was only too well assured. Eighteen fires were caused during the existence of the plant, fires that were traced directly to poor insulation, some of the arc circuits being of *paraffined cotton-covered wire* and cleated at that.

What is true of the plant in question is true of many plants in operation to-day throughout the country, both arc and incandescent. Arc loops left hanging with simply the ends twisted together; wires left hanging loosely on top of lamps; loose connections in hanger-boards and switches, etc., are common. It seems to be the sole object in life of some electric light workman to use any means possible but the right ones to keep the lights burning well, at the cost of safety to themselves, the company's interests and the property that is unfortunute enough to be at their mercy. I know of one case in particular where a lineman sent to remove the lamp closed the circuit (22 amperes) with a piece of No. 14 B. & S. *office wire* and allowed it to remain so for weeks simply because it was too much trouble to close up the loop in a proper manner; and he *expected* that the lamp would be put in again in a *few* days. It was not put in for some weeks, and when found the wire was thoroughly annealed and the insulation charred. Strange to say he was not discharged. As in arc work, so is it in incandescent and motor work. Numerous cases have come under my observation that were equally as "temporary" and unsafe in their character. The substitution of copper wire and in some cases iron baling wire (fact) for an overloaded fuse that persisted in blowing is a pernicious habit but one that is indulged in to an alarming extent. The connecting up of circuits around the fuse; the absence of fuses entirely; the overloading of circuits; the removing of "grounds," or short circuits by *burning* them off as is often done, and a thousand other subterfuges for the "temporary" removal of troubles, are noted methods that in the end only increase the same troubles and add others to the general confusion.

Any electrical workman who has the habit of repairing any defect in a "*temporary*" manner should be forever black-listed.

Are matters being remedied? Yes, to a great extent by the employment of competent electrical engineers for the construction of the plants and their subsequent management if possible. But if not, the management of the electrical department should be given over to a first-class man of known ability and a competent force of assistants. To him and him only should be intrusted the maintenance of the life-producing part of the concern. But it is a well-known fact that in spite of all the knowledge obtainable on the subject and all the free advice given, the management of one half of the plants throughout the country is vested in either a favorite relative without the least knowledge of the subject-matter, or what is worse still, in the local amateur electrician. Owners of electric plants wonder why insurance companies are loath to take the risk even at a higher premium. Can *they* wonder when the insurance inspectors with a far-seeing eye to such matters readily recognize the gross incompetency of those in charge and their utter inability to bring order out of chaos. Who *can* blame them? I am glad to see an earnest disposition on the part of all the well-known manufacturers of electrical apparatus to *insist* on the installation of their apparatus in a first-class, workmanlike and consequently *safe* manner either by their own trusted engineers or other equally competent. Such a disposition cannot fail to show its effects in a short time, and with the earnest co-operation on the part of manufacturers, engineers, owners and employees, no one need blush for shame when it is known whose apparatus is installed, who installed it, and who owns and manages it. Let the word "temporary" be forever banished from the electrical dictionary of every electrical worker, and be banned by every conscientious and painstaking member of the fraternity. Let it be relegated to the past, that unhappy past so fraught with vicissitudes and disasters, and strewn with the wrecks of incompetency, carelessness, and "temporary work."

ELECTRIC STORM PHENOMENA.

BY

W. Finn

THE magnetic storm which occurred on Friday, August 12th, was even more remarkable in point of intensity and for the wide range of territory disturbed than that of its immediate predecessor of July 16th last. It differed from the previous disturbance in being of shorter duration, but in other respects there were many points of similarity observed.

It was about 12.30 p. m. that the storm struck the wires with force enough to overpower the regular working currents, though premonitory warnings of its approach had been noted both on cable and aerial lines for several hours previous, as was the case on the former occasion. The storm had practically disappeared by 5 p. m., but during the interval it succeeded in prostrating more circuits at any given time than has been noticed on any previous occasion.

The height of the disturbance was apparently between 1.45 p. m. and 2.01 p. m., during which time a record was secured of some of the highest values of both pressure and current strength ever noted. These were obtained on wires between New York and Buffalo, the measurements being made from each end of the wires.

Although the area of maximum intensity was found between those two points, the singular fact was noticed, that one of the New York-Chicago circuits via Buffalo, over the Delaware, Lackawanna and Western Railroad was comparatively free from interruption during the whole of the disturbance. The explanation of the anomaly is probably to be found in the assumption that the route of this particular wire formed part of an equipotential surface over which, of course, no natural currents would flow.

Some earth current values taken by means of a tangent galvanometer at the New York end of a Buffalo wire measuring 2,280 ohms are as follows:

Time of observation.	Current strength.	E. M. F. developed.
1.46 p. m.	52.8 milliamperes.	120.3 volts.
1.47 "	285.4 "	650.7 "
1.48 "	281.5 "	641.8 "
1.49 "	29.3 "	66.8 "
1.50 "	91.9 "	209.5 "
1.51 "	2.1 "	4.7 "
1.52 "	20.6 "	45.9 "
1.53 "	31.5 "	71.8 "
1.54 "	80.0 "	182.4 "
1.55 "	264.0 "	601.9 "

The following are some milliammeter measurements taken in Buffalo over another New York wire measuring 3,200 ohms.

Time of observation.	Current strength.	E. M. F. developed.
1.40 p m.	190 milliamperes.	608 volts.
1.47 "	100 "	320 "
1.57 "	80 "	256 "
1.58 "	90 "	288 "
1.59 "	95 "	304 "
2.01 "	240 "	768 "
2.01½ "	105 "	336 "
2.05 "	55 "	176 "
2.05½ "	70 "	224 "
2.06 "	50 "	160 "
2.06½ "	110 "	352 "
2.07 "	70 "	224 "

Other observations taken in Buffalo at 2.30 p. m, over a wire between New York and Chicago, show a difference of potential of 297 volts on the western section, and 352 volts on the eastern section of the wire. Mr. Frank Kitton, the careful and accomplished electrician who made the above tests, remarked this distinction in every measurement taken, although the western section is the longer of the two.

He also noted the following curious effects upon two parallel wires, one terminating in Cleveland and the other in Chicago over which simultaneous observations were made at 2.15 p. m:

Chicago........	+ 50	+ 25	+ 75	+ 90
Cleveland.......	0	— 25	+ 25	+ 40

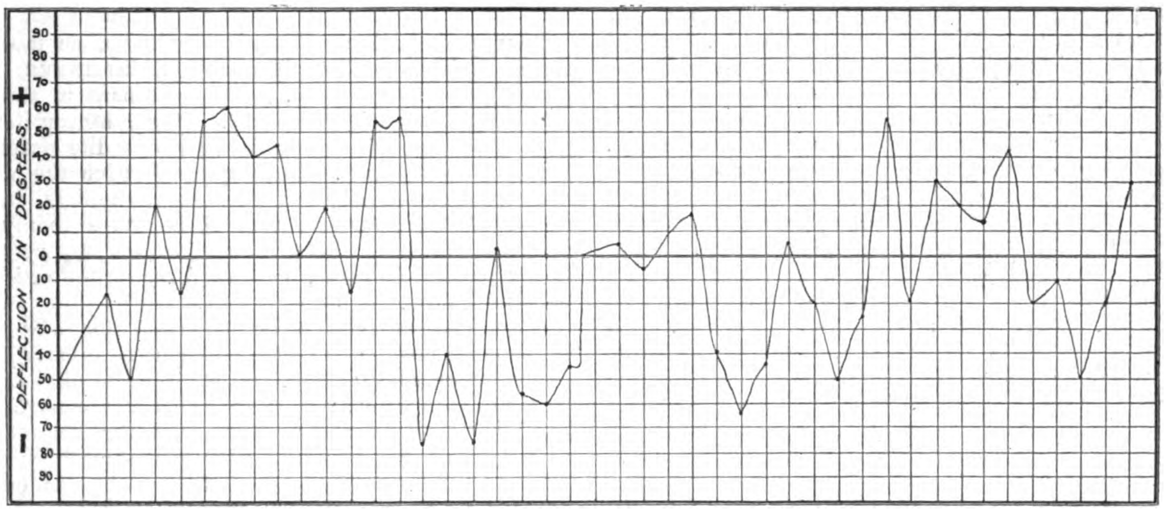
that is to say, a difference of 50 degrees was found to exist every time between the two sets of deflections.

An unusual circumstance connected with the recent storm consists in the fact that the forces completely changed their direction about 2.20 p. m. from the usual easterly and westerly line of flow to that of north and south, so that while circuits running in the latter direction were generally prostrated, those running at right angles could be operated with more or less success. Similar results were noted at Chicago and Richmond, Va., both of which points made tests about that time on some wires extending north and south, and which showed a range in the electromotive forces of from 50 to 340 volts.

Advices from all sources generally agree as to the time of commencement and cessation of the storm, and the characteristics of the earth currents as described by many of the observers correspond as a rule with the observations of the writer.

Some idea of the fluctuating value and reversibility of the current may be gathered from the accompanying illustration, which is a graphical representation of some readings taken on a tangent galvanometer over a Western wire between 1.49 p. m. and 1.54 p. m. The galvanometer has a "constant" of 24 degrees and was provided with a $\frac{1}{10}$ shunt so that the deflections shown, really represent but a tenth part of the actual current strength, the maximum value of which is as tan. 24 degrees: tan. 75 degrees or

$$\frac{3.732}{.4452} \times 10 = 83.8 \text{ milliamperes.}$$



Observations of Earth Current Fluctuations on a New York-Buffalo Circuit During the Electric Storm of August 12.—1.49 to 1.54 p. m.

The undulatory character of the current is quite apparent in the reproduction, from which it is possible to form a conception of the length of the waves during the time of observation.

The distances between the vertical lines do not however represent equal divisions of time in this case, but rather the beginning and end of the different electrical impulses, some of which were long and gradual in their motions, while others were either the very reverse, or of some intermediate grade.

The most interesting and important point associated with the recent storm is the evident relation it bears to the sun spot discovered July 16, which has been credited with all the trouble and inconvenience produced on telegraph lines on that day, besides being saddled with the responsibility for the more serious consequences arising from volcanic, seismic, meteorologic and other disturbances.

The period of revolution of the sun on its axis is about 27 days, which is just the interval that has elapsed since the previous magnetic storm, from which it may be reasonably inferred that the same sun spot was concerned in the production of both phenomena.

It is the first time, however within the experience or knowledge of the writer that the magnitude of the original forces has ever been surpassed by the recurrent phenomena, which have heretofore been either much less intense or altogether without effect upon the practical working of circuits.

WHAT SHOULD BE OUR FUNDAMENTAL UNITS?[1]

BY

Brown Ayres

Our modern systems of units are based upon the assumption of three fundamental quantities, a unit of length, one of mass, and one of time, and on these our whole system of measurement is built up. This is satisfactory as far as it goes, but there are some philosophical objections to it that are worth considering. We have a conception, that of energy, that is daily playing a larger and larger part in our physical reasoning, and the assumption is made that energy is an entity, indestructible and uncreatable in the ordinary processes of nature. Its *reality* is assumed as positive. Yet the best definition that we seem able to give of it is "the capacity to do work." To the question "What is work?" our answer is "the overcoming of resistance through distance," or "the product of a force into distance." And force? "That which applied to mass in time produces motion." And motion involves space and time, and in the sense here used, mass. In this way this real entity, more real to us than matter, as many claim, is only expressible and measurable in terms of units the very nature of which are in dispute. Would it not be better to take for one of the fundamental units a definite quantity of energy, say that liberated as heat by the combustion of so many atoms of carbon in burning to CO_2, and work backwards to our notions of force, and mass, or space, or time. In the language of the mathematicians, we have four related quantities, and the laws of their connection are such that three are sufficient to express all known conditions. The question is, then, which shall we choose?

The present system, under which we choose mass, space and time as fundamental, lends itself to the perpetuation of many confusions and complexities of expressions. For example, there is great confusion in the use of the word "force," it being continually confused with "stress," with which it is connected as weight is with mass, but between which there is no absolutely necessary numerical relationship, aside from experiment. If energy were a unit, the dyne (or the corresponding unit) would be defined as that rate of energy transference or transformation under which one erg (or the corresponding unit) would be transferred per unit space passed through. That is

$$\frac{dE}{ds} = \frac{d(\frac{1}{2}mv^2)}{ds} = m\frac{d^2s}{dt^2} = F$$

When there was no space moved through, or when the velocity was uniform, there would be no added energy and hence no force, although the pull or push—the stress—would continue. The notion we associate with the word stress is not that of a stress but of a force, that is of the rate of energy transformation in the tissues of the muscles, since it is by this only are we able to exert a stress on our tendons and hence resist a stress from, say, the attraction of the earth. The nature of a stress is unknown, and in the nature of the case it is unthinkable. It cannot be expressed in any absolute system, except by identifiction with the force to which it would give rise if motion were to take place. The use of energy as one unit would make the distinction clear and simplify the expression of many physical laws, notably the laws of motion. With energy as a unit, force would be defined as the space rate of variation of energy, power (or activity) as the time rate of variation of energy, and mass would be treated simply as the constant necessary to be introduced to make the laws of kinematics applicable to the motions of actual nature. A change of this kind would involve changes in the definition of many derived units, but it would be worth the trouble. The theory of the potential is a partial realization of the idea here suggested and will serve to give some notion of the improvement that would result.

A REPLY TO ENGLISH REMARKS ON RAILWAY POWER PLANTS.

BY

Wm Lee Church

I am glad to have attention called once more to my recent articles in The Electrical Engineer on power plants for electric roads, by the comment in the London *Electrical Review*[1] of July 22. It is a strong item in the general scheme of better intelligence on the practical subject of power plants. I can quite forgive the writer for his good-natured slant at past short-comings, in view of the excellent endorsement which he gives to my general recommendations. I shall ask space for a very brief running comment on same, lest the force of the article should be misdirected.

The *Review* needs to be instructed that a high rate of water consumption is now no longer an invariable accompaniment of a light load, and his remark that under fluctuating loads the "average rate of steam consumption per horse power is necessarily high and the boilers must be proportioned to give steam for this same high rate," no longer applies. As a matter of fact, the non-condensing compound engine will cover its entire range of power at an expenditure of steam lying between 23 and 29 pounds; the latter of course for the light loads. Heretofore the range would be from 26 to anywhere between 40 to 50 pounds, which fact only being known to the *Review*, leads to the remark above quoted. This point has been fully considered in my recommendations of the proportion of 60 h. p. of boilers to 100 h. p. of generators in a railway station, and it will be found that the 60 h. p. of boiler capacity will amply take care of the maximum as well as the average rate of consumption due to the variations of load.

The same misconception of the "state of the art" leads the *Review* to suggest that some mechanical device may be developed which would enable the speed of the engine to be augmented as the power increased without augmenting the speed of the dynamo. It think it beats even our boasted Yankee ingenuity to see a decent way to accomplish this. We submit that it is much more sensible to attack the problem from the other end and work out an engine which shall be insensible in its economy to variations of load, and thereby go direct to the point desired. The *Review* may at once dismiss from its mind any modification or mechanical devices to meet excessive fluctuations of steam consumption, and may deal with the problem as one of practical uniformity.

With reference to the question of condensing, I have only to say, that for years I have steadfastly refused to consider the condenser as a part of the power. In other words, I would proportion the engine so as to be adequate to the maximum load without the help of the condenser, and treat the condenser only as a device to secure additional economy. This is at least on the safe side, and brings with it no drawback.

---

[1] See page 175 of this issue.

In view of the foregoing paragraph, the question of how close a margin we should work to in the capacity of the engine itself, would depend of course upon the nature of the service to be performed, whether continuous, or subject to extreme fluctuations. I am quite inclined to coincide with the *Review* that in railway work, "the engine capacity should be such as to just overcome the maximum load with steam carried full stroke (?) in the cylinders." The only trouble is, that in said railway work, I have never yet been able to find out what the maximum load is, but I am always willing to work my engine up to the utmost extension of its valve motion, whether condensing or otherwise, to meet the extreme of load, whatever it may be.

It is true that the greatest extremes are to be found in the smaller stations, of which my articles are now treating, but engineers must not for a moment be deceived into thinking that a large station implies anything like a uniform load, as understood in mill work. Beautiful evidence of this fact is to be found in a recent issue of THE ELECTRICAL ENGINEER, in the report of Messrs. Shepardson and Burch on sundry tests in the Minneapolis Street Railway power station. In this station the load was seen to almost constantly fluctuate between 1,000 and 1,400 h. p., with occasionally spurts to nearly 1,800 h. p., a degree of fluctuation fatal to the economy of any type of engine as ordinarily designed.

POINTS IN POWER STATIONS.[1]

IN THE ELECTRICAL ENGINEER of July 6, Mr. Lee Church has some correspondence on the above subject, and with much of what he has to say it is not difficult to agree. On one point, especially, he is very much in the right, and that is the proportion of boiler power necessary. When Mr. Church confesses that he is a steam engineer, and yet boldly confesses also that he did not foresee any better arrangement than to put four boilers each of 60 h. p. capacity to drive two engines of 100 h. p. each maximum capacity, in an electric railroad power station, we admire his pluck and despise his judgment, for he did not see the folly of it until he found that two boilers would do all the work easily. If some electrical engineers had their own way, they would use boilers holding about a tenth the proper quantity of water, in utter disregard of the fact which Mr. Church sees now so plainly, that the steam boilers of a station merely require to be large enough to turn out steam at the *average* rate of daily consumption, but that the engines must be big enough to give the maximum power requred, even if they carry steam full stroke to do it. Of course, the average rate of steam consumption per horsepower is necessarily high, and the boilers must be proportioned to give steam for this same high rate, but not for more than this; for with a proper water capacity, the inertia of a steam boiler is large, and will enable it to yield steam to carry on over high points in the energy diagram, and absorb heat from the furnace at periods of comparative idleness.

These points have been drawn attention to in the columns of the *Electrical Review*, specially with reference to the advisability of carrying large amounts of water. The advocates of boilers with small water capacity are very apt to conclude that rapidity of steam generation implies economical performance, and go so far even as to state that when a station ceases work for the day, the stored heat in a large bulk of water is lost, quite forgetful that during the last few minutes of working, the fires will have been let down and steam dropped to its minimum, and the water level also allowed to run to a minimum, and they further overlook the fact that the smaller the water capacity in a boiler, the more nearly must the heating surface and furnace capacity approach to that corresponding with the engine power necessary to pull over the high points. Where the water capacity is zero, as it may be considered in that proposed boiler wherein water is injected upon heated surfaces and the whole is flashed into steam instantly, then it would clearly be necessary to maintain a maximum fire and maintain it, too, right up to the last instant of work. In what he has to say of boilers, Mr. Church now appears to have a clear insight into the matter and to have profited by the error for which he states he was a bit ashamed. He was in good company, however, in his error, for if the evidence against the proposed Central Subway Railway in 1889 be referred to, it will be seen that a noted "Sir" scientific witness, whose absolute veracity it would be flat blasphemy to doubt in the least, did not appear in his evidence to be at all clear in respect to proper allowances for varying loads.

We cannot, however, agree with Mr. Church that engine capacity must be determined without reference to condensation, when present; to neglect the power given by condensation is practically to allow of a more serious underloading than already compulsory, and where there is a sufficiency of condensing water there need be no occasion for the condenser to become choked, disabled or leaky, or to lose its vacuum under a sudden fluctuation. Any detail may become disabled, but there is no reason more for fearing this of a condenser than for any other part, and as to losing its vacuum, through overheating (which we assume is what Mr. Church means,) the same arrangement which gives a sudden accession of steam to be condensed can at least be made to give a sudden accession of water wherewithal to condense that steam, and, too, at least one stroke ahead of the advent of that steam to the condenser. To neglect the condenser is by no means a corollary of the action of the steam engine; for the injection valve is as easily regulated automatically as are the steam admission valves, only it is not so often done, because, ordinarily, steam engines work at fairly regular speeds and powers, and the injection valve is opened by hand by the engineer, who keeps his eye on the vacuum gauge as he does so, and usually gives a little more admission of water than he finds is sufficient to maintain a full attainable vacuum. Mr. Church's remarks here savor just a trifle of that rule of thumb, which he condemns when properly denouncing the errors in choice of boiler capacity.

Mr. Church makes the reservation that his remarks anent relative capacities of engine, boiler, and dynamo at what we may term a proper standard rating of each, are to be more especially understood as applying to small stations, rightly concluding that over a large system actuated from one station the chances are in favor of a far more close approximation of maximum and minimum load to the dead level of the daily average than can be the case on a small road of a few cars only. With numerous cars, the expenditure of energy will be in all likelihood extremely regular, and within the economical limits of variation of the engines, whilst, of course, the boiler capacity will be simply that of the engines. For small stations he inclines, however, to the proportion:

Dynamo	100
Engine	100
Boiler	60

For he considers the dynamo, like the engine, may for any short periods be run above its proper rating, as it will not become dangerously overheated in the short period of maximum effort.

It may not be an easy problem in mechanics to solve, or even within the range of practical possibilities, but one of the best methods of getting an engine to do more work with economical rates of expansion would be to so arrange the driving connection between the engine and dynamo that the speed of the engine could be augmented for the higher powers whilst keeping that of the dynamo constant. The change would require to be so quickly effected that it is not clear how it could be carried out.

Mr. Church considers 20 to 25 per cent. the outside excess above its rated capacity to which an engine should be made to work. Even with this the engine must be enormously too large for its minimum duty, which may be nil on the ampere diagram, and he gave illustrations in the original article to which he now refers, of some indicator diagrams showing 33 per cent. overload above normal; but as no scale or other figures are given, we cannot compare any of the diagrams fairly, or know if the standard diagram was such as to commend itself to our judgment; but our impression from this appearance is, that the normal load is a heavy one, and the true rated capacity less than that allowed, so that the maximum load is really more than 33 per cent. above a proper normal.

Considering how short is the actual period of maximum load, it almost seems that the engine capacity should be such as to just overcome the maximum load with steam carried full stroke in the cylinder. This may not be economical, but the loss due to a few cylinderfuls of steam thus expended will often be less than the long-continued loss consequent on so much running at almost a friction-diagram rate of work.

CAPTAIN WILLIAM BROPHY, well known to all electricians throughout the country as inspector of electric light stations for insurance purposes, has become connected with the Manufacturers' Mutual Insurance Company (commonly known as the Factory Mutuals), who have now decided to take up the risks of insuring electric light and power stations. Captain Brophy will himself inspect all the stations, wherever situated, insured by this company, and will at present make his headquarters at No. 31 Milk street, Boston.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, AUGUST 24, 1892. No. 225.

The discovery of magneto-electricity is the greatest experimental result ever attained by an investigator.—Tyndall.

ELECTRIC RAILROADS IN THE CITIES.

FOR some weeks past several of the New York daily papers, among which may be named the *World*, *Times* and *Post*, have been displaying an unusual amount of misinformation and prejudice on the subject of the trolley system. It would be difficult to give a synopsis or summary of their variously vituperative articles, for the reason that there are practically no facts and no figures, but simply a wearying reiteration of the statement that the trolley is a bold, bad, deadly thing, and therefore New York will have none of it. It is true that the *World* has presented a list or two of alleged trolley accidents in other cities, but when one comes to examine them the absence of *trolley accidents* is truly remarkable. Some people are unfortunately run over, and others again get hurt by putting their heads out of car windows or by jumping off on the wrong side of cars in motion, or by losing control of teams; but as for accidents in which the wires or the trolleys or the motors play any part, they are well nigh undiscoverable. That is just what might be expected. It is possible that some day one of these papers will invent a method of traction in which no accidents will happen; but in view of the fact that our steam roads, with all their magnificent advances and improvements are still killing and injuring about 30,000 persons a year, it does seem rather unreasonable that these critics should ask a new system, carrying annually in America the equivalent of the population of the globe, to be absolutely and entirely free of casualty.

A somewhat surprising aspect of the losing agitation against the victorious trolley is that one or two technical journals have joined in the chorus of dispraise. For instance, the *Engineering Record* says: "The problem of passenger transportation through the streets of New York is largely one of rapid transit. There is no good evidence to show that it would, or could, be solved by any of the trolley systems which have been held in view. The whole merit of the systems would be found simply in the low operating expenses, and in these, manifestly, the public could have little interest, deriving, as it would, no measureable benefit from them. Why, therefore, any sacrifices, important as they would be, should be made to the trolley systems, remains to be shown." We would like to know whether our contemporary is seriously and fully of the opinion that the public has but little interest in economy of operation, and whether it believes that an electric railway is any different in such a respect from any other work of public utility that adds to the public wealth by its greater product of some needed commodity at a lower cost of supply. If the *Engineering Record* is right, all inventors and engineers may as well stop right off.

But perhaps there are other advantages to the public from the trolley system than the mere reduction of operating expenses. As an alternative to horse cars it seems to have some merit. It is certainly far less unsightly and cumbersome than an elevated road. Beyond question it is far more cleanly and healthy in its operation and surroundings than either a horse railroad or an elevated steam road. We should suppose it had some superiority over a cable road as being less costly to build and operate, with greater control of the cars, and at least an ability to back a car instantly when necessary. We have understood that a great many electric roads have re-endowed many American citizens with their birthright—a free home—enlarging the area of prosperous municipalities and building up beautiful suburbs where the humblest may sit under his own verandah and apple tree.

It is a strange sensation for a New Yorker, like ourselves, to come back to the city after visiting other places blessed with electric roads, and to settle down to the old humdrum horse cars. A trip two weeks ago to Scranton showed us a city with not a single horse car in it, but with electric cars in every direction used as freely and gladly by the people as though they had been there since the year in which the city was founded. Or if one has been in the Northwest he will have visited Minneapolis, where the electric cars last year carried 26,500,000 passengers, and where this year the travel on the electric lines is many per cent. heavier than in 1891. Or perhaps we may take the report of Boston, where on the Fourth of July over 600 electric cars carried hundreds of thousands of people in comfort and safety. The annual report of the West End Company of Boston, just published, shows that electricity is there doing a work that no other motive power could have done, and that the trolley has been patronized by the public to such an extent as to make the stock of the company one of the best investments to be found in that staid and shrewd city, an investment, morever, that is pretty well distributed among the proletariat of capitalists constituting the conservative element of the community. If the trolley is a failure in Boston, as some of our New York newspapers contend, the price of the stock, the rapid extension of the electric system, and the demand for trolley roads where none have yet been put in, are good evidence to the contrary.

By all means, let us have every storage battery car we can; and conduit roads, too, when we may; and underground roads as soon as possible ; but their development and the general cause of rapid transit are not going to be benefited one bit by dispraise of one of the simplest and greatest inventions of the age—the humble, useful trolley. The trolley is here to stay.

A PROTEST AGAINST "TEMPORARY" WORK.

Cheapness, carelessness and ignorance have been chief banes of electrical progress, and the wonder in many cases is that the combination of these three detrimental elements has not resulted in greater disaster and loss. As Mr. C. O. Harris points out in this issue, in a characteristic and suggestive article, many electricians have been slaves of the word "temporary," and have allowed themselves to be ensnared by the idea that the best work is not required at all times. Even where a willingness is shown to spend large sums of money, temporary methods are adopted, as for example in Boston and Brooklyn, where the electric railway feeders may be seen over the tracks, when everybody knows that they would be much better underground and would cost less in the long run, to say nothing of the good effect on public opinion, secured by their removal from the poles.

As to installation work, there is still much room for improvement. The report of a well-known insurance inspector which is now before us, says of a leading town in New Jersey: "The wiring in this town is exceedingly poor. I inspected 25 buildings and found them with few exceptions in the same condition. I explained to owner of electric plant that it was useless to supply him with our certificates until improvements were made in the different buildings." Of another Jersey city, he writes: "The wiring in this town is exceedingly bad in many places; very little attention appears to be given it, the work being done in a very careless and incompetent manner."

If all contractors and central station managers were really earnest, conscientious and intelligent in their work, there would be little opportunity for such reports as these. In fact, we think that local companies should not wait for the coming of the insurance inspector, but should try to live up to a high standard and should reinforce their own efforts by calling in once or twice a year some outside engineer or firm to make an inspection of plant, circuits and wiring, and tell them of any defects. It would be a saving in the end.

IMPORTING SUBMARINE CABLE.

Under the new McKinley tariff law, importations by the U. S. Government are no longer free of duty. As the result of these changed conditions, Prof. Harrington, Chief of the Weather Bureau, informs the Secretary of the Interior that the cost of the cable for two proposed weather signal stations on islands in Lake Huron is doubled. His original estimate of the cost of seven miles of cable was $10,500 or $1,500 per mile, but he now wants $21,000 or $3,000, to meet the additional cost on account of the duty.

Aside from the point that this would seem to indicate that the consumer pays the tax, and not the foreign manufacturer, we would respectfully inquire what is the use of the duty, if the Government is still to go abroad for its submarine cable? Either the manufacturers here can make this cable, or they cannot. If they are able to make it, we object most decidedly to any purchase of foreign cable. If they cannot make it, or do not care to make it, the duty should come off, as it is certainly then a useless and senseless tax, like many others that the tariff imposes.

We believe that this country is able to make its own submarine cable if it chooses. What do the manufacturers say?

ZINCS FOR GRAVITY BATTERIES.

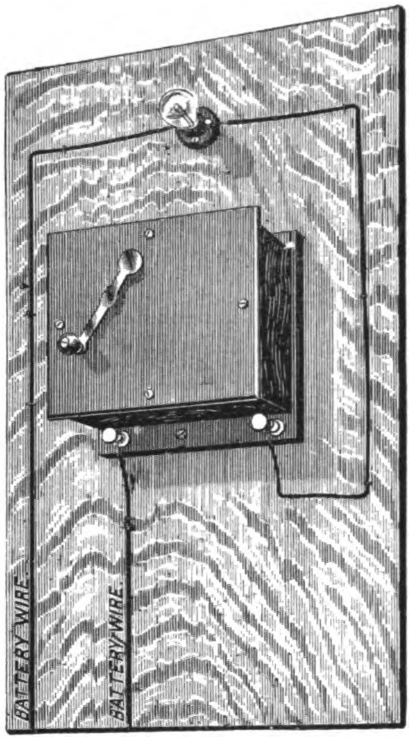
One of the most valuable improvements made of late years in gravity batteries is that to which Mr. Georges d'Infreville, formerly electrician to the Western Union Telegraph Company, calls attention in this issue. He has taken the old crowfoot zinc and so transformed it by his inventive genius that he may be said to have given a new and long lease of life to that familiar servitor of the telegraph. The economy that he proposes to effect is by no means insignificant. It is understood that the Western Union uses about 750,000 zincs every year, and if we allow but as many more for all the other telegraph systems and appliances of the country, including the Postal, the railway companies, the district messenger and other users, we find a consumption of about 1,500,000 zincs per annum. With Mr. d'Infreville's simple, beautiful and highly ingenious improvements, the consumption can be greatly reduced, the waste abolished, and the service materially bettered. We must confess our admiration of the inventive faculty that can thus see in the most familiar and commonplace objects a large opportunity for its employment, and we trust that Mr. d'Infreville will enjoy some return for the work and study by which through several years of steady experiment he has brought his devices to perfection. It will be noticed that his initial modification of the zinc has brought with it a number of corresponding changes throughout the gravity cell, each requiring careful adjustment and each yielding its better result in a wider application of this type of battery.

THE MODERN SEARCH LIGHT.

This week Mr. E. R. Knowles completes his very interesting and instructive series of articles on search lights by describing and illustrating one in which he has embodied the latest ideas in this field and has produced an apparatus of great value. The papers have lately been full of accounts of the wonderful search light installed on top of Mt. Washington, in the White Mountains, and sending its beam of pure white light over half a dozen States. It is worth remarking that the light in question is the same as that described by Mr. Knowles. The effects obtained with it are very beautiful, and there is no reason why every ambitious and self-respecting mountain hotel should not get a similar equipment, with which to fill in the pauses of the moon.

THE EDISON TIME SWITCH.

THE accompanying illustration shows the new time switch of the Edison Manufacturing Company, which is operated by a clock movement. It is designed for use in connection with miniature incandescent lamps for cellar or basement lighting; the current being supplied by six Edison-Lalande cells type, K. The battery and lamp can be placed in the cellar, and the switch at the entrance, so that the lamp can be switched on before entering. It is impossible for the lamp to be left burning, through negligence, as the switch opens the circuit automatically, at the end of either 2½, 5, 7½ or 10 minutes' run, the time depending upon the number of turns given the switch handle, each turn adding 2½ minutes to the length of contact.



EDISON TIME SWITCH.

The mechanism has a Geneva stop movement, one of the cogs being attached to a brass contact wheel having an insulated section with a V-shaped notch cut in it. When the switch handle is turned and the clock wound up, a contact spring is brought to bear against the metal part of the contact wheel, and the circuit is established. As the contact wheel slowly revolves, the insulated section on it finally reaches the contact spring which locks into the V-shaped groove breaking the circuit and stopping the clock. The switch is placed in series with the lamp as shown in the cut, and it is possible to operate three or four switches and lamps in different parts of the house from one battery of six cells, as only one lamp would be in use at a time.

The battery will maintain a four c. p. lamp for 100 hours without needing any attention, and, estimating that the lamp is used on an average 20 minutes daily, the battery would last about a year.

One great advantage offered by this system of lighting cellars, etc., is the absolute safety from fire; coupled with the great convenience of the light being always ready for use. The entire outfit which consists of a time switch, one four c. p. lamp and socket with the necessary wiring and six Edison Lalande cells, type K porcelain jars, can be seen at the offices of the Edison Manufacturing Company, 110 East Twenty-third street, New York, in actual operation.

THE STROM AUTOMATIC ELECTRIC SAFETY BLOCK SYSTEM.

A VERY interesting test took place recently on the Brooklyn and Brighton Beach Railroad of a new block system, differing from others in that it gives no visible signal, but instead automatically shuts off the steam, puts on the air brake and blows the whistle whenever there is danger of any kind, or any part of the apparatus is out of order.

In each locomotive cab, Fig. 1, an eighth h. p. dynamo, fastened to the ceiling, is kept constantly running by a direct-coupled rotary-engine, taking steam from the locomotive boiler. This supplies all the current, there being no batteries used. In front of the throttle a small cylinder, A, is so placed that when steam is admitted, its piston forces the throttle piston in, shutting off the steam; the piston of another very small cylinder, B, fastened to the ceiling, pushes the whistle handle down and blows the whistle, while a third cylinder, D, having a piston with a radial motion, puts on the air brake. These cylinders are connected to the boiler through a valve, which is normally kept closed by an electromagnet.

Underneath the locomotive are two parallel brushes (one to be used going forward, the other backwards) and on the track, at the end of every block are four steel contact plates connected to inter-locking boxes along the line, as shown in Fig. 2. The electromagnet and valve on the locomotive is a very compact and practical piece of mechanism. It is seen at E, Fig. 1, and again enlarged in Fig. 3. The valve has its parts so arranged that when open the steam goes from the boiler to the cylinders, but when closed the steam escapes from the cylinders to the outer air.

The magnet, Fig. 3, is iron clad with grooves on two sides, and slides up and down on a track on the frame. A coiled spring and pin are placed in the centre, which forces it from its armature as soon as released. Another coiled spring gives the armature a radial motion. A post in the armature forks down over the handle of the valve. When the magnet is up, away from its armature the current is short-circuited across it. In use the handle of the valve is turned to the right and the magnet is pushed down. This breaks the short-circuit, and it clicks down upon the armature A short rounded pin in the latter enters a hole in the magnet and prevents the armature from being twisted round. Friction will hold it, but the pin is considered safer. The magnet is about 3½ inches long by 3 inches outside diameter and will sustain over

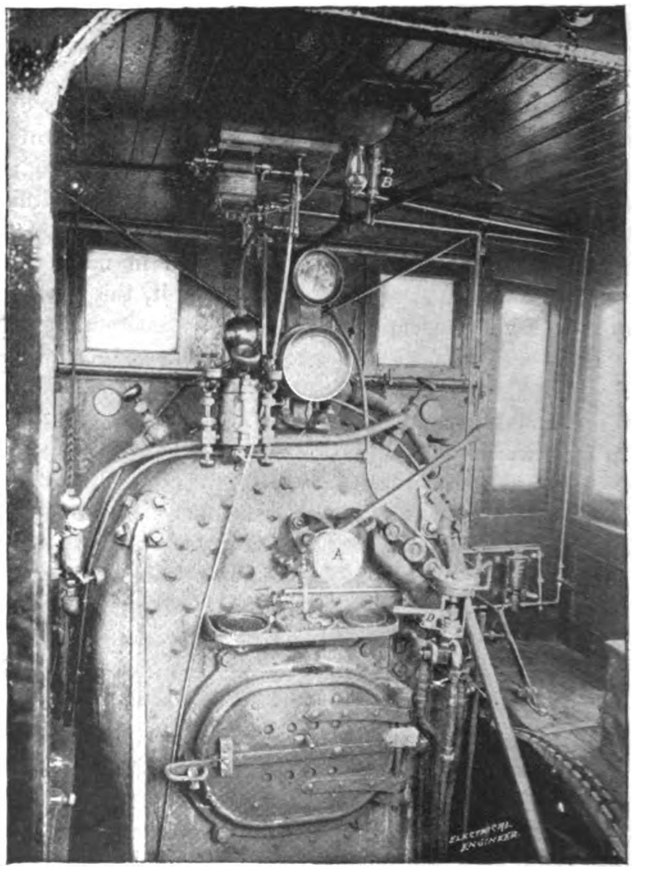


FIG. 1.—STROM BLOCK SYSTEM.

800 pounds, so there is no danger of its being shaken loose from the armature. When the current is broken the magnet springs up, the armature turns round, carrying the valve handle with it,

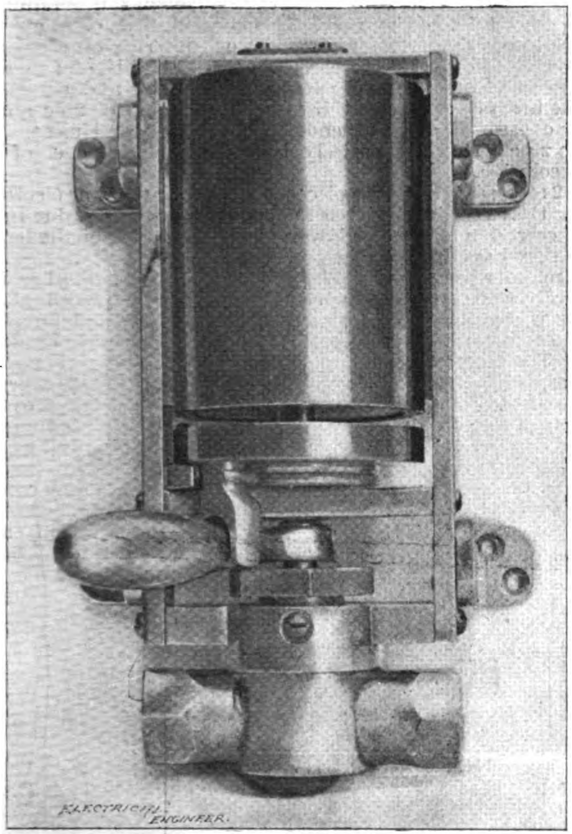

FIG. 3.—ELECTROMAGNET AND LEVER.

and allowing the steam to go to the three cylinders for stopping the train.

Except when going over contact plates the circuit is closed on itself on the locomotive, as shown in Fig. 4. From the dynamo it goes to an automatic switch that connects to either brush, thence through a contact to a resistance coil, equal to sum of line and inter-locking box magnet, thence to the engine frame and ground. In case of protecting against broken trains, a wire would be carried through the train and grounded on the last car. The other terminal of the dynamo is connected to the magnet, the other end of the magnet wire being grounded through its core.

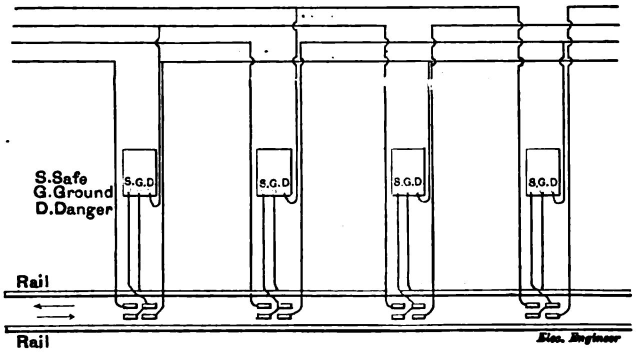

FIG. 2.

The line boxes, Fig. 5, also deserve special mention, being very simple, compact and substantial. There are no adjusting screws, pivots or hinges to get out of order. Once in order, always in order, is what is claimed for them. There is only one point of make and break and that has a quadruple platinum contact. The operation is as follows:

When the brush of a locomotive comes in contact with a plate the brush is lifted, breaking its regular circuit, but making it through the contact plate to the line through the quadruple contact in the box two blocks ahead, through the lower magnet in the line box, to the rail and engine. The lower magnet lifts its armature, which releases the vertical arm, and this in turn allows the other, as soon as the current is broken, to drop below its former point, and thus break contact at the platinum points. Another train coming over the same contact plate would meet this broken circuit and be stopped, as would also a train coming from the opposite direction two blocks the other side of the box, as a contact plate there is also connected to the same binding post. The brush immediately goes over another plate (the two are combined in one with insulation between forming a double plate, as shown in Fig. 6), which is connected to the upper magnet of the box nearest to it. The vertical arm is attracted, and this lifts the horizontal arm against the contact points and locks itself. This allows a train to pass over the contact plate two blocks in the rear, one block in the rear being still protected by the box one block ahead. Switches, drawbridges, etc., are protected by placing a contact plate at a safe distance for stopping, and connecting them to contacts that are made or broken by the closing or opening of the switch or bridge.

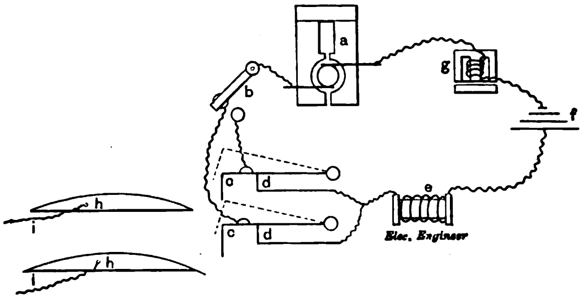

FIG. 4.

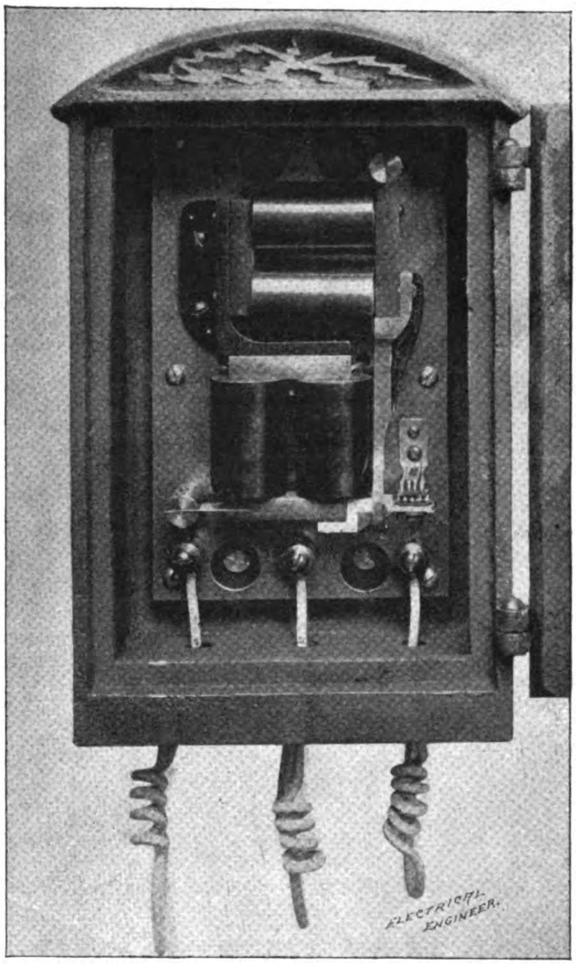

FIG. 5.—LINE BOX.

The dynamo used for the experiment was an eighth h. p. 50-volt shunt-wound Perret machine, running at 2,200 revolutions directly connected to a one-third h. p. Turner rotary engine. The same dynamo may be utilized for operating a head light and gauge light. The company are at present constructing a special dynamo and engine that will contain many novel features, and which will be described in a later issue.

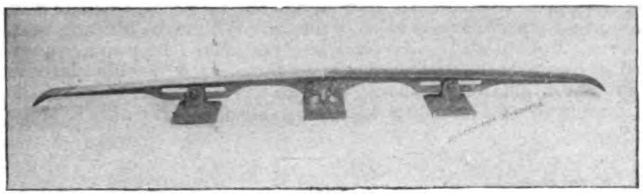

FIG. 6.—CONTACT PLATES.

This system is said to be less expensive than others to install, and the cost of operating is almost nothing in comparison. It is also said to take a great mental strain from the engineer. But the most important claim is that, in order or out of order, with the engineer asleep, dead or off his engine; in fog or darkness, it can never fail.

Great credit is due Mr. Harry E. Dey, the electrician of the company, for the energy and ability displayed in putting the system into successful operation. In two months he designed every part, and had two miles of track and two locomotives fully equipped, meeting with the most gratifying success at the first trial. Mr. Dey has an able co-worker in Mr. F. J. Clark, of Harrison, N. J.

THE D'INFREVILLE WASTELESS GRAVITY ZINC.

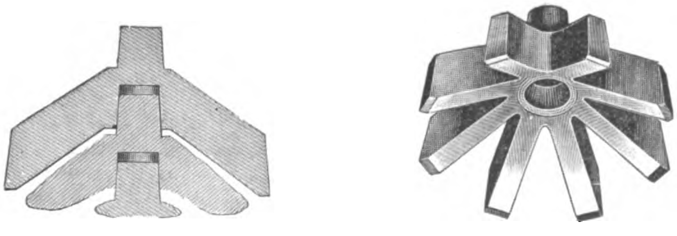
BY

G. d'Infreville

HERETOFORE there has been a great waste of zinc in batteries, owing to the fact that the zinc electrode must be removed before it is entirely consumed, the current having become too weak on account of the increased internal resistance due to the diminished size of the zinc electrode. This waste in the case of the best patterns of zinc for gravity battery, often reaches forty-five per cent. of the total weight of zinc purchased, 1½ pound being wasted out of 3¼ pounds of zinc.

In many places the stumps cannot be used to any advantage, nor sold, and it will not pay to gather and ship them to a place where they can be disposed of. Even when collected, they can at best be sold only as impure metal at but about half the price of spelter, so that in the most favorable case, where one-half of the value of the stumps is recovered, the loss will still amount to about twenty-two per cent.

The invention here illustrated was devised by Mr. Georges d'Infreville of this city, and consists in using for the zinc electrode a number of pieces adapted to be connected to one another in column by joints or connections which are liquid-tight or adapted to preserve the connecting parts from the action of the battery liquid, so that a partially consumed piece may be connected or attached to the bottom of a fresh or new piece, which latter, after being partially consumed, and after the still greater state of consumption of the first one, may in its turn be connected underneath a new piece, and so on.



FIGS. 2 AND 3.

In time the lower piece of zinc will have been *entirely consumed;* then the one directly above it and to which it was attached, and so on, so that practically every piece of zinc introduced into the battery will in its turn be entirely consumed. This fact has been repeatedly confirmed by experience, and the electrode is therefore called the "Wasteless" zinc.

This arrangement and process are shown in perspective in Fig. 1, which represents one complete gravity element fitted up with the "Wasteless" zinc electrode. This consists, first, of a new zinc piece suspended from a hanger resting on the rim of the jar so that the zinc dips about half way into the sulphate of zinc solution; a second piece of zinc partially consumed and suspended from the first one; and of a third piece or stump of zinc almost entirely consumed, and suspended from the second piece. The last two zinc pieces are entirely below the upper level of the battery solution.

Fig. 2 represents the three pieces constituting the zinc electrode, showing their relative positions and comparative sizes, due to the state of corrosion of the two lower pieces depending on the length of time they have been in use.

The manner in which a "Wasteless" zinc piece, whether new or partially worn out, is fastened to another one placed above, makes it perfectly secure, both as regards contact and guarding against any possibility of dropping down on the copper electrode below. The fastening is obtained by means of the slightly conical socket provided at the bottom of the upper zinc, Fig. 3, over the correspondingly tapered complementary stud or shank provided at the top of the zinc, Fig. 4. The socket below each zinc is an inverted cup and cannot allow, any more than a diving bell would, the access of liquid to its inside walls.

The two zinc pieces are so strongly connected that they cannot be torn asunder when pulled straight apart; but a twist, combined with light tapping sideways on the radial branches will easily loosen them when desired.

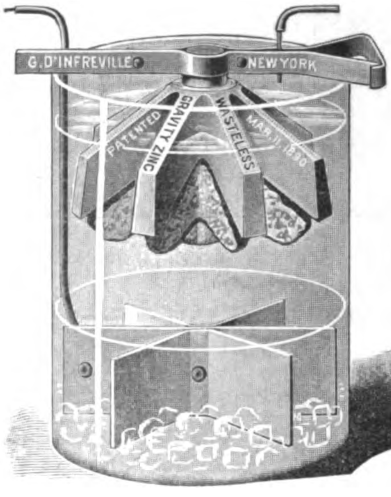


FIG. 1.

The conical stud or shank above and the conical socket below each are made to a uniform gauge, so as to leave about ¼ inch between two zincs when the branches of the upper one are exactly over the branches of the one below, which position permits the introducing of the blue vitriol, and the use of the hydrometer. The gauge will be preserved in the future for this size of zinc, so that the stud or shank of a zinc previously bought will always fit into the conical socket of a newly purchased one.

This is a simpler and cheaper method than connecting them by a screw thread and has proved to be quite effective and reliable in practice.

A new feature with this is that the radial branches are slanting downwardly from their supporting trunk so that they will wear out gradually from their extremities as shown in Figs. 1 and 2, which are lower in the solution or nearer to the copper electrode, towards their point of support which is higher in the solution or farther from the copper, and hence less acted upon chemically; the branches will thus become entirely consumed before their support is itself too much corroded.

Another advantage secured by the downward slant of the branches of the zinc, is, that some of the hydrogen gas runs up from under the branches towards the socket under the trunk of the zinc where it helps to preserve it from corrosion and whence it bubbles out from time to time when in excess, while it leaves the branches free to be acted upon by the solution. The slanting direction of the branches also furnishes at the lower part of the zinc a space which a partly worn-out piece or stump will fill advantageously, so that the zinc electrode will be more even at its lower part.

When a battery is started a single "Wasteless" zinc, or, if a greater ampereage is needed, two, one on top of the other, can be suspended in the same jar, the upper zinc from a hanger connector, Fig. 5, which rests on the rim of the jar, and the lower zinc under the upper one as explained before.

The "Wasteless" zinc furnishes in itself means for connecting firmly together two or more new or partially worn-out pieces of zinc, without the help of mercury or anything else below the outside level of the battery solution, and beyond the possibility of being corroded by it.

This radical departure brings with it, besides the possibility of totally consuming the zinc, several other advantages, some of which are of great importance.

As a new "Wasteless" gravity zinc can at any time be put over another partially consumed one, there is no occasion for hesitating about the proper time to replace a partially worn-out zinc, for fear that doing it too soon would entail too great a waste of metal, or that doing it too late would allow the internal resistance of the battery to so increase as to fail to produce the necessary amount of current.

This special property is of the utmost value in many cases, as for fire-alarm telegraphs, railroad telegraphs and signals, police telegraphs and alarms, and whenever the utmost reliability outweighs any other consideration. Among the immediate beneficial results derived from the lower internal resistance due to the simultaneous use of two zincs, one under the other, and one stump under the lower zinc in the same jar, is the saving of 50 per cent., it is claimed, in the expense of now superfluous jars and coppers, of 50 per cent. in amount of room required, and of 40 per cent. in total battery weight, and also the resulting saving of money and time in packing, handling, shipping, storing and attendance, with the reduction of risks, delays, etc.

In addition to this, the internal resistance falls to 0.7 ohm per cell, the E. M. F. being 1.07 volt as usual, giving a current of about 1¼ ampere; they are, therefore, well suited for operating circuits of moderately low resistance, such as local telegraph circuits, electro-plating and the working of small motors, in which case one single cell equipped with two zincs will do about as much work as three ordinary cells alike in every respect except as regards their zinc electrodes, which necessarily are single and generally placed further away from the copper.

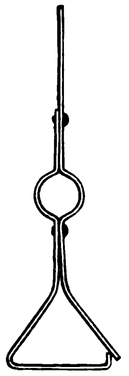

FIG. 5.

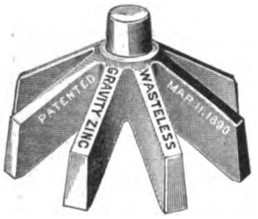

FIG. 4.

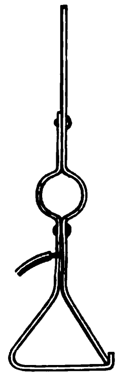

FIG. 6.

The projecting stud or shank of the "Wasteless" zinc, being less than one inch in length and in diameter, and free from holes, is strong and less liable than any other of its parts to get broken in handling or transportation. The radial branches are eight in number, all alike, and separated one from another by an angle of 45°. They are also sufficiently short (2¼ inches) and thick (from ⅜ inch at the top to ¼ inch at the bottom) to not be easily broken.

These zincs when packed are placed on top of one another in piles of ten, and a small metal ring of proper dimensions is placed around the stud of each zinc to prevent its being wedged into the socket of the zinc placed directly above; they thus occupy much less room than other patterns and are easily packed in a wooden crate.

Five or ten, as desired, of the hanger connectors can be easily and safely packed with ten zincs, at the upper part of the crate. Five or ten coppers, if needed, can also be packed at the lower part of the crate and are there maintained by an extra strip of wood. No other pattern of gravity zinc takes less room and material for packing and storing.

The "Wasteless" zinc is made only at present for the standard and most generally used glass jar which measures six inches in diameter and eight inches in height. The zinc weighs nearly three pounds, as this weight for several reasons has been deemed most advantageous for this size of jar, while, should it be desired to have a much larger or heavier zinc electrode in the jar, it could be readily obtained with the "Wasteless" zinc, for when two pieces and a stump are assembled in the same jar, the total weight of the zinc reaches about seven pounds.

This zinc has been in actual continued use for the last year in many places. It is finding a steadily increasing demand and general favor as it becomes known and understood, and has as yet given no cause for complaint. It has also, it is claimed, opened new fields of application for the gravity battery. It has enabled the sulphate of copper gravity battery to be now economically applied to the operating of printing telegraphs, the running of small electric motors, electroplating, medical apparatus, the charging of small accumulators, etc.

The hanger connector, Figs. 5 and 6, is made simply of two pieces of brass fastened together, has no screw whatever, weighs but about two ounces and takes little room. It provides a broad, elastic and tight connection all around the stud of the zinc which it supports. On one side it is triangular, so that the whole rests by three points on the rim of the jar, giving sufficient steadiness to the zinc, while its edgewise position gives it all the rigidity necessary to safely support at the same time two or more zincs connected in a column.

Its triangular end serves also to fasten and securely lock either a wire or a metal strip, not necessarily by the end, as when a screw with a hole is used, but at any place, from the smallest magnet wire to the largest telegraph office wire, always with a nearly uniform pressure, ample contact and an elastic grip not liable to get loose. It does not strain nor tend to break the edge of the glass jar, and renders the connecting and disconnecting easier and quicker than with a screw, an advantage often very important in large battery-rooms or in unforeseen emergencies.

THE BALTIMORE AND PIKEVILLE ELECTRIC RAILWAY CO.

THE first regular car of the Baltimore and Pikeville Railway Co. was recently run over the newly constructed line. This is the first line to be equipped by the Baltimore Traction Co., and marks an era in rapid transit in Baltimore. This line runs from the northern boundary of the city to Pikeville, through a thickly populated region, which is being rapidly built up. It replaces an old horse car line, which made the trip in about 1¼ hours, the new schedule on the electric line being 25 minutes.

The equipment consists at present of two Short, and two Westinghouse motor equipments. The station equipment consists of two 100 K. W. Edison generators, which are driven by two engines of the Ball Engine Co., of Erie, Pa. The switchboard is of marble and is tastefully arranged, the entire station work having been put in by the General Electric Co., of New York.

The track work was put in by Messrs. E. D. Smith & Co., of Baltimore, and consists of girder rail on chairs in the city, while beyond the city limits the 56 lb. T rails, made by the Maryland Steel Company, of Baltimore, are used. The track is well laid and ballasted, and the cars run extremely well on it. There are several grades on the road, one being of 8 per cent., but the cars move easily and smoothly.

The line work was done by J. G. White & Co., of New York. It is an excellent piece of line work, consisting of iron poles, side construction in the city, and outside the octagonal Norway pine pole is used with bracket construction.

The manner in which the engine foundations are built deserves attention. They are placed on the main floor of the Traction Co's Retreat street power house. As the cellar is used for splicing and repairing cables, the space was too valuable to occupy with foundations, so it was determined to use four steel girder I beams, resting in the wall of the building and the cable engine foundations, to support the engine foundation. Between each of these beams was thrown a brick arch on top of which was built the foundation. This answers admirably, and the engine runs without a jar of any kind. In fact, the whole line runs extremely well and promises to be a splendid feeder for the cable line as well as carrying large numbers of people to Pikeville and other suburban towns along the route.

THE NEW ORDER OF THINGS AT CAMDEN, N. J.

ONE by one the earlier electric roads started at low voltage, etc., are coming over to the new order of things, and Camden, N. J., is the scene of the latest of these changes. Mr. J. Stanford Brown, the electrical engineer of New York City, has been busy lately making the necessary alterations in the old Daft system there, running at 220 volts and with double overhead wires, and has now started up the first car on the Westinghouse system at 500 volts, single-trolley circuit. The change over was made without a hitch on August 9, and if nothing interferes, the Merchantville extension will be ready to operate this week, the track being already completed. It is noteworthy, and creditable to Mr. Brown, that the change on the old line has been accomplished without any stoppage of the cars. Mr. Brown is in full electrical charge of the work for the Camden Horse Railroad Co., owners of the entire system of lines.

"AT ANY PRICE."

THE electrician of an electric light company in the South writes us: "I am a subscriber to your paper and would not be without it at any price."

Letters to the Editor.

THE TYPE TELEGRAPH OF THE EXCHANGE TELEGRAPH CO., LONDON.

As an old subscriber to your weekly journal of electrical engineering, I was rather surprised to find in the number just to hand, dated 27th July, an account of an "American Type Telegraph," in which the employment of my apparatus, which is of a similar character, by the Exchange Telegraph Co. in London for many years past is completely ignored, while at the same time a statement is made that a page printing machine by Mr. J. E. Wright, of New York, has been working successfully for the past three years *in all* the leading newspapers and clubs in London, while the fact is that the bulk of the business is and has been done by the Exchange Telegraph Co., and the apparatus of later production of Wright & Moore is at work in a small proportion only of the London clubs, about a dozen at the outside—most of which would be rather surprised at being distinguished as leading clubs.

I enclose a specimen of the performance of our "Column Printer," which last month delivered a total of 5,465,740 words.

The high speed of 400 revolutions per minute said to be obtained by the Wright apparatus must be unnecessary for turning out only 40 words a minute.

We can manage that number of words at 140 revolutions per minute or 80 words at our normal working speed of 100 revolutions.

J. HIGGINS,
Engineer, the Exchange Telegraph Co., Ltd.

LONDON, ENGLAND, August 4, 1892.

LAMP AND WIRE CALCULATIONS WITHOUT TABLES OR CURVES.

IN the article on "Lamp and Wire Calculations Without Tables or Curves," by Mr. E. P. Roberts, in your issue of Aug. 3, 1892, which I have read with deep interest, I noticed a slight error in the formula for lamp resistance, viz.:

$$\text{Lamp } R = \frac{V}{C} = \frac{C \times V}{ab}.$$

This latter expression is wrong, inasmuch as

$$C \times V = \text{total watts} = ab \therefore \frac{C \times V}{ab} = 1.$$

But from definition

$$C = \frac{ab}{V} \text{ or } V = \frac{ab}{C}.$$

Therefore, formula should be:

$$\text{Lamp } R = \frac{V}{C} = \frac{V \times V}{ab} = \frac{V^2}{ab} \text{ or } = \frac{ab}{C \times C} = \frac{ab}{C^2}.$$

J. B. CAHOON.

LYNN, MASS.

A PROPOSAL TO POSTPONE THE STREET RAILWAY CONVENTION.

MY attention has been called to the fact of the opening exercises of the World's Columbian Exposition, which will be held on the 21st of October, and which is the last day of the meeting of the Street Railway Association.

It seems to me and to others with whom I have talked over the matter that it will cause confussion unless the date of the association meeting is changed. Members of the association from the West will undoubtedly want to attend the exercises, while the Eastern members, being in Cleveland, will no doubt feel disposed to attend such exercises.

The exercises in New York being held on the 11th, 12th, and 13th, it has occurred to me that it would be advisable to change the date of the convention meeting either to the first week of October, or the 18th, 19th and 20th, in which case the delegates could leave the night of the 20th and reach Chicago in time to attend such exercises.

Not being a member of the association, but simply a supply man, I trust you will pardon the liberty I take in calling your attention to the matter.

W. R. MASON, General Manager.

RAILWAY EQUIPMENT CO., CHICAGO, ILL., August 13, 1892.

A FRENCH PATENT ON VACUUM BULB LIGHTNING ARRESTERS.

REFERRING to your issue of July 20, I perceive that a correspondent wants information concerning existence of a vacuum bulb lightning arrester. For a reference for such construction let him consult French patent Bianchi, May 15, 1854, No. 19594. As this patent is not printed a copy will have to be obtained in Paris. It has good drawings and a full description.

A. M. TANNER.

NO. 7 RUE DU LOUVRE, PARIS, FRANCE, August 4, 1892.

Personal.

MR. W. R. MASON, general manager of the Railway Equipment Co., of Chicago, was in New York a few days ago. During his visit he gave several of his friends much pleasure by entertaining them at dinner. In a quiet room of the Holland he assembled the following guests: Mr. Geo. Flett, of the engineering firm of Dick, Kerr & Co., London, England; Mr. Chas. L. Pullman, Mr. John F. Barry, Mr. Thos. J. McTighe, Mr. Herbert L. Webb and Mr. Geo. M. Phelps. The dinner was excellent but not better than the ensuing three hours' chat. Electric railways, of course, were talked about, but not to the exclusion of much fun and many good stories.

MR. MORTON E. EDEN, who has recently returned to this country from Spain, where he had been engaged on some special construction work, has been appointed by Mr. A. E. Braddell, as assistant electrical inspector of the Underwriter's Association of the Middle Department, with his headquarters at 22 Clinton street, Newark. Mr. Braddell will continue to do his own part of the work from Philadelphia.

MR. H. L. WEBB left for London on August 17, with his wife, who has been an invalid for some time past, and who, it is hoped, will benefit by the change. Mr. Webb will attend to several professional matters while abroad, and his address for about two months to come will be the Institution of Electrical Engineers, London.

THE BOSTON WEST END STREET RAILWAY CO.'S ANNUAL REPORT.

THE annual report of the West End Co. just issued contains some very interesting figures It appears that the earnings have increased from $460,249 in July of 1887 to $596,157 in July, 1892, a result largely due to electric traction. By January, 1893, about 15,000,000 of miles run by its cars, or seven-eighths of the total will be electric. In 1888 the operating expenses, with horses, were 78.29 per cent.; in 1891 they were 74.48 per cent.

The subjoined table shows the progress of the electric system:

Horse cars.—Nine months.

	1891.	1892.
Miles run	9,615.736	7,258,689
Net earnings	$543,497.34	$367,036.68
Net earnings per car mile	5¾ cts.	5 cts.

Electric cars.—Nine months.

Miles run	3,491,231	5,477,571
Net earnings	$342,765.01	$810,024.00
Net earnings per car mile	10 cts.	15 cts.

Electric.—Three months.

	1891.	1892.
Total mileage	1.131,847	2,240,012
Total earnings	$432,947.70	$950,446 89
Net earnings	179,069.17	418,648.43
Net earnings per car mile	16 cts.	19 cts.

Estimated earnings of electric cars for current year.

	Nine months.	Three months. Estimated.	Total.
Total mileage	12,736,260	4,500,000	17,236,260
Electric mileage	5.477,571	3,000,000	8.477,571
Net earnings	$810,024	$570,000	$1,380,024
Net earnings per car mile	... .	....	16 cts.

The company is earning interest on its funded debt, 8 per cent. on the preferred stock, and 10 per cent. on all common stock outstanding. The fixed charges and dividends for 1892 amount to about $1,850,000.

A MEETING OF ELECTRICAL INSURANCE INSPECTORS.

A MEETING of electrical insurance inspectors was held in this city last week under the auspices of the Board of Fire Underwriters. Among those who attended the meeting were W. A. Anderson, A. E. von Giesen, A. E. Braddell, F. E. Cabot, W. H. Merrill, Jr., C. M. Goddard, M. E. Eden, A. B. James, W. McDevitt, Eaton, J. T. Ryan, C. L. Hedge, E. A. Fitzgerald, H. K. Miller, J. H. Washburn, Dr. W. Geyer, E. Leloup, W. Low.

The chief object of the meeting was the revision of rules, seeking to arrive at uniformity of practice among inspectors. Various questions were discussed, and after further decisions have been arrived at in later meetings, the rules will be published. From what transpired it would seem that wooden cleats have had their day. Steps were taken looking to the formation of an association of inspectors, a committee of which shall approve or reject proposed improvements and innovations. A lively discussion arose on the subject of interior conduiting and tubing for buildings, about which various opinions were expressed, the drift of which was that conduits were a decided step in the right direction but still open to improvement.

During the meeting a visit was made to the Edison station in Pearl street, where a series of tests was carried on of a remarkable new wire to be introduced by Washburn & Moen, and to which the name of "Salamander" has been applied. The tests were of a competitive nature, and went to show an extraordinary ability on the part of the wire to resist heat, fire and overload.

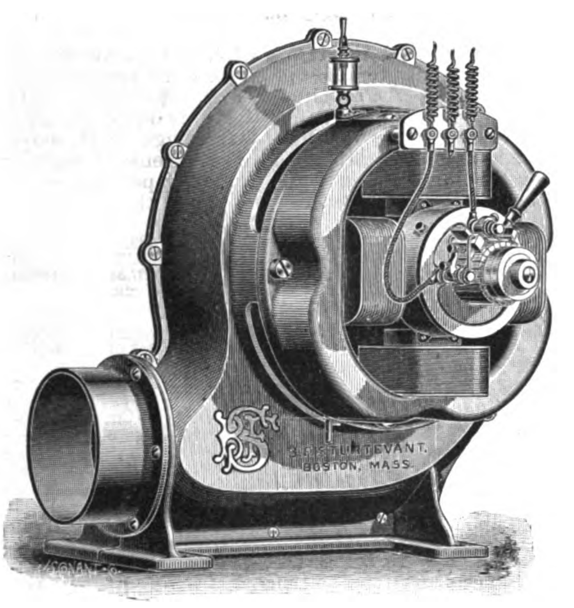
THE STURTEVANT ELECTRIC FAN.

THE rapid introduction of electricity as a motive power is continually making the convenience of the Sturtevant electric fans better appreciated. Nothing, it is claimed, can approach them in adaptability in all locations and to all classes of work for which they are specially designed. Neither engine nor belt is required, and starting and stopping is merely a matter of adjusting the switch. It can be readily seen that the fan can be set in any position without affecting the running of the motor. For this reason the fan may be located to discharge in exactly the required direction and connection easily made by pipe which can be made straight and direct to the point desired.

These fans are all of the standard high grade, and specially designed for the application of the electric motor. All running parts are carefully balanced, and designed for quiet running at a high speed.

The electric motor is of approved design, specially arranged for fan propulsion, and capable of extensive and continuous use without attention. It has been designed and is manufactured complete in every detail by the Sturtevant Co., and all parts are made on the interchangeable plan so that repairs can be executed quickly. The motors are wound for any voltage, and special designs will be brought out from time to time.

Obviously any type of fan can be fitted up in this way, and fans can be supplied for any conceivable purpose. For ventilation they are readily adaptable, particularly in the case where the introduction of an engine and boiler would be entirely out of the question. A mere connection of a wire to the power circuit does away with this and places the fan under immediate control. The high speed at which it is possible to run these fans gives them a large capacity, so that a small fan occupying but little space and easily located overhead can be used to ventilate apartments of considerable size. When run at a proper speed they are noiseless and there is no inconvenience whatever.



B. F. STURTEVANT.
BOSTON, MASS.

STURTEVANT ELECTRIC FAN.

In the dynamo-rooms of electric light plants they are naturally to be preferred for ventilation, while for ventilating dynamo, engine or other rooms on shipboard they have been largely introduced and found very efficient.

These motors fitted to the Sturtevant pressure and monogram blowers are being extensively introduced and found efficient for blowing forge, boiler and furnace fires of any description. Iron works of all descriptions find that this machine is particularly adapted to blow their forge fires or heating furnaces. Several have been introduced in malleable iron foundries, for which purpose they are particularly adapted. The Sturtevant Co. have contracts now in hand for a number of electric fans for the above use.

A notable example of a very complete plant is the contract which the Sturtevant Co. have taken for blowers and exhaust fans for the new blacksmith shop and foundry at the Pennsylvania State College, State College, Penn., in their new engineering building. The Sturtevant forges with special exhaust fan driven with electric motor are to be used in the blacksmith shop, and the blast for these forges is to be supplied by the Sturtevant electric pressure blower, and the blast for the copula furnace will be supplied by another Sturtevant electric fan. It is seen that this company has facilities for furnishing a plant of this kind complete, including forges, blowers, exhaust fans and electric motors, together with a complete system of blast piping for supplying the forges and furnaces with air blast, and suction piping for taking away the smoke from the fires. Everything is installed complete ready for the electric wiring.

When contracts of a similar nature are to be placed it is claimed that purchasers can save money and a great deal of trouble by availing themselves of the extensive experience of this company in the suitable placing and erection of fan plants, complete with electric motors specially designed for each and every case and guaranteed throughout.

The B. F. Sturtevant Co., Boston, Mass., will be pleased to recommend the proper size of fans and to furnish them with motors for any voltage with plans for installation.

THE ELECTRIC RAILWAY ON THE MADISON SQUARE TOWER.

ONE of the most interesting features of the electrical work at the Madison Square Garden Tower is the electric railway at the fifth loggia. In some respects it may be considered the highest electric road in the world.

The railway was conceived by Mr. Stanford White, of the well-known firm of McKim, Mead & White, who are architects of the garden, to carry the projector, built by the General Electric Company, around the tower.

The projector consists of a mortar-shaped band mounted on a standard built of sheet iron and insulated from the base by a large wooden gasket. To supply current to the lamp, heavy mains are run from the dynamo-room to the tower. One wire of the same polarity as the neutral of the street service is connected directly to the rails. The other, after being intercepted at the second loggia by a rheostat, is connected to a strip of copper which is fastened to the inner circumference of a large insulated support, placed between the rails. The construction of this support is such that a good promenade is made around the tower.

Current is taken from this conductor by means of a heavy brush, fastened to an insulating arm, and kept in firm contact on every portion of the circuit. The arrangement of the carbons, and mechanism for regulating them, is of the finest and most sensitive nature conceivable. On the top of the lamp just above the carbons is placed a box containing the motor and relay, the latter capable of reversing the motor, with a sensitiveness of a fraction of a volt.

The mechanical operation of the carbons is as follows: A right and left threaded shaft, to which the carbons are connected by adjustable nuts; the difference in the pitch of the two screws is calculated to be proportional to the difference of the consumption of the carbons; and a tangent screw which operates the shaft by means of the small motor.

The electrical operation is effected by the use of a relay which is a shunt from the two carbons, so that when the arc becomes greater its resistance as compared with the relay is greater, and the latter is allowed to act and switches the motor so as to feed the carbons together and consequently reduce the resistance of the arc till they rest at a point of equilibrium which is regulated according to the size and density of the carbons and the amount of current given the lamp. The motor is differentially wound so as to avoid sparking of the relay armature in changing the contacts.

In the rear of the projector is placed a reflector of the Mangin type, specially imported for this installation. In its centre is fastened a crystal prism which transfers the image of the carbon points to a little ground glass plate at the side of the projector, similar to the inverted image of a camera focusing glass. This arrangement is indispensable to the operator who can at all times view his arc without the blinding rays of the direct light. Another good feature consists in the glass being a gauge as regards the focus of the reflector and with its aid and the adjusting screw at the base of the lamp, a perfect centre is at all times maintained. In the Edison projector, an alternative is taken from the general construction of focusing lamps of this kind Instead of adjusting the carbons to the reflector, it is vice versa, and a beam of varying intensities and magnitudes may be attained by the use of the hand wheel at the back of the lamp.

In setting the carbons great care is taken to keep them in perfect alignment in one direction and to place the positive carbon a little in advance of the negative in the other, so that the crater on the former may in itself act as a reflector to throw the otherwise diverging rays directly into the larger reflector. To aid this and to concentrate the heat at the arc, a hemispherical crucible is fastened to the carbon frame and is lined with a refractory material.

To supply current to the motor for propelling the car, and also the smaller motor which feeds the carbons, both of which are wound for a higher potential than the lamp requires, a special trolley wire is suspended from the iron railing on the side, by porcelain insulators. Bearing on the lower surface of the wire is a brush which is connected down the trolley to the two motors respectively.

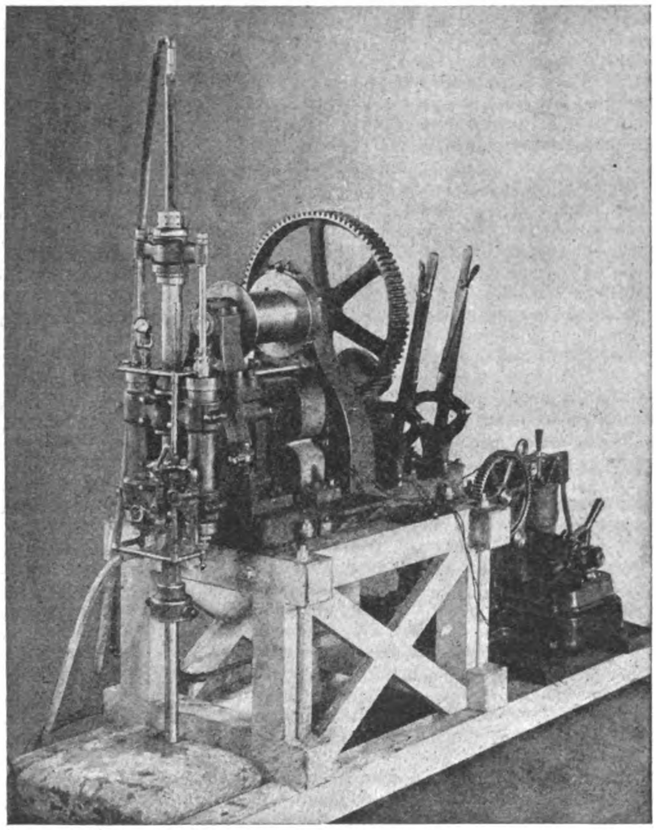
One of the Crocker-Wheeler motors was selected to propel the car, which is also furnished with a Crocker-Wheeler reversible regulator, so as to place the whole in perfect control of the operator. An insulated tangent screw is connected to the motor shaft, thus reducing the speed to a maximum of 15 revolutions per minute, it being thought that a greater speed than that would be dangerous in case of any carelessness of the operator.

The projector carriage was especially designed for the purpose by Mr. John Van Vleck, of the Edison Electric Illuminating Company, of New York, and his assistant, Mr. Wm. Erickson, whose method of installation of the insulated support for the central conductor has given a surprisingly high insulation test under very unfavorable conditions of the weather.

At a pressure of about 45 volts, the lamp will operate with the best results with 50 amperes of current, which is about $2\frac{1}{4}$ kilowatts, to produce a light which will enable one to plainly distinguish objects at a distance of over three miles. Such statements will show the whole installation to be rather an economical advertisement, and doubtless will be taken up by many architects in designing pleasure resorts of this kind.

THE GENERAL ELECTRIC DIAMOND DRILL.

The application of electricity in mining operations has caused in recent years the evolution of many new and perfected pieces of apparatus. One of the most important of these, the drill, has formed the subject of long and special attention on the part of electricians and mining engineers for a considerable time past, on account of its almost universal use in the mining industry. The General Electric Company has just perfected a new diamond drilling machine for which are claimed many points of superiority.



General Electric Diamond Drill.

The drilling apparatus is shown in the illustration mounted upon a heavy timber frame. Behind this is the electric pump supplying water to the drill and having a capacity about 700 gallons per hour against a pressure of 150 pounds to the square inch. It also supplies water to the hydraulic cylinders of the drill as well as the drill rod. Valves are set in the pipes leading to the pressure cylinder so that any desired pressure may be put upon the drill bit. A valve also controls the supply of water to the drill rod, the pump being able to supply an ample amount to keep the cutting rim of the bit perfectly free and clean. The drill head is arranged with a heavy hinge so that when uncoupled from the drill rod, it may be swung away from the frame, and allow room for hoisting the drill rods from the hole. At the top of the main standards of the iron frame is arranged a small hoisting drum, which, by the simple movement of a lever is geared to the armature of the motor, and the machine is ready, with the aid of a block and fall, to hoist out its own drill rods. In the experiments which were made with one of these drills at the factory, the drill under pressure of 120 pounds per square inch on the pistons of the pressure cylinders bored through twelve inches of solid granite in three minutes. Under a pressure of 75 pounds the drill cut through twelve inches in six minutes, and at a pressure of 35 pounds it cut through the same amount in about sixteen minutes. These cutting speeds were made with the drill bit and short barrel coupled directly to the drill head, and will necessarily be slightly dimished when a considerable length of rod has been driven into the rock, but they are sufficiently conclusive to show that the even motion of the electric motor makes it the ideal power for this work. The satisfactory performance of the drill apparatus under the stringency of the different tests to which it was subjected should lead to its wide adoption in the mining world.

THE ENTERPRISE ELECTRIC CO.

The above company, of 313–315 Dearborn street, Chicago, report that business is on the increase, surpassing even their fondest expectations. During the past week they have opened a branch house at No. 15 North Ninth street, St. Louis, Mo., with Mr. Will H. Ferris, formerly with their company in Chicago, as manager. Pres. W. C. McKinlock, of the Enterprise Electric Co., has been in St. Louis perfecting arrangements, and they will be ready for business there at once.

The National India-Rubber Co.'s wire, manufactured at Bristol, R. I., and for which the Enterprise Co. were recently appointed general Western agents, is being well and favorably received by the trade, and it is only a question of a very short time when its excellent insulating qualities (whereby it is rendered non-susceptible to the destructive influence of heat, cold, moisture and gases), will be recognized and appreciated by the trade throughout the West and Northwest.

STORAGE BATTERY CAR COAL CONSUMPTION.

The following is a very interesting letter, as bearing upon the question of storage battery car operation:

Washington Park Street Railway,
Sioux City, Ia., Aug. 12, 1892.

G. M. Dunbar,
General Manager B. and S. Storage Battery Co., City.

Dear Sir—Below you will please find the cost per car mile of coal consumption used in generating electricity for charging Bradbury-Stone Storage Batteries in use on the car now operating on the Washington Park car line in this city. The record is not the result of a single trip, or day's run, but is verified by daily operations. At the end of each run of $25\frac{34}{100}$ miles the batteries are changed; this distance including all stops and a wait at each end of the line, being covered in three hours and thirty-eight minutes. For this run of $25\frac{34}{100}$ miles we consume two hundred and forty pounds of slack coal, costing $1.52 per ton, being eighteen and a quarter cents, or a fraction less than three-quarters of one cent per car mile.

Very truly yours,
(Signed) Ed. Hankinson,
President.

ELECTRIC RAILROAD WORK IN PHILADELPHIA.

The Philadelphia Traction Company has contracted with the Westinghouse Electric Company for the motors and generators for all of the lines which the company intends to equip with electricity. The only line affected at the present time is that on Catharine and Bainbridge streets.

The contract fixes the price for the different sizes of motors which the Traction Company will require, and virtually gives the Westinghouse Company the contract for all the motors that will be needed to equip all of the Traction lines with electricity. As about 1,000 cars will be needed in all, the transaction involves about $1,500,000.

Twenty-one cars will be put on the Catharine and Bainbridge streets line. They are being built by the J. G. Brill Company, of West Philadelphia. The cars will be handsome, and larger than the ordinary street car. Each car will be equipped with two 20 h. p. motors, which will be ample power to propel the car and a trailer, both filled with passengers. The Westinghouse Company will furnish with the motors the other necessary electrical equipment for each car. Two generators, to begin with, will be furnished by the Westinghouse Company, of 250 h. p. each. They will be driven by two 250 h. p. Corliss engines, for which the Wetherills, of Chester, have the contract.

The Field Engineering Company, of New York, has the contract for the street equipment of the Catharine and Bainbridge street lines and work is to begin at once. New rails are to be laid and the very best material used. It is expected that the electric cars will be running by October 1.

TRADE NOTES AND NOVELTIES

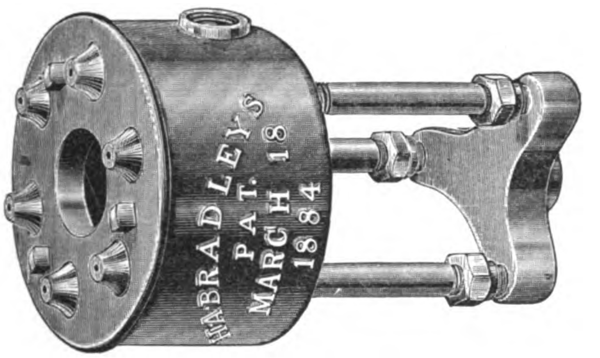
AND MECHANICAL DEPARTMENT.

No wideawake merchant will allow the exploded theory that August advertising is not productive of results, to interfere with his summer trade hereafter. —N. Y. Times.

THE BRADLEY HYDROCARBON BURNER.

THE Bradley gas generator, shown in the accompanying illustration, is a device due to the inventive skill of Mr. Henry A. Bradley, of this city, for the instantaneous and continuous conversion of crude and refuse oils or coal dust into a gas of high heating and illuminating power. Instead of volatilizing and burning the liquid fuel, as is frequently the case in oil burners, the Bradley generator changes the chemical composition of the fuel by introducing steam into a mixing chamber within the apparatus, which at the same time is maintained at a high temperature. A hydrocarbon gas is thus formed which may be stored or used immediately, as desired. The device may be applied to any furnace or retort without drawing the fire, and is claimed to produce gas at half the cost of any other method.

The operation is exceedingly simple. The cylinder of the apparatus is divided into two compartments, into the outer of which oil is introduced by means of the tubes seen in the illustration. Steam is then admitted through an opening in the side to an inner compartment. From this steam chamber project nipples corresponding with, and extending part way into, those from the oil chamber seen at the end of the cylinder. The steam issuing from these openings produces a partial vacuum and draws the oil after it, and at the same time the heat changes the chemical composition of the mixture and produces a rich hydrocarbon gas. The heaviest grade of oil can be used in this apparatus. This oil contains about double the heating and illuminating power of naphtha and costs about one-half as much.



BRADLEY HYDROCARBON BURNER.

As an instance of the readiness with which this burner may be installed, may be cited the case of a New Jersey gas company. One Bradley generator has been placed just within the door of the fire-box, and takes steam from the boiler, while a tank of oil stands at one side and feeds the generator as required. The gas from this is burned immediately and takes the place of the coal fire, supplying heat to six other generators whose output is led to the retort and finally to the gasometer for general use.

Coal dust has also been successfully burned in this apparatus. Inquiries in regard to further particulars may be addressed to the Bradley Gas Generator, care of this office.

THE PACKARD LAMP IN CANADA.

THE PACKARD LAMP COMPANY, Limited, of Montreal, have, for some time past, been quietly engaged in fitting up a commodious factory, Nos. 96 to 100 King street, Montreal, Canada, with the most improved machinery for the manufacture of incandescent lamps. The equipment of the factory is now complete, and the company are making incandescent lamps in all their details, of any candle power, adapted to any base and voltage, which they are prepared to supply to the Canadian trade. These lamps are the latest improved and well-known "Packard High Grade" in all respects similar to those manufactured by the New York and Ohio Company, at Warren, Ohio.

The new company are very fortunate in having their factory under the personal management of Mr. J. W. Packard, with Mr. F. E. Cavanaugh as superintendent; and, with the additional advantage of the established reputation of the Packard lamp, they should be able to command an extensive trade in Canada.

IMPROVEMENT IN STEAM SEPARATORS—THE STRATTON SEPARATOR.

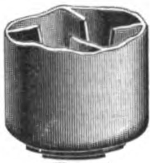


FIG. 1.

WITH the constant and growing demand among engineers for *dry steam* in connection with all power plants, the inventive genius of the engineer has kept pace in providing separators of various designs and merit that may be connected into the main steam pipe going to the engine for the purpose of separating the water, oil or dirt from the steam, so that dry steam free from foreign substances may be supplied to the engine.

Among the various appliances for the purpose stated above, that manufactured by the Stratton Separator Company, 32 Cortlandt street, New York, has won for itself a high place in the estimation of engineers throughout the country that could only be obtained by the real and undoubted merit of the apparatus.

The Stratton separator is based upon the principle that if a rotative motion is imparted to the steam as it enters the separator, all the liquid particles it may contain, being heavier than the steam, acquire centrifugal force and are projected to the outside of the current.

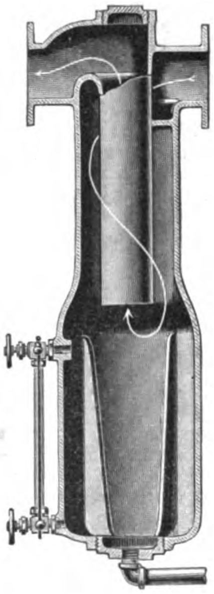

FIG. 2.

Practical results have, it is claimed, proven this theory to be correct, but in some cases where high pressures of steam are used, it was found that the water gauge on the side of the separator would show "full of water," while steam would blow out of the drain pipe at the bottom. While this clearly proves the centrifugal principle of the separator, the force was so great as to hold about the interior walls of chamber a volume of water whirling so rapidly as to be hollow in the centre, allowing steam to blow out of the drain pipe.

To meet this slight objection, the Stratton Company have patented an improvement, as shown in the accompanying cuts, and briefly described as being a centrifugal steam separator provided with wings or plates projecting from the interior surface of the well chamber at an acute angle therewith, and to the course of steam or water thus breaking the whirling body of water and allowing it to settle quietly in bottom of separator chamber from whence it can be drained.

Fig. 2 of above illustrations shows a horizonal view of the separator in section, and Fig. 1 a cross-section of the water chamber showing wings or plates placed at an acute angle to current of the water as described.

The Stratton separator, long favorably known, has gained greatly by the improvement as explained and illustrated above, making it to-day, the makers believe, without question the best and most efficient apparatus yet devised for extracting all entrained water so that *steam absolutely dry* may be supplied to the engine.

THE ELECTRICAL EQUIPMENT CO.

THE above company of Detroit, Mich., J. J. McKenna, general manager, has contracted with A. Saks & Co., of Washington, D. C., to place about 800 lights in front of their building as a special decoration for the approaching Grand Army of the Republic encampment. The contract was secured by the Electrical Equipment Co. on account of its success in decorating the city hall of Detroit for the municipal authorities, last year. The company now have ten men at work preparing special emblems and devices for these decorations.

The equipment Co. has also awarded the contract for wiring the largest private residence in the State of Michigan, that of Mr. David Whitney, Jr. There will be over 1,000 lights in the building, and one of the principal features worthy of note is that there will be no gas piping, and that sole dependence will be placed on electricity.

THE AMERICAN ELECTRO-ENAMELITE CO.

THE above corporation has been formed at Chicago with a capital stock of $250,000, in shares of $100, to make, sell and lease electric heating apparatus and enameled conductors. Among the officers and stockholders are such well-known men as George Cutter, B. E. Sunny, J. S. Cummins, O. H. Olson and Jesse Scribner. It is understood that Mr. Cutter claims a prior and controlling patent on enamel heaters and conductors and that he intends pushing his invention through this new company.

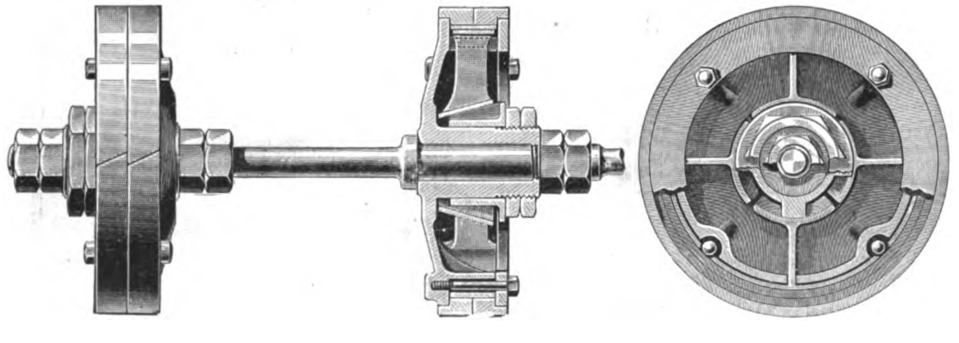
THE HERSHEY ADJUSTABLE PISTON VALVE.

A LARGE experience with piston valves has led to some improvements for which there has recently been granted a patent, covering some of the most essential features in the make-up of a thoroughly practical adjustable piston valve, of any size, limited only by considerations other than its mechanical construction.

These valves have been placed in a number of Ide and Ideal engines of various sizes, manufactured by the Harrisburg Foundry and Machine Works, with the most satisfactory results, the valves ranging in diameter from 6 to 18 inches, in simple and compound engines, under high and low steam pressure, establishing the fact that with ordinary machine-shop appliances, and this form of construction, the highest degree of accuracy and efficiency is obtained, and those conditions readily maintained.

The piston valve has so many practical and commendable qualities that its use is preferred by some of the best engineers to any of the well-known types of balanced valves, especially as applied to marine engines. A solid and chilled piston valve, working in hard cages, all accurately ground, makes an excellent valve, and is entirely practicable in very small sizes, but for the larger diameters it becomes impracticable and dangerous. Assuming, of course, that the valve should be absolutely steam-tight, the necessary close fit to make it tight under high pressures will cause it to stick either when the engine is at rest or under steam, occasionally stripping all connections from valve to eccentric.

To obviate this difficulty, Mr. M. E. Hershey, of the Harrisburg Foundry and Machine Works, Harrisburg, Pa., has designed the valve shown in the accompanying illustration. The primary object of this improved construction is to provide a piston valve which shall be capable of rigid adjustment to compensate for wear, so that the adjustment is maintained throughout the stroke of the valve and while subjected to peripheral pressure in passing over the ports, and which, when the parts are cooled, will contract and prevent sticking or injury to wearing surfaces, as for instance, when the engine is started after a period of rest.



HERSHEY ADJUSTABLE PISTON VALVE.

To accomplish this purpose an adjustable sectional spider is introduced of composition metal or brass, having a greater range of expansion than the metal in the valve proper or its seat. Live steam is admitted between the valve discs and the adjustment made when hot, the normal working condition. When steam is stopped off from the valve and the parts cool, the sectional brass spider contracts to a greater extent than the rest of surrounding metals, and releases the packing rings, leaving them entirely free in their seats. When steam is admitted, the expansion of the spider being proportionately greater, the valves necessarily quickly assume their original adjustment. It is the employment of the metals of varying expansibility that makes the positive valve adjustment practicable. The brass spider, having the greater range of expansion, is so constructed as to be most susceptible to the change of temperature.

By reference to the illustration it will be observed that the peripheral adjustment to compensate for wear does not affect any other adjustments for steam distribution.

ON "AMERICA'S GREATEST RAILROAD."

A PROFUSELY illustrated volume of 392 pages, exclusive of maps, is the latest addition to the literature of the New York Central and Hudson River Railroad. The work contains an enormous amount of cleverly condensed information relative to the cities and resorts on the line of the road and its branches, as well as a list of hotels and a score of minor details. The Adirondack region especially is described by one who knows, and the illustrations, many of which are reproduced directly from photographs, bring back the scent of the woods and the tingle of the crisp mountain air.

By way of frontispiece, is a large folding map of the region of the Great Lakes, showing the entire road together with its connections and dependencies from New York to St. Louis.

A NEW STATION FOR ST. JOHNS, NEWFOUNDLAND.

THE ST. JOHNS ELECTRIC LIGHT CO., of St. Johns, Newfoundland, whose station was completely wiped out at the recent conflagration, have now nearly completed a new brick station on a much larger scale than their old one. This is being equipped by John Starr, Son & Co. Ltd., of Halifax, N. S., with two Leonard-Ball compound engines of 100 h. p. each, two 50-light arc dynamos and one 1.200-light alternating incandescent dynamo, made by the Royal Electric Co., Montreal.

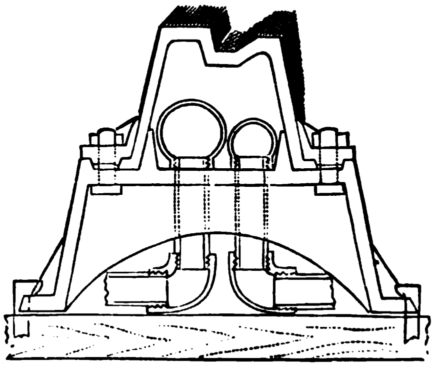
An incandescent plant of the Lahmeyer system has been installed by Messrs. Starr in the machine shops of James Angel & Co. and they have contracted for another of the same system for the new bakery establishment now being built by Messrs. A. J. Harvey & Co. St. Johns will soon rise from its ashes a finer and more modern city than before.

THE WRIGHT RAIL AND CHAIR FOR ELECTRIC RAILWAYS.

THE accompanying illustration shows a new form of rail and chair for electric railway use, devised by Mr. W. H. Wright, of Buffalo, N. Y. This rail is especially adapted to the induction system, although its use is not by any means confined to that system alone.

The two tubes under one of the tracks, shown in the engraving, carry the feed wires, and the power reaches the wheels and the motors through the tracks, coming back through the others to form the circuit.

A company is being formed for the manufacture of the rails, and it is stated that a syndicate of Grand Island property owners have offered a river frontage for a large plant They have offered as an inducement for the company to locate there the necessary land, and will build dock, carry electric cable from the Niagara Falls Tunnel Power Co. to the grounds and will pipe natural gas for the furnaces.



WRIGHT RAIL AND CHAIR.

AN ELECTRIC RAILWAY DEAL AT TROY, N. Y.

THERE are rumors of all sorts in connection with the Troy and Lansingburgh Railway stock, and as yet nothing positive can be stated, writes our Troy correspondent, except the fact that Clark, Dodge & Co., of New York, have been acting for a syndicate of capitalists (names and addresses not given) who offer to take the entire stock of the company on the basis of $225 for each two shares. As each share is of $50 par value, this amount represents, therefore, $225 for each $100 in stock.

It is stated, this week, that the sale is virtually by the company to itself, and that signatures have been obtained for all but 750 shares.

The deal is said to include also a consolidation of the Troy City Railway Co, bringing both companies under one management, but so far nothing definite has been learned, pointing towards such an event.

BIDS FOR AN ELECTRIC PLANT WANTED AT ELKTON, MD.

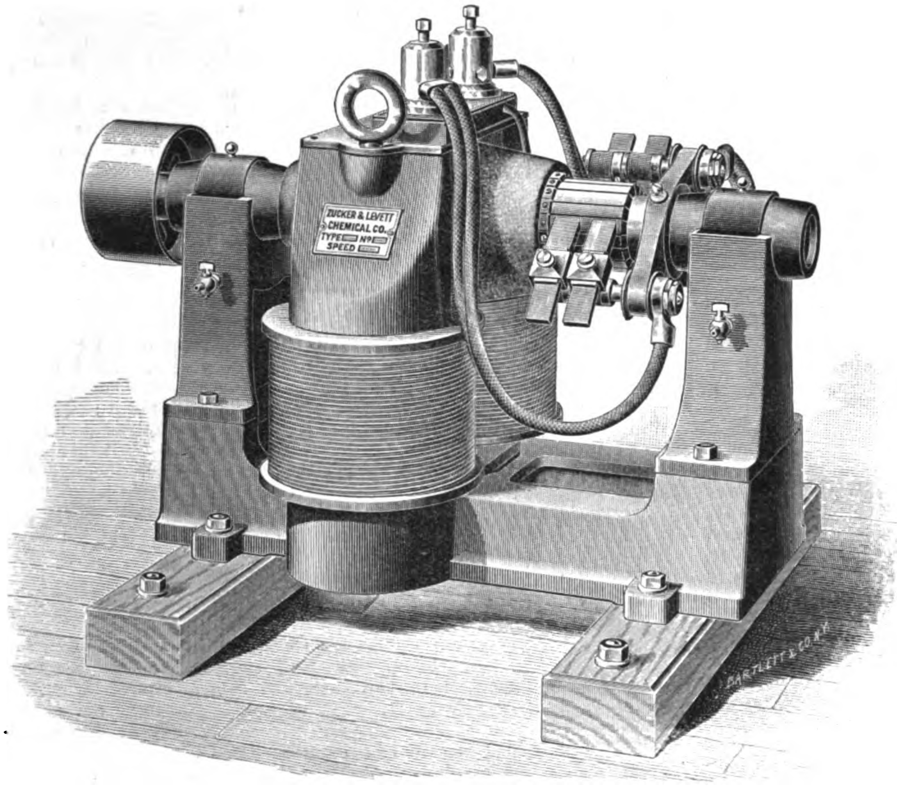
SPECIFICATIONS for electrical apparatus, poles, wiring, lamps, boiler and boiler setting, steam pump and injector, automatic cut-off, steam engine and connections to boiler, and for a power house for the Elkton Electric Light and Power Company are now ready and can be seen at Elkton, Md., in possession of Chas. R. Maxwell, secretary. Sealed proposals will be received at the secretary's office up to September 5, 1892, at 7:30 p. m., for furnishing the above supplies and placing them for use. The company reserves the right to reject any or all bids.

THE NEW IMPROVED AMERICAN GIANT PLATING DYNAMO.

THE accompanying cut illustrates the "New Improved American Giant" dynamo for electroplating and electrotyping, which is placed upon the market by the Zucker and Levett Chemical Co. of this city, and designed by their electrician, Mr. M. Mayer.

The machine is of the inverted horseshoe type, having a laminated field in the smaller, and a special cast iron equal to wrought iron, in the larger sizes. There is also a groove on the end of the bearing shell which prevents the well-known slinging of the oil. The field coils are separately wound on brass spools and are interchangeable. The armature, which is of the modified "Siemens" type, is large in diameter, having very few turns and a large number of sections. The windings of the armature consist of a large number of wires connected in parallel, thus preventing the generation of "Foucault" currents in the coils themselves, and facilitating the winding. The magnetism of the field is very powerful in proportion to the armature, thus preventing all sparking and insuring good regulation.

The machine is practically self-regulating, that is, the voltage is practically the same, whether one or the total number of articles are in the bath; also, the power consumed is exactly in proportion to the load, a very important factor if the coal bill is taken into consideration. The efficiency of the machines is also very high, varying from 75 to 90 per cent according to the size of the machine. The machines are shunt wound, and reversing is impossible. The mechanical details of the machines are very carefully worked out and the workmanship is of the very best. The shafts are short and very large in diameter. The bearings are long in proportion to the diameter and are made of phosphor bronze. The commutators, which are made out of drop-forged copper, are perfectly insulated with mica, and baked to prevent short-circuiting of the strips.



AMERICAN GIANT PLATING DYNAMO.

The brush holders are of an improved pattern and are adjustable in every respect. The brushes can be lifted off the commutator by means of a spring catch provided for this purpose. All other parts are made to standard gauges and are interchangeable.

A large number of these machines have been in use for some time under the most severe tests. They have proven to be most durable and highly efficient machines. There is absolutely no sparking, excessive heating or wear at the commutator or brushes, features which will surely be welcomed by users of plating dynamos.

AT the Troy, N. Y., electric light station, work has been begun on the foundations for the new 500 h. p. engine.

ELECTRIC LAUNCHES FOR THE WORLD'S FAIR.

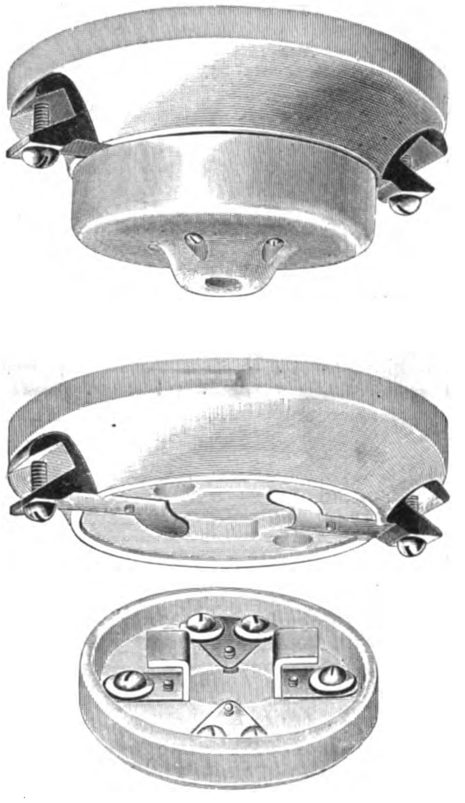
THE ELECTRIC LAUNCH AND NAVIGATION COMPANY of New York, has been awarded the contract for running electric boats on the interior waterways at Jackson Park during the World's Fair. It will pay the Exposition 33⅓ per cent. of the gross receipts. These boats will convey visitors from one point to another or on a general three-mile tour of the grounds, as desired. Such a tour affords some of the finest views of the buildings and grounds, and is sure to be popular.

THE BALL & WOOD CO.

THE BALL & WOOD COMPANY of No. 15 Cortlandt street, New York, are crowding their works night and day to fill their orders, and among the more recent contracts closed was one for two of their large tandem compound engines for Bethlehem, Pa.

THE "IONA" CEILING CUT-OUT.

WE illustrate herewith a new design of ceiling cut-out, the Iona, which is meeting with marked favor among electric light men. As will be seen from the cut, the cap which holds the fuse is fastened to the base by a long clip interlocking with the V-piece of the cap; but this is further fastened by a phosphor bronze spring, making a connection absolutely positive and secure, while obviating the inconvenience of screws. This cut-out is being placed on the market by the Redding Electric Co., 41 Federal street, Boston.



"IONA" CEILING CUT-OUT.

A $35,000,000 CENTRAL STATION.

THE INTERNATIONAL ELECTRIC LIGHT CO., now in process of formation, propose to utilize the power of the Niagara River above the falls to furnish current to all the principal cities in the United States and Canada. The prospectus of the company states that the central station will be three times as large as any other building in the world, and will cost about $35,000,000.

THE RIES REGULATING SOCKET.

A LITTLE pamphlet, whose cover is resplendent with the national colors and the representation of a Ries regulating socket and lamp in silver, has been issued by the Ries Electric Specialty Co., of Baltimore. The pamphlet contains eight pages of reading matter calling attention to the various advantages of this socket and giving reasons why it should be adopted wherever the alternating current is used.

NEW YORK NOTES.

The Short Electric Railway Co. through their general Eastern agent, Mr. Edward J. Wessels, have just closed contracts for a 183 h. p. generator and four 30 h. p. single-reduction motors for the Syracuse, Eastwood Heights & DeWitt Railroad Co., of Syracuse, and also a double equipment of 20 h. p motors for the Hartford & Wethersfield Horse Railway Co , Hartford, Conn.; also seven double equipments of 20 h. p. single-reduction motors for the Trenton Passenger Railway Co., Consolidated, Trenton, N. J. This last is an additional order as the company has equipped its entire line with Short generators and motors and gave this additional order after finding how satisfactorily the apparatus worked.

The Havemeyer Building, which is the handsomest office building now being erected in New York City, is going to be equipped electrically in the most perfect manner. It will have an installation of over 3,000 incandescent lamps. The wiring will be done in interior conduits throughout, and the generating plant will be of the most modern type, the dynamos being directly coupled upon the shaft of the engine. The contract for the entire electrical equipment has been awarded to H. Ward Leonard & Co.

The Edison Electric Illuminating Co., of Brooklyn, have decided to build a new plant, and have adopted the plans of the Berlin Iron Bridge Co., of East Berlin, Conn. The building will be 74 feet wide by 100 feet long with brick wall, the roof being the Berlin Company's well-known patent anti-condensation corrugated iron construction. The floor space will be controlled by a traveling crane having a capacity of eight tons, which crane will also be furnished by the Berlin Company.

Mr Avery P. Eckert, of 203 Broadway, has returned from a highly satisfactory business trip through Canada, New England, New York and Pensylvania, in the interests of Kerite. He reports the outlook as bright. While in Ottawa, Mr. Eckert saw some Kerite wire that has been exposed to all the variations of temperature for the past twelve years and is still giving good service.

A. M. Mason is carrying on at 366 Myrtle avenue, Brooklyn, the battery, motor and medical supply business established by James H. Mason. The concern has just issued a neat and useful pamphlet devoted to the Mason specialties. It can be had, with cash discount sheet, on application.

NEW ENGLAND NOTES.

Mr. R B. Pierpont, formerly manager of the Chicago branch office of the Gould-Watson Company, has resigned his position, and has formed a co-partnership with Mr. James W. Longstreet, under the firm name of Longstreet, Pierpont and Company, with offices in the Exchange Building, 53 State street, Boston. The new firm in addition to the transaction of a general banking and brokerage business, will make a specialty of handling electric street railway and electric lighting securities and municipal bonds, and are prepared at any and all times to purchase first-class securities, and will be glad to communicate with companies contemplating the issue of bonds. Mr. Pierpont needs no introduction to the electrical trade, having been connected with that business for a number of years, and it is needless to say, has made in that time many friends who wish him success in his new venture. Mr. Longstreet has for many years been connected with the banking and brokerage business. He is the nephew of D. F. Longstreet, formerly general manager of the West End Street Railway Company, of Boston, and is well known in railway circles. The new firm will be pleased to have any of their friends make their headquarters with them while in the city, and will be glad to extend any courtesy in their power.

Waterhouse Brothers, of Hartford, Conn., are issuing one of the most tastefully designed pamphlets ever gotten up, to show the construction of their arc lamps for either arc or incandescent circuits. The cover is of plain white paper, with a heavily embossed cut of the lamp, in black, gold and silver, which gives it an extremely handsome appearance. The cuts in the inside of the book show the details of the construction of the lamp, and point out well the numerous valuable features which the lamp possesses.

The Pettingell-Andrews Company, of Boston, are issuing a large number of the new catalogues of the Bryant Electric Company, of Bridgeport, for which company they are agents in New England. The new catalogue is very handsomely gotten up, and comprises cuts of every kind of single and double pole switch, plain and ornamental, sockets, rosettes, cut-outs and other useful novelties. The book is well worth having and will be found useful.

WESTERN NOTES.

Clark & Marshall are in communication with several Eastern firms for the Western agency for several good specialties which they will soon have on the Western market.

The American Manufacturing & Engineering Co. are to be congratulated on securing the agency for the Hewett oil insulator, which was described and illustrated in The Electrical Engineer of March 30 and May 18. Their rights cover all territory east of the Alleghanies. Recent tests have proven the Hewett Insulator to be all that is claimed for it. Information regarding this radical departure in insulators is cheerfully given on application to the company.

South Pittsburg, Tenn.—The South Pittsburg Electric Light & Power Co. is doing a good business despite the recent depression in Southern trade and industry, and has declared a semi-annual dividend of 5 per cent. payable at once. Geo. E. Downing is president; J. C. Beene, vice-president; W. B. Garrett, secretary and treasurer, and W. N. Shelley, electrician.

The Enterprise Electric Co., No. 313-315 Dearborn street, Chicago, have just been appointed Western agents for the Holtzer-Cabot fan motors. These machines are some of the handsomest ever put on the market, and are meeting with the same favor in the West that has already been accorded them in the East.

Mr. E. R. Crolius, who is well known in electrical circles throughout the West from his connection with the supply and fixture trades, has associated himself with the Chicago Electrical Manufacturing Co., as their manager, and will be pleased to see his friends at Nos. 73–75 West Jackson street, Chicago.

The Buckeye Electric Co. report that their business is increasing to such an extent that they are putting on additional help as fast as it can be secured. The Western States contributed some large orders during the past week. Their coiled filament lamp is meeting with great favor.

The Hall Signal Co. will use 125 miles of Simplex wire for their block signals on the Illinois Central Railroad at Chicago. This, together with the 270 miles used for the same purpose on the Chicago and Northwestern Railroad signals, a point for Simplex.

Mr. Lucius T. Gibbs, consulting engineer to the Pabst Brewing Co., of Milwaukee, has recently closed a contract with the Siemens & Halske Co. for two 2,500-light dynamos and one 1,000-light dynamo. These are to be run by Lake Erie engines.

PHILADELPHIA NOTES.

The La Roche Electric Works are very busy on several very large orders for both arc and incandescent plants. They report the following recent sales in this city: Standard Theatre, 500-light plant; Standard Iron Foundry, 500-light plant; Moore's Windsor Hotel, 100 light plant; J. and G. Rich, 75-light dynamo; R. H. Miller, 50-light dynamo; N. S. Miller, 30-light dynamo; Star Electrix Co., 100-light alternator; Richard Hay & Sons, 100-light dynamo; Falwell Bros. & Co., 100 light plant. They have also sold plants and apparatus to the following out-of-town parties: I. S. Champion, Ocean City, N. J.; Wm. Hallowell, Hatborough, Pa.; Crescent Paper Co., Marsailles Ill.; James McGrew, Chicago; Lake Bluff Hotel, Lake Bluff, Ill.; Vienna Cafe Co , Chicago, and Charles C. Lockstaldt, Chicago.

Pepper & Register.—The above firm of electrical and mechanical engineers, Provident Building, Philadelphia, have secured the contract to build the Easton, South Easton and Phillipsburg Electric Railway, now consolidated, and called the Easton Transit Co. Work will begin not later than September 10, and is to be completed by Thanksgiving Day.

Messrs. Wright & Starr have contracted to furnish William Sellers & Co. with twenty Waddell-Entz motors ranging in size from 5 to 40 h. p. Most of these motors will be used in operating traveling cranes, of which this company make a specialty.

The Pennsylvania Electric Engineering Co. have the contract for equipping a trolley system for electric cranes for the Midvale Steel Company, and are doing all the wiring about their buildings.

CANADIAN NOTES.

Messrs. H. P. Dwight, the president, and G. D. Perry, the secretary of the Great Northwestern Telegraph Co.; F. H. Waycott, the manager of the Anglo-American Telegraph Co.; Wm. Wainwright and F. Roper have given notice to the Quebec Legislature of application for incorporation under the name of the Anglo-Provincial Telegraph Co., with a capital of $25,000. This company will carry on a general telegraph business in the province of Quebec, with headquarters at Montreal.

A factory is being fitted up at Ottawa, Canada, for the manufacture of the Beacon incandescent lamp.

☞ Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.

THE
Electrical Engineer.
VOL. XIV. AUGUST 31, 1892. No. 226.

THE ELECTRIC AND GAS PLANT AT PLATTSBURGH, N. Y.

ONE of the most interesting electric light stations in New York State is that of the Plattsburgh Light, Heat and Power Co. A solution has been reached, or at least attempted, of the problem of combining services that would appear to be injurious to each other, and of operating them in harmony and prosperity. The company owns both the gas and electric light plants, and so far from aiming to promote the popularity of one at the expense of the other, is seeking to get the best results out of the two illuminants, and, while giving satisfaction, to earn the largest possible dividend. The following brief illustrated sketch of the company and its work will be found instructive.

The electric light plant is situated on the banks of the Saranac River, from which power is taken, about half a mile from the centre of the village. The building is of stone and brick 40 feet wide by 160 feet long. A view of it is given in Fig. 1, which also shows the dam headgates and flume. The flume runs clear across the end of the building, inside, and in it are placed three Hercules wheels of 99 h. p. each, with ten-foot head. Each wheel is operated separately, and is provided with a governor. The wheels are vertical, and are geared to a jack shaft above the flume, and below the floor of the dynamo-room. They are belted from jack shaft to countershaft on the floor of the dynamo-room, which is shown in Fig. 2. The countershaft is divided into three sections, and each section is provided with friction clutches. The belts from the pulleys on the jack shaft of the water-wheel to the pulleys on the countershaft are provided with belt releasers, so that steam power can be used alone if desired. The Hill friction clutch and steel rim pulleys are used.

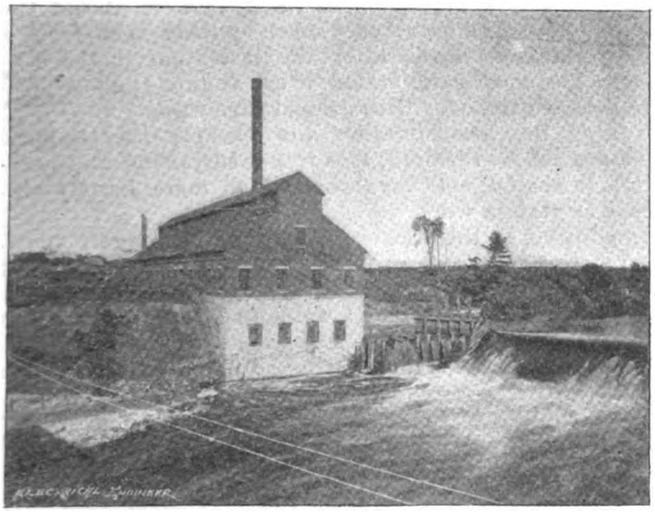


FIG. 1.—WATER POWER OF THE PLATTSBURGH LIGHT, HEAT AND POWER CO.

The steam generating plant comprises two boilers of 130 h. p. each with pumps and injector. The electrical plant proper consists of three Westinghouse alternators of 750 lights capacity each, and two exciters; and two Excelsior arc machines of 45 lights capacity each, all of which are shown in Fig. 3. There are three incandescent circuits, all of which run to one centre of distribution, the extreme end of one circuit being one and a half mile from the station. The power plant was well designed and installed by the Lang & Goodhue Manufacturing Company of Burlington, Vt.

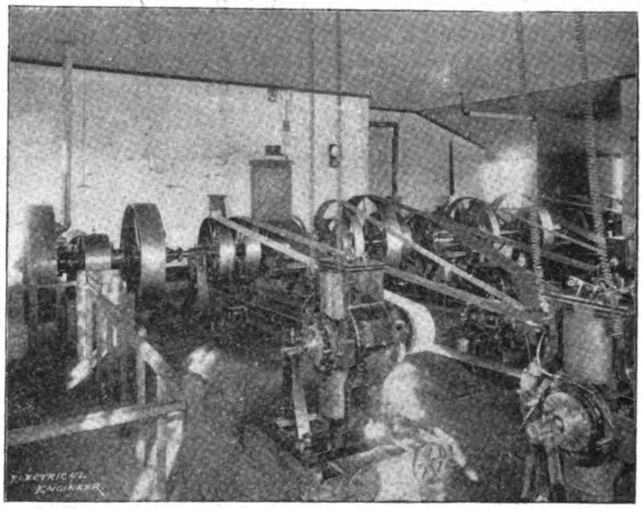

FIG. 2.—DYNAMO-ROOM SHAFTING, PLATTSBURGH STATION, N. Y.

The policy of the Plattsburgh Company is to supply gas and electric light at the lowest possible price, and at a rate so that one will not compete with the other. This end has been arrived at as follows: The price of gas was placed at $2.10 per 1,000 cubic feet, with a discount of ten cents per 1,000 feet for prompt payment, making the net rate $2 per 1,000 cubic feet. The gas being of not less than 20 c. p. to a five-foot burner, this brings the price down to one cent per hour for 20 c. p. gas lights. The company now sought to place the incandescent electric light on the same basis as gas, holding the opinion that the majority of consumers care little of the advantages of one light over the other, except in case of price, and that they will always want the light that gives the most illumination at the least possible expense, regardless of other considerations. To meet the cost of a gas burner consuming five cubic feet per hour and giving equal to 20 c. p. at a cost of one cent per hour, the company placed the price of incandescent light at one cent per lamp hour for a 16 c. p. lamp with a discount of 25 per cent. for prompt payment, which makes a net rate of ¾ of a cent per hour for 16 c. p. incandescent electric light as against 20 c. p. gas at one cent per hour, or practically equal for the same illumination. The plan appears to have worked admirably, as there is a remarkably general use of the incandescent light in residences, and yet its introduction rests wholly with the consumer, primarily on the ground of equal cost, and secondarily because of ulterior advantages.

The total number of incandescent lights now wired is equal to 3,000 16 c. p. lamps and is daily increasing. Over fifty dwelling houses have been wired. All inside wiring is done at the expense of the consumer.

The amount of current used is determined by the use of meters. The Westinghouse-Shallenberger meter is used, and meter rent is charged.

The gas plant comprises two complete sets of apparatus for the manufacture of water gas with scrubbers and purifiers and holder capacity of 10,000 cubic feet, which is inadaquate, and it is proposed to erect a large holder at the location of the electric plant, and to remove the apparatus to the same place. The annual output of gas is 4,000,000 cubic feet. Gas for cooking purposes is sold at $1.50 per 1,000 cubic feet, while gas stoves are supplied to consumers at actual cost, and a number are now in use, giving satisfaction.

The Plattsburgh Light, Heat and Power Company was organized in December, 1889, for the purpose of supplying gas, electric light, heat and power to the citizens of the village and town of Plattsburgh. The incorporators were Messrs. A. L. Inman, general manager of the Chateaugay Ore and Iron Company; John H. Myers, president of the Iron National Bank; S. A. Kellogg, judge of the Circuit Court, all of Plattsburgh; H. M. Pierson, gas engineer of New York City, and George M. Cole of Plattsburgh. The officers of the company are A. L. Inman, president; J. H. Myers, treasurer, and George M. Cole, secretary and manager. The above named and Messrs. Kellogg and Pierson comprise the board of directors. On January 1st, 1890, the company acquired the plant of the "Plattsburgh Electric Company" and the plant of the "Plattsburgh Gas Works," consolidating the interests in the manner already described.

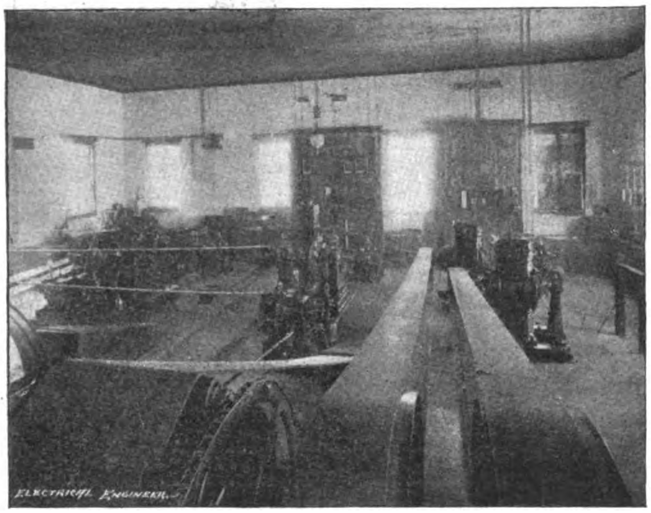

FIG. 3. DYNAMO ROOM, PLATTSBURGH STATION, N. Y.

WATER-POWER IN SWITZERLAND.

A PLANT has recently been erected to utilize the falls of the Valoirette, a tributary of the river Arc, near Mont Cenis. Near the confluence of the two streams a canal, 2,625 feet long, 6½ feet wide and 3¾ feet deep, has been constructed to the reservoir. The canal has a fall of 0.22 per cent., and passes 106 cubic feet of water per second. The entire hydraulic plant is capable of supplying 6,000 h. p., but at present only one establishment—an aluminum factory—has been connected with the reservoir. Connection is made by a 24-inch pipe line sufficient to generate 1,000 h. p. One turbine is connected to a dynamo running at 135 revolutions, and giving an output of 4,000 amperes at 500 volts.

SOME ADVANTAGES OF GRAMME ARMATURES FOR STATION GENERATORS.

BY

Lucius [illegible]

IT is noticeable, though drum armatures have been considered electrically more efficient, that the Gramme type is obtaining much favor because of the accessibility and cheapness as well as the reduction in speed and sometimes of weight which its use permits.

While time is showing how great an enemy to the life of a dynamo is the destructive factor, heat, it may be allowable to emphasize what seems to be one of the most important advantages of the Gramme ring type of armatures, viz., the ability to dissipate internal heat quickly.

Few of the older stations have dynamo-rooms with anything like proper ventilation. In warm climates, stations not systematically ventilated are sometimes unbearable. In several such, where drum armatures were in use, repeated cases have come under my observation of armatures burning out while starting up in the morning, before even the normal E. M. F. had been reached.

These instances almost invariably followed after a particularly hard day's work, when the armature had been stopped on the previous night in a sizzling condition.

A close inspection showed that the cause had been, in all probability, the carbonizing of the insulation on the conductors.

These instances recurring always at starting seemed to show conclusively that the baking received by the armature in its own heat on the previous night had been the last straw needed to break down the insulation.

Usually the paper insulations in the core were loosened and charred, while the wooden or other coverings at the ends were mere pieces of charcoal, the result of slow combustion. Clearly enough, here in these ill ventilated stations the Gramme type would have had unquestionable advantages that should have prevented such untimely deaths by slow combustion.

With the amount of surface exposed and the draft of air kept up constantly by the "spider" of a Gramme ring it is difficult for the heat in the core to become sufficient to carbonize the insulation, and when the dynamo is at rest the internal heat disappears very much quicker than from a drum armature. Even after the insulation in the conductors has much deteriorated, it can endure the low pressure between the coils with comparative ease.

Taking into consideration how cheaply the Gramme armature can be repaired, it is rather surprising that heretofore it should not have been much more largely employed in station work.

In addition to this, the economy of a thoroughly ventilated station free from grit, dust and bituminous coal-soot seems no less evident.

It would doubtless be of value to learn from various comparisons of the two forms of armatures under like conditions, what is the actual average difference in length of life.

AN ELEVATED RAILROAD FOR BOSTON.

THE *Journal* says that a syndicate of New York and Philadelphia capitalists has been trying to secure the passage of a bill which will give them the right to build an elevated railroad in Boston and its suburbs. It is said that the men behind the movement are the same who recently purchased the Belt Line, Lynn and Boston, and Naumkeag and Essex roads. Capt. Griffin of the General Electric Company is mentioned as being in the syndicate.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY—XI.[1]

BY

A. E. Kennelly

STRESS DISTRIBUTIONS—(*Continued.*)

As a case next in order of complexity, we may consider a wire bent into the form of a square with length of side l, but so situated that the normal to its plane makes an angle θ with the direction of a uniform field of intensity B. This differs from the case last considered only in the departure of θ from 90°.

Let B be withdrawn, and a current of uniform strength C pass steadily through the wire. The compression on the wire's substance, and the stress acting on the sides of the square, tending to force them outward—systems 1 and 2, according to the results of the preceding chapter—are evidently unaffected by the direction of the plane assumed by the square in space, these forces being only dependent on the distribution of current.

Now introduce the external flux B, whose direction, indicated by the arrow O B, makes an angle θ with the plane normal O N, Fig. 27, drawn positively, or upwards from the plane, on that side which presents the current as flowing counter-clockwise, and its magnetic potentials therefore positive. We may first assume that θ is less than 90°. By rules already discussed, the resultant force on the sides A C and D E will be the vector products of the currents through those sides into B, or numerically $C B l \cos\theta$ dynes in the plane of the square, as represented by the arrows at c and d. Upon the sides A D and C E, B acts perpendicularly, so that the stress it produces on each is numerically $B C l$ dynes in the directions perpendicular to both wire and B, as shown by the arrows a_3 and e_3. These forces make an angle θ with the plane of the square, but resolving into components in and normal to this plane, there remain forces $B C l \cos\theta$ dynes acting along a_1 and e_1 outwards, and $B l \sin\theta$ dynes along a_2 and e_2, tending to rotate the square about an axis in its plane, which, by symmetry, must connect the middle points c d, of A C and D E.

These results may also be reached from a slightly altered point of view. B may be resolved into two components,

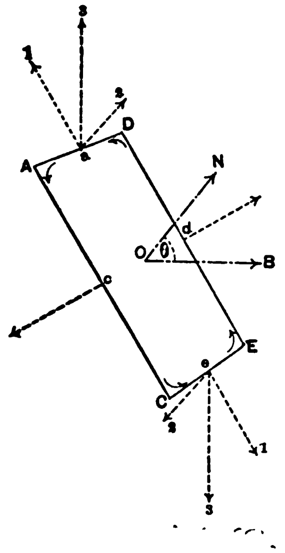

Fig. 27.

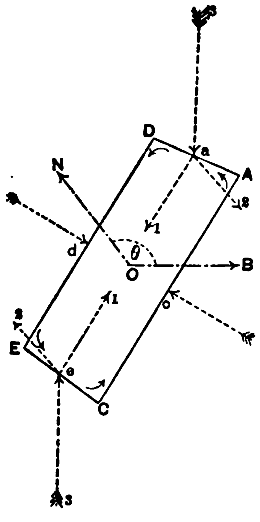

Fig. 28.

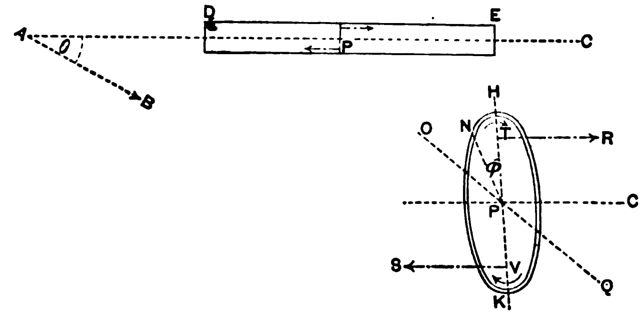
one $B \cos\theta$ normal to the plane, the other $B \sin\theta$ lying in the plane. The resultant stresses produced by $B \cos\theta$ on each side of the square are all directed outwards with side resultants $B C l \cos\theta$. The stresses produced by $B \sin\theta$ are $B C l \cos\theta$ upon the sides A D and C E in the directions c_2, e_2, and the remaining sides A C and D E, parallel with this component, are unaffected by it.



Figs. 29 and 30.

If then the resultant system of flux distribution from C and B were completely mapped out, and the consequent stress distribution in virtue of $\frac{B^2}{8\pi}$ duly determined, there would be equilibrium at all points everywhere outside the wire, while the effect on and in the wire may be represented by four systems of forces. The first two, pertaining only to C are the above-mentioned compression and outward push in the plane. The third will be $B C l \cos\theta$ on each side, also directed outwards, and the fourth will be a couple of moment $B C l \sin\theta$, tending to rotate the whole square about its central line c d.

The direction of rotation would be such as to bring the square perpendicular to B, or in other words diminish the angle θ; and if the square were actually constructed as a rigid frame pivoted on an axis through c d, it would be necessary, excluding the consequences of pivot friction, to apply a couple of $B C l^2 \sin\theta$ dyne-centimetres to the frame to maintain its equilibrium under these conditions.

Fig. 28 represents the similar stress system when the angle θ exceeds 90°, so that the flux from the local circuit is opposed to B within the square. In the equivalent quadruple stress system for this case, the first two components regarded from the normal O N are unchanged, but the last two are reversed. $C B l \cos\theta$ now acts on each side inwards, and $C B l \sin\theta$ acts on A D and C E in the directions of the arrows a_2 and e_2, forming a couple $C B l^2 \sin\theta$. This couple tends to rotate the plane first into parallelism with B, and then to continue the rotation through the angle θ until the normal O N coincides in direction with B.

We may apply these principles to the case of a rigid, active solenoid of N turns, pivoted in a uniform exterior flux. This is represented in Fig. 29, where D E is the section through the axis of the solenoid, which is pivoted about its centre of figure P, so as to be capable of revolving as a rigid body in the plane of the paper, about a pivot line through P. The current of C units supplied to the helix in such a manner as not to influence its rotatory freedom, circulates clockwise as viewed from A, so that A B C is the positive direction of the solenoid's axis. A uniform prime flux of intensity B, directed in the plane of the paper, as shown by the arrow A B, makes an angle θ with A B C.

If we withdraw B for a moment, it is evident that the flux in the circuit of the solenoid will bring a system of stress to bear upon its walls. As a rigid body, the helix can undergo no distortion from these, and by symmetry, they cannot tend to rotate it. We may therefore banish them from present consideration. Now restoring the exterior intensity B, we may resolve this into components $B \cos\theta$ along the solenoid, and $B \sin\theta$ perpendicularly across it. $B \cos\theta$ will only produce a radial outward stress on each turn of wire in its own plane, an influence that the rigidity of the walls will keep in check. $B \sin \theta$ will set up a couple in each turn.

---

[1] *Copyrighted, 1892, by A. E. Kennelly.*

To examine this effect more closely, a single turn of the solenoid is represented, in Fig. 30, to a larger scale; P C is the axis, O Q a line through the axis perpendicular to the component $B \sin \theta$. which acts in the direction H P K. Upon all elements of the turn situated on the same side of O Q as H, the vector force set up by $B \sin \theta$ on C, will be parallel to the axis and in the direction of the arrow T B; while with those on the other side the force will follow the opposite direction, that of the arrow V S. At the points H and K, a small element of the wire, $d\,s$, meeting $B \sin \theta$ at right angles, will be urged with a force $C\,B \sin \theta\, d\,s$ dynes; on elements at O and Q, the force will be nil, and at any intermediate element, such as N, whose position angle N P H is φ, the force will be C B $\sin \theta\, d\,s \cos \varphi$. If all these elementary forces be summed round the circle (whose radius is r), the total force will be $2\,C B \sin \theta\, r$ dynes in each semicircle. This total force applied at the points T and V, whose distances from P are each $\frac{\pi r}{4}$ will be the resultants of the elementary system.

Since each turn of wire will contribute an equal pair of resultants, the total forces referred to the mid-plane of the solenoid will be $2\,N\,C\,B \sin \theta\, r$, at distances $\frac{\pi r}{4}$ on each side of P. The moment M of this couple will therefore be

$$2.2 N\,C\,B\, \sin\theta\, r . \frac{\pi r}{4} = N\,C\,B \sin \theta\; \pi r^2 = A\,N\,C\,B \sin \theta,$$

where A is the area of cross section, and if a pulley of radius R were attached to the pivot axis at P, it would be necessary to apply a force of $\frac{M}{R}$ dynes, or $\frac{A\,N\,C\,B \sin \theta}{981\;R}$ grammes weight at the periphery of the pulley, in order to maintain the coil's equilibrium, assuming the absence of pivot friction.

To take numerical values that might be readily attainable experimentally, if $N = 500$ turns, $B = 1{,}000$ C. G. S, $A = 2$ sq. cms., $C = 2$ amperes or 0.2 C. G. S., $\theta = 30°$, so that $\sin \theta = 0.5$, we have for M, $2 \times 500 \times 0.2 \times 1{,}000 \times 0.5 = 100{,}000$ centimetre-dynes.

A solenoid in a uniform prime flux, experiences therefore, no tendency to translatory motion, but only to rotation; (a tendency to translation would in general be set up if B were not uniform). This rotatory tendency, or moment M, for a given solenoid, exciting current, and prime flux B increases with the deviating angle θ, varying at its sine, from unity when B lies across the solenoid, to zero when B is in line therewith.

Further, the formula for M takes no cognizance of the shape of the solenoid, which is represented simply by the area turns $N\,A$. It might be short or long, thick or thin, the moment would be the same so long as $N\,A$ remained unaltered. The rotatory power of a solenoid carrying a given current in a uniform prime flux, therefore depends only on its total area turns, and a single-turn of 50 sq. cms. will exert the same force as 20 of 2.5 sq. cms. each. These turns need not be all equal of size, provided that they are all concentric; ten in the inner layer might have 2 sq. cms., the outer layer of ten having 3 sq. cms., the sum of the area turns would remain 50. Strictly speaking, this assumes that the wire is filamentary; but if the diameter of the wire is sufficiently great to introduce sensible error, further approximation may be attained by supposing the wire to be subdivided into filaments sharing the current, and summing the area turns again on this basis. The proposition may be true even if the turns be not circular, for it is evident that they may successfully vary in size and shape, if each is symmetrical about a line in its own plane perpendicular to the component $B \sin.\ \theta$ and that all the successive median lines lie in one plane, which will be a plane of symmetry for the coil. Whenever such symmetry is preserved, as is usually the case in practice, the moment of rotatory force is $C\ B \sin \theta$ multiplied by the area turns for the coil.

These are characteristic of the behavior of magnets temporary or permanent in a uniform prime flux. They tend to set their own local and internal flux parallel with that in the exterior field, and the tendency to this alignment, the moment of restitution, is proportional to the sine of the deviating angle. A uniformly magnetized rod is in fact equivalent to a solenoid of the same dimensions carrying a number of current turns that will produce the same magnetic potential difference between its terminal planes, as actually exists between the rod's extremities. In practice, magnets are seldom shaped like solenoids, and are never quite uniform in magnetization, but whatever their shape, and however irregular the space disposition of their M. M. F., there will always be some combination of superposed solenoids of various lengths, shapes, and excitations that would form their magnetic equivalents, so that all problems connected with magnets are reducible, ideally at least, to cases involving only the corresponding virtual solenoids.

All these stress distributions are subject to a general law, whose recognition tends to connect and coördinate their various consequences. In any loop, or coil of wire carrying a current, there is as we have seen, a flux $F = \frac{M}{R}$. If flexible or extensible, the loop will tend by its motion to augment F, by reducing R. It will not only compress the wire so as to shorten the paths immediately encircling it, but the loop will spread into a circle, the form of minimum reluctance for a given length of conductor, and radially extend that circle until held in check by mechanical forces. Similarly, when the loop is subjected to the flux from an external magnetic circuit, it will tend to enclose a greater total flux, and to move to a position wherein F may become a maximum. Magnetic equilibrum whenever attainable in other positions will be unstable.

INSULATED ELECTRIC CONDUCTORS[1]—VIII.

BY

James Bowstead Williams

Shellac.—Found upon twigs and extreme branches of trees growing in Arabia and other parts of the Orient are crusts of resinous matter which, when gathered, are known as *stick lac.* When this stick lac has been boiled in an alkaline solution and the coloring matter removed it is then called *seed lac;* and when this second product has been melted, strained, and poured upon smooth hard surfaces to cool, the resulting thin scales form the *shellac* of commerce. When pure, shellac is one of the most important insulating materials known on account of its high specific resistance, its durability and value as an ingredient of rubber compounds and insulating paints; but, as sold, it is almost always adulterated with rosin. If the rosin used for adulteration be pure, the specific resistance of the shellac is not materially lowered, but its durability is affected in proportion to the amount of rosin used.

Ordinary shellac is not a pure resin but contains wax, gluten, etc., in varying proportions. To obtain the highest insulation of the shellac, the resin must be separated from these other bodies. This can be done in various ways. One process of extracting the resin consists in first dissolving the seed lac in alcohol and letting the impurities settle; then filtering the solution and allowing the filtered liquid to drop into distilled water; and lastly collecting the resin and drying it in a current of warm dry air. If the resin is to be applied in solution, *e. g.*, to saturate paper used in the manufacture of condensers, or to varnish the surfaces of hard-rubber or glass pillars, it is dissolved in absolute alcohol.

---

[1] *Copyrighted* 1892, *by J. B. Williams.*

The resin can also be extracted from seed lac by dissolving the latter in pyroacetic ether, which dissolves out the resin only. To apply as a varnish this solution should be diluted with absolute alcohol, as the ether evaporates too rapidly when used alone.

Shellac and, in fact, all resins should be carefully strained or filtered before being used for insulation, in order to remove bits of wood and other foreign matters which exist in all commercial resins. Colophony becomes quite fluid when sufficiently heated, and can then be passed through a filter press or other filtering apparatus; but shellac cannot with safety be made sufficiently liquid by heat, and should therefore be passed through the filtering apparatus while in solution in alcohol or other suitable solvent.

The following items of importance regarding shellac and its uses have been obtained from experiments made by the writer, and are here given as they may be of interest or use to the profession:

1. Shellac does not unite, by melting, with the asphaltes or petroleum, and should not be used in compounds containing such substances if the compounds are to be mixed and applied while in a melted state. This statement does not apply to rubber compounds containing asphaltum, which are mixed and applied while in a plastic state.

2. If it is to be added to any kind of compound containing rosin, the best results will be obtained if the rosin and shellac are combined by heat, the rosin being melted first, and the combination of the resins then added to the other ingredients. When thus used it will, if in sufficient quantity, often remove the stickiness of compounds containing a large proportion of rosin.

3. When finely powdered it can be used as an ingredient of almost all rubber compounds, as it does not attack the rubber when heated.

4. If dissolved in alcohol or linseed oil it combines with other substances which have been dissolved in the same solvents; otherwise, it is generally precipitated.

5. It requires about five hours to fully dissolve in boiling linseed oil.

6. It will combine with paraffine by prolonged heating and stirring if the paraffine does not exceed one-fourth of the weight of the shellac. Such combinations are very durable, and form excellent ingredients for rubber compounds.

7. It combines with most of the resins, if they are in a melted state before it is added.

8. It should never be used alone, or in composition of which it forms the principal ingredient, on any bodies which are alternately heated and cooled, as it is certain to crack and loosen from them.

9. When melting shellac, always use as low a temperature as possible. Most resins can be melted several times and at comparatively high temperatures without injury, but this is not the case with shellac.

10. Shellac readily dissolves by boiling for a few minutes in an aqueous solution of borax or other alkali. But such solutions, while forming excellent cements for various purposes, are of no practical value for insulating purposes unless, after their application and drying by artificial means, they can be *kept* dry. No substances which are applied by means of alkaline solutions and no substances which are soluble in water make efficient insulating material, when used alone, for they invariably absorb moisture when exposed to the atmosphere, even though they may have been baked after their application to fibrous material.

ELECTROSTATIC DISCHARGES.

BY

Philip Atkinson.

Forty years ago, when the fluid theory of electricity was popular, and the one-fluid and two-fluid theories were earnestly discussed, the burr projecting in opposite directions on opposite sides of a card or book perforated by an electrostatic discharge was relied on as a strong point in favor of the two-fluid theory. In Dr. Morton's article on the "Nature of Electric Currents" in The Electrical Engineer of July 20, the same experiment is adduced again in proof of the dual nature of the electric current and the simultaneous movement of electricity in opposite directions, and certain peculiarities in the perforations noted, which he has observed, which seem to sustain this theory and also to indicate a spiral movement of the current.

Having performed this experiment many times and carefully noted the results, I have been led to reject the theory which attributes the double burr to two electricities moving in opposite directions, and to adopt the simpler and more rational one of electric induction and difference of electric potential.

The most striking results are obtained by discharging a Leyden jar or battery through a book or tablet of 50 or more sheets, though the characteristic double burr will be observed when the discharge takes place through a single sheet held between the poles of a Töpler-Holtz machine. The phenomenon is easily explained on the following simple principles. Assuming that electricity is a manifestation of that universal energy which exists in matter, we find that when a difference of potential is produced between the coatings of a Leyden jar or battery by a charge from a static machine, the energy accumulated on one coating is exactly equal to that taken from the other, producing the relative electric conditions known as positive and negative. If now the two coatings be connected by a discharger, one knob of which is in contact with the outer coating, and a book, placed in contact with the other knob, is brought quickly into contact with the knob of the jar, the discharge and perforation will take place; the electric energy employing the paper and discharger as its medium of transfer from positive to negative to restore the equilibrium. As paper is a very imperfect conductor, the discharge is confined to a limited space surrounding a straight line between the knobs; and the electric potential of the paper being zero, is higher than that of the negatively charged coating and lower than that of the positively charged coating; and by virtue of this difference of potential the leaves, on opposite sides, are attracted outward in opposite directions and torn, producing the double burr; being oppositely electrified by induction from each surface inward.

It is important to distinguish between the movement of electric energy and of electrified matter. Electric energy always moves from higher to lower potential, but electrified matter moves, or tends to move, either from higher to lower potential or from lower to higher, with equal facility; oppositely electrified masses being mutually attracted by their difference of potential. Hence while the electric charge, in the above experiment moves from the positive to the negative coating, the paper tends to move in opposite directions.

Dr. Morton quotes explanations from Mascart and Sprague, which are substantially the same as the above. In my "Elements of Static Electricity," published in 1886, pages 81 to 84, the same explanation is given, and I was not aware of a similar one having been given by any one else.

With reference to the indentation on one side of the perforation and outward burr on the other, which Dr. Morton regards as proof of a dual discharge in opposite directions, I find that where this occurs, the line of perforation is diagonal, and not at right angles to the surface of the paper, and that the burr is always on the side next a perpendicular to the surface, and the indentation on the opposite side; as if a pointed instrument had been thrust into the paper and lifted toward the perpendicular. This result is to be expected from the inductive, attractive force acting in the manner described, which is much stronger on the side next the perpendicular than on the opposite side, its strength being proportionate to the angle between the line of perforation and the perpendicular. Suppose this angle to be 85°, it is evident that, the line of perforation being nearly parallel to the surface, the inductive, attractive force would be almost wholly on the side next the perpendicular. Suppose, on the other hand, that the two lines should coincide, the line of perforation being then at right angles to the surface, the attractive force would be equal on all sides of it, resulting in an outward burr all around.

The indentation is evidently due to the repulsive force of the static charge on the paper, which pushes it inward on the side of the perforation farthest from the perpendicular and outward on the side nearest the perpendicular, adding its force to the outward attractive force. As the paper on the farther side of the perforation is forced against the leaves beyond it, the indentation is comparatively slight, while on the nearer side, the outer leaves being lifted by attraction, there is space for the prominent burr produced by the two forces of attraction and repulsion, as described.

These perforations do not occur in single lines on each sheet, as shown in Dr. Morton's diagram No. 1, but are star-like, several lines radiating from a common centre; and I fail to find any evidence of a spiral perforation, such as he describes; in fact his diagram and description show that the perforation occurs in a very irregular manner, being influenced probably by the looseness or compactness of the leaves, and the different relative positions assumed by them under the influence of the electric force. The electric perforation itself is confined to a very limited space, a mere point on each leaf; and the surrounding, star-like perforation, being the result of the force applied to this central point, cannot properly be adduced as evidence of spiral electric action.

Very interesting and instructive results may be obtained by producing a discharge through a book between whose leaves thin sheets of metal have been placed. When the discharge is made between the poles of a Töpler-Holtz machine through a few leaves inclosing two sheets of tinfoil with paper between them, the tinfoil and the paper outside of it will be perforated, the burr on the paper turning outward and that on the tinfoil inward, while the paper between the tinfoil sheets will not be perforated. When the discharge is made between the poles of a large Leyden battery through 30 or more leaves, between which two sheets of tinfoil have been similarly placed, the perforation will extend through a few of the inside leaves between the tinfoil sheets, the burr on these, on the tinfoil, and on one or two of the outer leaves next it turning inward, while that on the other outer leaves will turn outward. If the metal sheets are rigid, like thin spring brass, they will not be perforated, but indented inwardly, if thin enough, nor will any of the leaves between them be perforated.

These results show that while most of the outer leaves are perforated by outward attraction, as shown by the outward burr, the tinfoil sheets and leaves adjacent to them, both inside and outside, are perforated by inward attraction and the brass sheets indented. This inward attraction is accounted for when we consider that the interior insulating paper, with conducting metal on its opposite surfaces, produces exactly the conditions found in a Leyden jar, two charged conductors insulated by a dielectric. The outer leaves become inductively electrified, positively and negatively in the usual manner, the charge being concentrated on a central line, but when it reaches the metal sheets, it is instantly distributed through their entire mass, acting inductively through the intervening paper, and attracting the opposite metal sheets and adjacent leaves. But the paper, being an imperfect insulator, the charge thus distributed passes quickly through it from positive to negative without disruption, unless it is too large to be entirely absorbed by the metal, in which case the surplus will perforate a few of the interior leaves, and indent others till its force is expended; the tinfoil being always perforated, and the brass indented, at the central points of concentration; the metal and the interior leaves of paper which are perforated yielding to the inward attractive force.

I have frequently examined Leyden jars perforated by an overcharge, and find that the perforation is confined to a central spot, about $\frac{1}{32}$ of an inch in diameter, in which the glass is pulverized without being removed, and around which is a star-like fracture. In this case the electric energy traverses the glass from positive to negative, at a thin spot where the resistance is least, on which it becomes concentrated during the discharge; and the glass, being hard and a good insulator, is pulverized by the molecular electric action; but the particles, being attracted toward each other from the opposite surfaces, are not removed.

TWO SIMPLE METHODS FOR TESTING STREET CAR MOTORS.

BY

Cary T. Hutchinson

HAVING occasion recently to make tests on certain tram motors, and not finding any other methods altogether satisfactory, I finally adopted the methods described here. They seem to be simple in the manipulation and readings required, and as there is a certain amount of newness about them, it seems worth while to give a brief description of them.

The description here applies directly to series motors; the changes for shunt motors are obvious. Two motors are required which must be identical; in measuring the efficiency at the armature, the armatures of the two are placed in line and a coupling put on, either solid or flexible. Belts could be used with pulleys on the armature shafts, but this would not insure exactly the same speed for the two, and this is necessary. In measuring the efficiency with the gears, that is, on what would correspond to the car axle, the axle gears of the two motors are connected to a common shaft, just as if two motors were mounted on the same car axle. One of the machines runs as a motor and drives the second as a dynamo; in the first method the dynamo returns its current to the motor, as in Hopkinson's method; in the second method, the dynamo works on resistances.

First method: Fig. 1, A and B are the two motors under test; G is a 500-volt dynamo, which must be of sufficient size to supply the difference between the current in A and B; D is a dynamo, which must generate an electromotive force equal to the loss of potential in the resistances of the machines A, B, D, and must carry the current of B, G, then, supplies the loss of current between the two machines, and D the loss of potential. The fields of B and D are both separately excited.

The rationale of the method is this: The adjustments are made until the value of the field current in the separately excited fields of B is the same as the current in the motor A; the two motors are then running at the same speed in fields of the same strength; hence the hysteresis, eddy-current and friction losses of the two are equal. Knowing then the input of A and the output of B and allowing for the field heating in B, the total loss in the couple is determined; half this loss is in each machine, and so the efficiency is known. It should be noted that it would be incorrect to take the efficiency of one machine as the square root of the couple efficiency; this has always seemed to me to be an erroneous assumption in Hopkinson's original method; the reason of course being that the two machines are not working at the same load, the input of one being the output of the other. The error probably is a small one in most cases, but I think it is much better to arrange that the losses in the two should be identical.

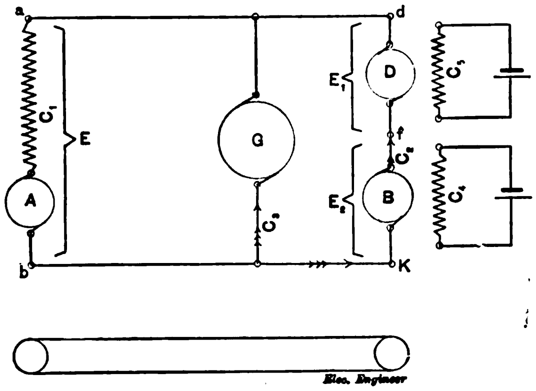


FIG. 1.

Let E be the potential difference at the terminals of the motor A, always kept 500 volts.
E_1 be the P. D. at the terminals of D.
E_2 be the P. D. at the terminals of B.
E_3 be the P. D. at the fields of A.
C_1 be the current in A.
C_2 be the current in the armature of B.
C_3 be the current in G.
C_4 be the current in the fields of B.
C_5 be the current in the fields of D.
R be the resistance of the fields of A or B.
r be the resistance of the armature of A or B.

The manipulation is simple: The current in the fields of B, C_4, is adjusted to whatever load is desired on A, then C_5 is adjusted, by resistances, until the current in A, C_1, is equal to C_4; C_4 is then given another value and the same process repeated. A simplification of this, used later, consists in connecting the fields of B in series with A; the objection to this is the high E. M. F. required from the dynamo G which must be driven considerably over speed.

Call φ the efficiency of the motor; then

Output of motor A $= \varphi\, C_1 E$
Losses in " $= E\, C_1\,(1-\varphi)$
Input of B $= \varphi E\, C_1$
Output of B $= C_2 E_2 = C_2\,(F - E_1)$
Losses in B $= \varphi\, C_1 E - C_2\,(E - E_1)$

Total actual losses in A and B $= E\, C_1 - C_2\,(E - E_1)$ (1).

To this must be added, in order to make the losses in B equal to the losses in A,

For armature of B, $(C_1{}^2 - C_2{}^2)\, r$
For fields of B, $C_1{}^2 R = C_1 E_3$.

This makes for the total losses which would occur in the system if B were running with the same loss as A,

$$2\,H = [E\, C_1 - C_2\,(E - E_1) + r\,(C_1{}^2 - C_2{}^2) + R\, C_1{}^2] \qquad (2).$$

The efficiency of A is

$$\varphi = \frac{E\, C_1 - H}{E\, C_1}$$

$$= \tfrac{1}{2}\left[\, 1 + \frac{C_2}{C_1}\left(1 - \frac{E_1}{E} \right) + \frac{C_2{}^2\, r}{C_1\ E} - C_1\,\frac{R+r}{E} \right] (3).$$

But the machines are identical and therefore the E. M. F.'s of the two are equal.

Or, $E - C_1\,(R + r) = E - E_1 + C_2\, r$

$$E_1 - C_2\, r = C_1\,(R + r) \qquad (4)$$

$$\varphi = \tfrac{1}{2}\left[\, 1 + \frac{C_2}{C_1} - (C_1 + C_2)\frac{R + r}{E} \right] \qquad (5).$$

This formula gives what may be called the measured efficiency, that is, the efficiency for the degree of heating at which the motor happens to be at the moment; measurements made at intervals of half an hour and calculated by this formula will not agree among themselves, particularly when the motors have high resistances as most tram motors have. To take an example; a No. 6 Sprague motor, switch in first position:

$R + r$, (cold) $= 10.5$ ohms.
$R + r$, (hot) $= 12.5$.
$\frac{C_2}{C_1} = .5, \quad C_1 + C_2 = 30.$
Then $\varphi = 43.5$ per cent., for 10.5 ohms.
$= 37.5$ per cent. for 12.5.

Even for the running position, the seventh, the resistance will vary from 1.9 to 2.3 ohms, and

if $\frac{C_2}{C_1} = .7 \qquad C_1 + C_2 = 50,$
$\varphi = 75.5$ per cent. for 1.9 ohms.
$= 73.5$ for 2.3.

These figures are from tests and might easily be exceeded.

This shows how important it is that all such tests should be reduced to standard conditions of heating; this can be done very simply by first determining upon the standard resistances, R_0 and r_0, by preliminary measurements. They should be taken at a mean value of the rise of temperature. The efficiency becomes for standard resistances R_0 and r_0,

$$\varphi_0 = \tfrac{1}{2}\left[\, 1 + \frac{C_2}{C_1} - (C_1 + C_2)\frac{R_0 + r_0}{E} \right] \qquad (6)$$

The substitution of the standard resistance for the actual, as just made, involves the assumption that the resistance is an independent variable; that is, it may vary without causing changes in any other of the quantities entering the expression. This is not strictly true, for when the resistance of the motor increases, its speed diminishes, and therefore C_1 will change; this in turn will change C_2. It will be noticed, however, that the main term is $\frac{C_2}{C_1}$, and although the quantities themselves may change, their ratio remains constant well within the limits of error of work. This I have verified by a number of experiments; the error is trifling. But $(C_1 + C_2)$ enters also; this is, however, merely a correction term, and the slight variation in $(C_1 + C_2)$, less than 2 per cent. will not affect the result appreciably; it might make a difference of .2 per cent. This is within the limits of error.

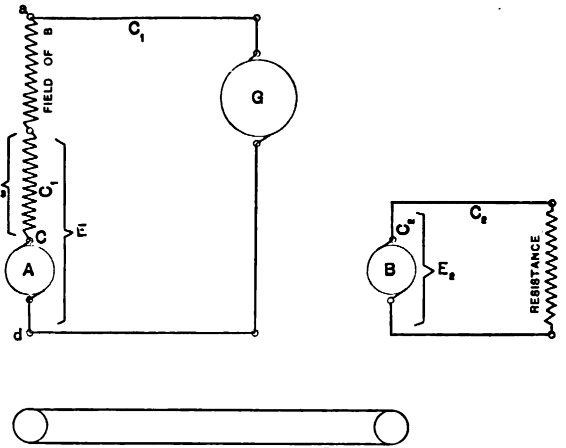

FIG. 2.

Formula (6) is then the expression for the corrected efficiency; this makes the observations very simple, and the possible accuracy very great. There are only two readings to be taken, C_1 and C_2; E is kept constant at 500 for tram motors, and not read; $\frac{R_0 + r_0}{E}$ is a constant; the accuracy of the ammeters is not a matter of great consequence, provided only that they agree between themselves; in fact, one instrument might be used, first in one circuit and then in the other. The only place at which any inaccuracy in the instruments causes error is in the last term, and here an error of 10 per cent. in the instruments would cause only 1 per cent. in the result at maximum load, and at smaller loads, a proportionally decreased error.

The second method is shown in Fig. 2. Here the fields of B are kept in series with the motor A; making exactly the some assumptions as before the efficiency is readily found to be

$$\varphi = \tfrac{1}{2}\left[1 + \frac{C_2}{C_1} - (C_1 + C_2)\,\frac{R + r}{E}\right] \qquad (5)$$

and for standard resistances,

$$\varphi_0 = \tfrac{1}{2}\left[1 + \frac{C_2}{C_1} - (C_1 + C_2)\,\frac{R_0 + r_0}{E}\right] \qquad (6)$$

These are the same formulæ as found in the first case; it may at first glance seem a little strange that with two more machines the efficiency formula should be the same; but the additional machines are used to permit the output of B to be returned to A; the disposal of the output of B should not in any way affect the formula for efficiency.

This last method is simpler as it requires two fewer machines; but in practice the conduct of the tests is as simple in one case as in the other.

Having the efficiency curves, the torque is deducible when the speed curve is known; in taking speed measurements it is again very important that they be reduced to the speed for standard resistance.

To accomplish this in taking speed readings, the P. D. at the motor terminals and at the armature must be measured for every speed reading; the armature resistance should be measured before and after each set of speed readings, and its value for any time determined by interpolation. Knowing the actual armature and field resistance it is easy to reduce the speed to the standard.

The assumption that E. M. F.'s of the machines are equal requal, requires a word; it need not be rigorously true; a considerable variation between the two will affect the efficiency slightly, as the difference enters only in the correction term.

It will be noticed that this latter method affords a very simple means of testing tram motors when on the car; the car can be jacked up, and a pulley put temporarily on each car axle, so that one can drive the other by a belt; then making the connections as in Fig. 2 and using the regulating rheostats as resistances in the circuit of the machine which acts as a dynamo, the efficiency can be easily determined approximately.

A number of tests have been made by these methods, some of which may be published later.

CHANGES IN THE CANADIAN PATENT LAW.

THE Canadian patent law has been further amended and changed so that, when a previous foreign patent exists, the foreign inventor is given the same protection enjoyed by the Canadian inventor, which prevents any one from acquiring the right to manufacture and sell the patented article by reason of his having commenced its manufacture in Canada before application had been made for the Canadian patent.

The first line of the last clause of the article in our issue of August 17th should now read, "Any inventor electing, etc," instead of "A citizen of Canada electing, etc."

MORE REMARKS ON RAILWAY POWER PLANTS.

BY

COMailloux.

THE discussion on "Railway Power Plants" going on in these columns has developed some interesting facts and some valuable engineering knowledge and experience for which we are largely indebted to Mr. Wm. Lee Church, who appears incidentally to have scored a few good points in favor of his views, and of his *engines*. The writer, though greatly interested in Mr. Church's clever presentation of his views, had no intention of taking part in the "symposium" until after reading the *défi* which Mr. Church gives the Yankee, when he says: "I think it beats even our boasted Yankee ingenuity to see a decent way to accomplish this."

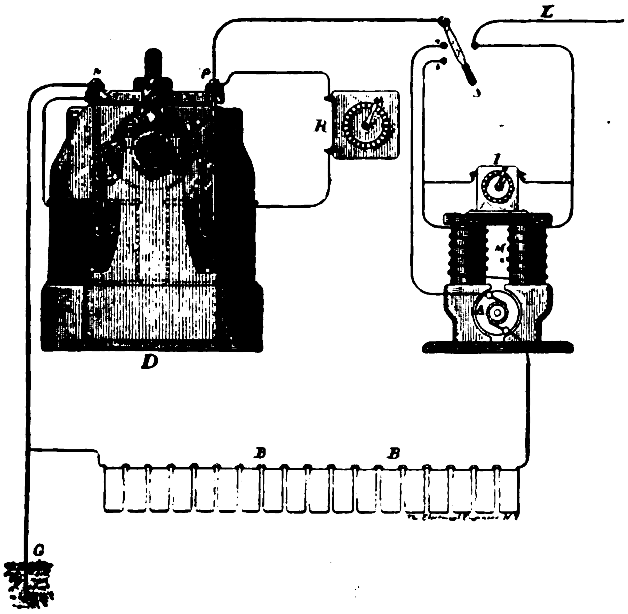
This has emboldened the writer to remind Mr. Church that Yankee ingenuity, when attacking the problem of securing constant fuel economy under variable loads, need not necessarily confine itself to *mechanical devices*, when a "more decent" way can be found in *electrical devices*. The writer expresses candid admiration for the mechanical skill and ingenuity which Mr. Church and his associates have brought to bear on the evolution of the compound engine, and he applauds without stint the *tours de force* exhibited by the performance of their engine. At the same time he feels a certain sense of humiliation in the consciousness of the fact that the American electrical engineer is tacitly acknowledging his inability to "hold up his own end" when he imposes such additional responsibilities on the steam engine. It has, indeed, seemed to the writer as though electrical engineers had already asked enough, if not too much, of the steam engine, in the way of speed regulation; without being too captious on the score of economy. The writer believes that when the electrical engineer rises to the full height of his mission in connection with the design and operation of railway power plants he will himself attend to the load fluctuations *electrically*, without assistance from the steam engine, which he will thus relieve of much serious and unfair responsibility concerning regulation, economy, and, above all, repairs. That is what is meant above by "holding up his own end." There will doubtless be found many ways of accomplishing the purpose. The writer has devised one way, which he described in THE ELECTRICAL ENGINEER of Dec. 3, 1890. It may be of interest to the electrical public to reproduce the diagram used in describing the method. The object in view is thus defined in the article: "The method aims to accomplish electrically for the dynamo what the fly-wheel does in a mechanical way for the engine. It provides the circuit with a kind of reserve fund of energy, that is ready to instantly appropriate any surplus of electric power when the load is light, or make up the deficit when it is heavy."

As for the method itself it consists in attaching to the generator D at the station, a series of small storage batteries, and a small supplemental dynamo, whose armature A (driven by the same engine as D or by a motor supplied from the trolley line), is in the battery circuit, while its field magnet coil M, consisting of a few turns of large wire, is included in the trolley circuit. A switch S can be introduced by which this "compensating circuit" can be thrown on and off at pleasure, as the diagram readily shows. When there is no current on the line, the supplemental armature A revolves in a dead field and there is a large "overflow" of current into the batteries B, B, which charges them. As the current sent over the trolley rises, however, it causes the magnetism in field magnet M to rise correspondingly. This causes the E. M. F. of the armature A to rise and add to the E. M. F. of the accumulators, B B. Hence as the current used on the trolley *increases* the charging current sent into the batteries *decreases*, thus maintaining the *production* (by the engine) nearly or quite constant. If now the current on the trolley rises above a certain normal predetermined value regulated by adjustment, the battery begins to discharge into the trolley circuit *in proportion to the demand, i. e.*, it furnishes the surplus required, and again the production at the engine and dynamo remains constant[1]

By some such system of electrical equalization and compensation we obtain the condition of a practically constant load, not varying probably 10 per cent. either side of the average load, and we thus relieve the engine of the difficulty and responsibility of maintaining close regulation of speed and keeping up good fuel economy.

Mr. Church's plan for the promotion of fuel economy, involving, as it does, in its complete essence, a special make of engine, may be good enough for new plants. But what is to become of the scores of plants equipped with "the other kind" of compound engines?

There is only one remedy:—electrical equalization of the load by some such method as that referred to! These companies and their managers can then hope to bring back the water consumption from 50 pounds to about the amount promised by the agent who sold them the engines; and they *can keep it there.*



Accumulators in a Railway Power Station.

They will also find their engines running much more smoothly than ever thought possible in a railway plant and a material reduction in the cost of repairs will also be observed. This is one point where the electrical method of compensation has the advantage over Mr. Church's; as the latter method can scarcely be expected to decrease repairs. The most pleasant surprise perhaps, will be to find that the plants have now a much greater margin of power than before, for it is not necessary then, to run the engine normally underloaded. In fact the proportions may now be, (taking Mr. Church's illustration) as follows:

Dynamo	60
Engine	60
Boiler	60

Hence, even with Mr. Church's ideal small plant (dynamo 100, engine 100, boiler 60), the operating capacity can be increased 66 per cent. by simply putting in 40 h. p. more of boiler capacity.

The storage battery in the compensating circuit at the station would readily supply as much as 100 h. p. more for the brief "spurts," experienced in railway working so that the plant has ample margin. It is a mere question of size of battery. A fluctuation of 1,000 h. p. can be "compassed" quite as easily as one of 100 h. p.

It is not, as generally supposed, small stations alone that need some form of "load compensation." The paper of Messrs. Shepardson and Burch on the Minneapolis Street Railway station tests (referred to by Mr. Church) shows that some large stations would be benefitted by it. The use of the planimeter and a few calculations enabled the writer to deduce from the curves given in Fig. 11, by the authors, some data which may be of interest in this connection, even though their accuracy may not be absolute.

The following table exhibits these data:

	Main ammeter. Station No. 1.	Main ammeter. Station No. 3.	Feeder No. 1. Station No. 1.
No. of cars supplied..	190	72	30
Calculated mean current value in amperes..........	2,138	1,148	485
Highest point reached by ammeter.	2,680	1,600	725
Percentage of highest current over mean value....	25 %	39 %	60 %
Lowest current value, amperes	1,400	830	300
Percentage of same below value..	35 %	28 %	38%
Average fluctuations of 10 per cent. and more above mean current, (per minute.)	1.4	1.4	4.0
Average fluctuations of 10 per cent. and more below mean current, (per minute)................	1.4	1.6	3.6

These figures would indicate that there is still room for electrical compensation even with circuits supplying a large number of cars.

The sole objection that has been urged against electrical compensation methods such as that referred to, is that they involve using a *storage battery*,—an appliance which is far from being popular with trolley roads, for reasons which their managers would in most cases be at a loss to define. Until lately the average trolley man would not listen with patience to any project having a storage battery connected with it, no matter how palpably evident and certain its advantages or its economy could be made. The writer has indeed "fallen from grace" in the estimation of several of these worthies, because he happens to retain faith in the storage battery. The trolley roads are nevertheless bound to come to the adoption of methods of electrical load compensation or equalization with storage batteries, just as they are bound to come to multipolar slow-speed generators coupled direct to multiple-expansion engines, and other improved methods for reducing the cost of power.

THE TROLLEY SYSTEM FOR NEW YORK.

The aldermen of New York have voted an extensive franchise to the Union Railway Co. for a number of trolley lines in the suburban or annexed northern district of the city. It is provided that the road shall begin to pay the city one per cent. of its gross receipts when the income averages $1,700 per day. This is a decided victory for the trolley.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed*, EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, AUGUST 31, 1892. NO. 226.

Nothing is so good as an experiment which, while it sets an error right, gives as a reward for our humility in being reproved, an absolute advancement in knowledge.—Faraday.

STORAGE BATTERIES IN CENTRAL STATIONS.

AN American electrical engineer who was recently in Europe, made it a part of his duty there to inquire into the reason of the large use of storage batteries in the central stations there. In view of the fact that so little use is made of batteries in American stations, the inquiry was very interesting, but it cannot be said that any argument or condition was discovered likely to change the state of affairs here. Our informant tells us that he was struck with the smallness of the plants and the extreme lightness of the load at certain hours. The load diagrams were alpine in the sharpness of their peaks and the sheer depth of their valleys. Of course with a demand tapering off to nothing, say between 3 a. m. and 9 a. m., it would be easy to utilize batteries very nicely, and to treat the batteries during the hours of full operation as though they were a steady customer for a fixed amount of current. But he did not discover any instance in which the batteries came in as a valuable auxiliary to relieve a station at times when the load became abnormally heavy. That was a pretty theory not borne out by the practice.

Another point that impressed our informant was the undue proportion of the batteries to the generating plant in space occupied. The dynamo-room seemed to be very much like the ideal smoking-room that Barrie describes in "My Lady Nicotine"—a vanishing quantity, its fair proportions too often inviting annexation. It also appeared that the batteries themselves were given a wonderful amount of care and attention. If one became "sick," it went into hospital, and its nurse thought nothing of sitting up all night with it. On the contrary, an American when he gets a troublesome battery, heaves it into the scrap heap—and makes an assignment.

This criticism from one who is a trained observer may discourage the idea of the use of batteries in large central stations, but we are still of opinion that the smaller stations have a place for them. As for the care bestowed on apparatus, that is a lesson we still have to learn from the Europeans and the Japanese. Not only in moderate sized lighting stations should room be found for storage batteries, but Mr. Mailloux contends that there is a rôle for them to play in the smaller electric railway plants.

THE TROLLEY FOR NEW YORK.

IT is matter for congratulation that the aldermen have granted, with the Mayor's confirmation, an extensive franchise, with reasonable conditions, to the Union Railway Company, which will operate a number of trolley roads in the northern suburbs of the city, beyond the Harlem. The trolley is pre-eminently the best means of service for that region, and the inhabitants will, without doubt, soon be glad that they enjoy it. A few of them may now oppose it, but they will be like the people in other cities who have no sooner seen the trolley cars go into operation than they have become frantically anxious to get them on every possible and impossible route.

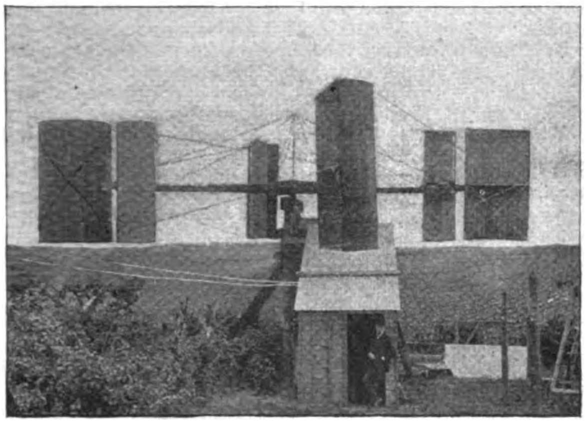
This victory has been achieved in spite of the abuse and misrepresentation of a large part of the press, including not only some of the respectable papers but also the *World*, which has been just as ready and facile in faking "trolley accidents" as it has in manufacturing "special cable dispatches." The trolley is not deadly and is not dangerous. It is a great and lasting boon to those in need of better transportation in our great cities; and we are glad to see that the *New York Sun*, with its wonted strong common sense in dealing with practical affairs has recognized the good qualities of the trolley and has said the kindly, true word on the subject. The trolley car is here to stay and is destined to have at least as long a life as the steam locomotive, no matter what other great advances may be made in electric traction.

THE ELECTRIC UTILIZATION OF THE WIND.

THE arrangement of wind-wheel for generating electricity adopted by Prof. J. Blythe, of Scotland, and described on another page,is of especial interest, completely obviating as it does two of the greatest complications heretofore contended with; namely, automatic means for keeping the wheel to the wind, and also to prevent racing. By the clever adaptation of the principle of the ordinary anemometer, Prof. Blythe has succeeded in charging his accumulators in all kinds of weather, from a gentle breeze to half a hurricane. The device should be of especial value in flat countries and upon the coast where water-power is scarce, coal expensive, and atmosphere plentiful. It will be remembered that Mr. C. F. Brush has made some very interesting experiments, once illustrated in these pages, in the electrical utilization of wind power, and we would suggest that at least one dynamo or storage company would find it advantageous to illustrate practically either the Brush or the Blythe method at the World's Fair.

WIND POWER FOR THE GENERATION OF ELECTRICITY.

An interesting application of the windmill for generating electric power and light through the medium of accumulators has recently been made by Prof. J. Blythe, of Scotland, and is the result of a long series of experiments.



Prof. Blythe's Windmill.

In the summer of 1887 Prof. Blythe erected his first electric windmill in the village of Marykirk, Kincardineshire. At that time he procured a set of 13 accumulators and constructed a windmill of the old English type, having four arms or whips and canvas sails. The length of the arms was about 14 feet, and the sails over 8 feet by 3 feet. The mill was provided with bevel gearing at the top, a vertical shaft and bevel gearing below, so arranged that the driving wheel moved always in the same vertical plane, no matter in what direction the wind shaft pointed. The mill was turned into the wind by hand, having no tail or other gearing for keeping it automatically head to wind. The dynamo was driven by a belt from the driving wheel, and with this he was able on two or three windy days to store his cells. Although the experiment was not on a very large scale, it was sufficient to show that accumulators could quite well be charged, when the electrical connections were properly made, by a dynamo driven at the irregular speed characteristic of a windmill. Sails were not a great success, especially since there was no way of reefing them. To prevent their being torn to pieces, the mill had to be stopped when the wind was high; just at the time when it should have been going at its best.

To remedy this partially the wind-wheel was altered from the English to the American type, having a number of arms and blades of sheet iron. He also introduced the further improvement of doing away with the necessity of having the driving wheel always in the same plane. This is absolutely necessary if the windmill is to drive a sawmill, a cornmill, or anything of that sort, but for electrical purposes the dynamo can quite easily be attached to the wind shaft platform so as to turn with the mill as the wind changes. In this way all gearing is avoided, as the dynamo can be driven by ropes from a large wheel keyed directly on to the wind shaft. This answered very well so long as the wind had a moderate speed, but like all other windmills, it had either to be made self-reefing or stopped altogether when a gale came.

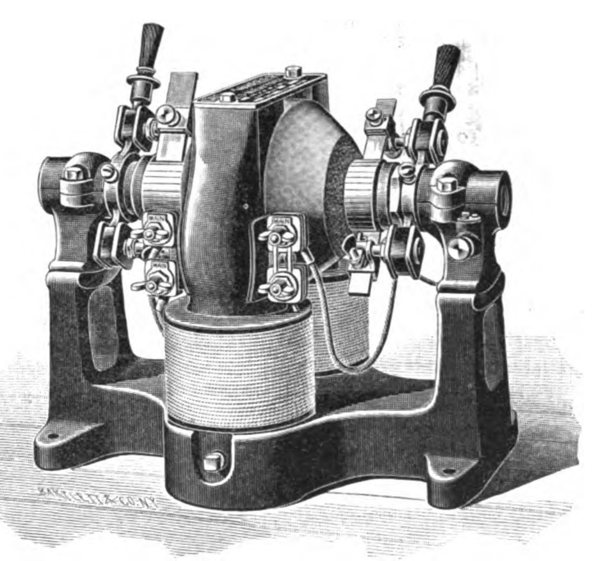
A possible solution of the problem was presented in the Robinson anemometer, which consists of four hemispherical cups attached to four arms, and moving in a horizontal plane about a vertical axis. From the theory of this instrument, which is however only approximate, it appears that whatever might be the speed of the wind, the speed of the cups attained a certain *terminal* value, such that the couple due to the wind pressure was exactly equal to that produced by the resistance to the motion through the air and the friction on the bearings.

Last summer he erected a machine of this kind, a good idea of which is given in the accompanying illustration, which has been considerably improved within the past three months. The cups are replaced by semi-cylindrical boxes attached to four strong arms, each about 26 feet long; the opening of each box is 10 feet by 6 feet, and the vertical shaft is a long rod of iron 5 inches in diameter. At the lower end it carries a massive pit wheel, which actuates a train of gearing, and drives a flywheel 6 feet in diameter with the requisite speed for driving a dynamo connected with it by a belt in the ordinary way. This machine worked most satisfactorily, and with a fair wind speed, gave about two electrical h. p. It was also tested in a strong gale, by allowing it to run with no load, and the result was perfectly satisfactory, as a safe terminal speed was attained and all racing avoided. During the past few months the power of the machine has been increased by adding an auxiliary box to each arm with a gap between it and the previous one. As the whole is a case of vortex motion the theory is very difficult. Information can only be got from models and by applying the principle of dynamical similarity.

All that is necessary is that the circuit be broken when the dynamo is running at less than the storage speed. This is easily managed by a governor attached to the dynamo shaft, and which makes and breaks contact in a mercury pool at the required speeds. A form of governor has also been tried which throws a greater or less number of cells into the charging circuit as the wind varies and in this way the machine is always doing some work.

THE CROCKER-WHEELER MOTOR-DYNAMO.

The Crocker-Wheeler Electric Company, on account of the growing demand for direct current, for special purposes, differing from the three great standards of voltage, have gone into the manufacture of machines to transform direct current from one potential to another. These transformers, or motor-dynamos, resemble motors or dynamos in all respects, except that the electrical parts are in duplicate. One side of the machine is devoted to receiving the current from the standard source, and, after transformation, the other side distributes it at the potential desired.



Crocker-Wheeler Motor-Dynamo.

It is often customary for shops which do silver and gold plating in moderate amounts, to take their current, which must necessarily be of large ampereage, from 110-volt Edison mains, cutting down the voltage by means of large incandescent lamps. They are thus paying for their current at 110 volts when they are only using two or three volts. By the use of a direct current transformer, a consumption of 10 amperes in this manner would be reduced to about ¾ of an ampere, saving thereby from 90 to 95 per cent. of the expense. Another instance which does not recommend itself as much on the ground of economy for actual current consumed as on the ground of compactness and absence of attendance required is the ringing of bells, etc., in large hotels, which now employ from fifty to one hundred primary cells, at a cost per year of about one dollar each. The smallest size dynamo-motor made, weighing about 30 pounds, will do the work of two hundred and fifty of these cells, and at the end of the year would cost for the equivalent output about one quarter as much. The larger sizes take current at from 600 to 6 volts at the motor end, and deliver it at the dynamo end at from 6 to 600 volts, and may be used as well as the smaller sizes for charging storage batteries, generating currents for telegraph circuits, transforming from direct to alternating current for telephone bells, etc.

The Crocker-Wheeler Electric Company, New York, is now making these machines in sizes from type ⅙ to 3 h. p., the smallest size taking current at the motor end at from 230 to 6 volts and delivering current at the dynamo end at from 6 to 230 volts. The shaft of type ⅙ can be so arranged that a dental drill may be attached to it, an emery or polishing wheel put on for polishing and sharpening tools, a fan for raising a breeze, or current taken from the dynamo end for heating cautery wires, and for other medical uses. These machines, one of which is shown in our illustration, are made with the great attention to details for which the Crocker-Wheeler Electric Company is noted, and the demand for them will grow as they become better known.

THE PURCHASE OF SUBMARINE CABLE ABROAD.

In the last issue of The Electrical Engineer, attention was called to the fact that despite the obligation now resting upon the United States Government under the new McKinley tariff law to pay duty on its taxable imports, as a private citizen does, the Weather Bureau proposed to buy its submarine cable abroad, and that Prof. Harrington, having to purchase two light cables for signal stations in Lake Huron had simply doubled his estimate for the purchase of such cables in Europe. We are now in receipt of the subjoined interesting letters on the subject from American cable manufacturers:

DAY'S KERITE.

New York, Aug. 24, 1892.

Replying to your favor of the 23d inst. relative to the importation of submarine cables, I see no reason why our manufacturers cannot make such cables.

My facilities are such that the manufacture of a "Kerite" cable, meeting every requirement is practicable, and at a considerably less cost than an imported cable.

You do not state the specifications for the seven-mile cable for two proposed weather signal stations on Lake Huron, without which it is impossible to give exact figures.

I suppose it is hardly necessary for me to more than suggest the recognized fact that "Kerite" possesses qualities which have stood all submarine tests for a great many years, and that I am constantly making cables for this purpose.

There is no reason why our Government should go abroad for its submarine cables.

W. R. Brixey,
Manager.

BISHOP GUTTA-PERCHA CO.

New York, Aug. 24, 1892.

In answer to your request for a reply from me to the article in The Electrical Engineer August 24th, relative to the manufacture of electrical cables in this country:

It is true that there are no manufacturers in the United States capable of making the long ocean cables, as that requires *ships* to lay, as well as factories to make, and since iron wire is the largest item of cost in the long cables, and that is much cheaper in Europe than in this country, as are also the labor and the ships, the long cables cannot be made here. Of course we could have no protection on them.

On the other hand, the McKinley bill did not affect the tariff on cables,—the duty being before and since its passage 35 per cent. ad valorem.

There are several cable factories in this country, and the Western Union Company and all telephone companies are supplied by them. We are almost constantly making cables for the Government for different departments—Light House, Life-Saving and Signal Service—and two years since made 40 miles for the Sandwich Islands.

Under the Cleveland administration the Government imported its cables "in bond." This gave the home manufacturer no show. The McKinley bill makes the Government pay the same duty as individuals, viz., 35 per cent., and this enables us to make cables in competition with Europe and make a small profit, unless work is very slack in English factories when they make them very cheap. The McKinley bill does not change the cost to citizens and only adds 35 per cent. to cost of Government cables.

We would be very glad of the order to make and lay the Lake Huron cable at $1,500 per mile now.

Whatever may be said in favor of *free trade* generally, I think few people will consider it more onerous for the Government to pay the duty than for individuals.

We have just offered to make for 10½ cents per foot, $554.40 per mile, 12 miles of cable for life-saving stations: and the English in this case beat us at that. I am sure that is as low as the Government ever got one, even without duty—notwithstanding the fact that gutta-percha is worth fully 50 per cent. more than it was four years ago.

Henry A. Reed.

THE INDIA-RUBBER AND GUTTA-PERCHA INSULATING CO.

New York, Aug. 26, 1892.

In re "Importing Submarine Cables"—under the old tariff the Government paid no duty on submarine cables, but it was understood that the home manufacturers would be given the preference at equivalent prices.

The McKinley tarriff requires a duty on this article from every importer, Government or otherwise, but inasmuch as the duty is paid to the Government, an imported cable costs them no more than it did formerly.

All specifications for submarine cables for the Government that I have seen require gutta-percha as the dielectric, notwithstanding the fact that some of the best underwater cables are made with india-rubber. As there is but one manufacturer in this country who makes gutta-percha cables, and would probably take advantage of the protection to increase the price, the Government, it appears to me, in paying duty to itself, would naturally buy in the cheapest market.

If india-rubber cores were acceptable they could be manufactured here as well as abroad; in fact, many of our large companies have supplied underwater cables for a number of years, and, as far as I know, they have given satisfaction. I have a number of underwater cables running successfully under a pressure of 500 volts, and am now making some long lengths for the same pressure with a copper capacity of over 400,000 circular mils.

W. M. Habirshaw, F. C. S.

THE TROLLEY DOG FOR EUROPE.

One of our subscribers on the other side of the Atlantic was struck by the beauty and originality of the scheme for the utilization of waste animal power lately described in this journal under the heading of "The Trolley Dog." The genuineness of his interest is evidenced by the following questions, in regard to which he has asked us to communicate with the engineer of the plant in question: 1. What grades exist on the track? He thinks that abnormally steep grades could be overcome by this system. 2. What kind of feeder system is used? 3. Have the ears to be insulated, as in other trolley systems? 4. Is the motor noiseless? 5. Would a break in the trolley wire disable the motor? 6. What is the daily dog mileage made? 7. What are the running expenses per dog mile? 8 Have any patents been taken out on the system in Europe?

Some valuable data may be forthcoming in response to our correspondent's inquiries. The outlook for business in this direction in Europe would appear to be exceptionally good, for we hear that a company—the members of which are all owners of yellow dogs—is being organized to buy up every living yellow dog they can get hold of for future motor work, in order to monopolize the system in Europe. We fancy we hear with our prophetic ears the buzz of many trolley dogs over the water.

"THEY ARE MAGNIFICENT WORKS."

A reader in an Ohio city writes us: "Allow me to state that for the last two years I have been a subscriber to your paper, and have the several volumes, so far, bound. They are magnificent works, and I would not part with them or be without them. In fact in my estimation there is no electrical work of its kind that can outrank them."

FORTY-FIRST MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The Forty-First Meeting of the American Association for the Advancement of Science held at Rochester, N. Y., Aug. 16–23, was characterized by an unusually large and representative attendance. Over 150 new members have been elected since the Washington meeting. Nearly 200 papers were presented to the various sections most of them embodying the results of patient and thorough research.

As usual, excursions and evening entertainments formed no small part of the week's enjoyment. On Thursday evening a reception was given at the Powers Art Gallery and on Saturday excursions were arranged for Niagara Falls, etc. On the Tuesday following, the Physical Section by invitation of Dr. Nichols visited Cornell University, where unlimited pains were taken to exhibit the facilities which the physicist enjoys there.

It is rather lamentable that the number of papers read in the Physical Section was not large; the short session of but two days being somewhat indicative of the fact that the physicist is not doing what he should in the line of research. However, the shortness of the session was quite fully compensated for by the excellence of a majority of the papers presented, a few of which will be briefly outlined.

A photographic method of mapping the magnetic field, was the title of the first paper of Thursday's session presented by Prof. Chas. B. Thwing. The method consisted in sprinkling iron filings on a sensitized plate placed over a magnet in a dark room, then exposing to light, developing, etc.

Prof. Frank P. Whitman, in a brief paper on the "Magnetic Disturbances Caused by Electric Railways," gave the following results of recent observations: No magnetic instruments dependent on the earth's field can be used for reasonably accurate work at less than 1,500 feet from an electric railway, and the distance must be made greater still if the building in which the instrument is placed is fitted with a system of iron pipes. Minor galvanometers must use iron shields and artificial fields, while earth indicators and other similar methods of finding the constant of a ballistic galvanometer must be abandoned. Experiments are under way for providing the thinnest shield of soft iron which will serve as complete protection to magnetic instruments under such conditions as just mentioned.

A paper was read on the E. M. F. between normal and strained metals in voltaic cells, by Prof. Franklin. The E. M. F. of a Daniell cell was modified by placing under strain the copper wire employed as one of the plates. As soon as the wire became coated with a fresh deposit of copper, so that the surface was under normal conditions, the E. M. F. assumed its normal value although the wire underneath the coating was still under strain. When the wire was released the E. M. F. again became abnormal, but returned as soon as the wire had been again freshly coated with copper.

Among the papers that may be mentioned, in Friday's session, briefly, was one on "An Experimental Comparison of Formulæ for Total Radiation between 15° C. and 110° C." by Prof. Stevens. The total radiation formulæ of Weber, Stefan, Rosette and Doulong and Petit were discussed, and their variations shown by means of curves. Similar curves were shown, obtained from experimental data. An iron disc was used as a source of radiation and the thermopile method employed. The work was carried on in Prof. Weber's laboratory. On the whole Prof. Weber's formula, deduced from a careful study of Langley's work, was considered the rational formula, the others being exterpolations.

Prof. Snow presented three papers embodying the results of his two years' study abroad, just completed. The method employed in the first paper on the dispersion of radiations of great wave lengths in rock salt, silikite and fluorspar is due to Dr. Rubens. The method and results have already appeared in foreign periodicals. In his work on the distribution of energy in the arc, Prof. Snow projected the image of the arc on a large paper screen by means of a convex lens. A slit was cut in the screen between the images of the carbon points, which allowed to pass through only the radiation from the centre of the blue ball of the arc itself, the radiation from the carbons being entirely excluded. A spectrophotometer and bolometer were employed. Owing to the appreciable width of the bolometer wire, the bands ran into each other, so much so that the energy of each could not be separately determined. By means of the eye the spectrum was found to be not a continuous spectrum, not a band spectrum, but a spectrum of fine lines grouped together into bands. Although the energy in the ultra violet was extremely small, yet it was readily measured with a very delicate galvanometer of sensibility 1.5×10^{-11}, of 140 ohms resistance, with a double period of twenty seconds.

Prof. Snow's third paper was on the infra-red spectra of the alkalies. In this work the same methods as above described were employed, with the exception that cored carbons were used, the core being replaced by a salt of the metal to be tested, the chlorides being principally used. The salt of the metal boils and sends out a perfectly uniform stream of the vapor of the metal to be tested. Sodium was found to give some fifty or sixty lines. The only difficulty is to get the temperature high enough to see them. The arc does this readily. The principal sodium lines discovered were the well-known D lines, one just at the red end of the visible spectrum and one far out in the infra-red. These three groups were nearly alike, all the others being quite small in intensity. Potassium exhibited a rich field in the infra-red. With lithium there was absolutely no energy beyond the visible red end of the spectrum just after passing an extremely bright line. Many other salts were similarly examined.

Prof. Nichols gave a paper on the distribution of energy in the spectrum of the glow lamp. Two incandescent lamps of the same make were employed, connected so as to possess the same vacuum. The filament of one lamp was coated with carbon and the other was not. On the same voltage, the two lamps consumed the same number of watts, the carbon coating thus evidently furnished little or no conductivity. Under the microscope the treated carbon presented a rough surface, similar to a thick bark on a twig, consequently this lamp had a somewhat larger radiating surface. The lamps were tested throughout a great range of temperature, the lower temperatures probably being within the range of the mercurial thermometer. When the work is completed Dr. Nichols hopes to be able to express the law of radiation of carbon under the two conditions, treated and untreated, throughout its whole range of temperature. From this preliminary work the conclusions may be safely drawn that gray and black carbons differ in their distribution of energy and that the law of radiation does not vary sufficiently to appreciably shift the maximum. The linear thermopile and carbon disulphide prism were used in these as well as in the investigations by Mr. E. F. Nichols on the absorption spectrum of certain substances in the infra red, which paper was also presented.

Nelson H. Genung.

Society and Club Notes.

THE NORTHWESTERN ELECTRIC LIGHT ASSOCIATION.

The electricians, managers and officers of the electrical plants of the Northern Peninsula of Michigan and Northern Wisconsin effected on the 19th inst., an association at Marinette, Wis., at a well-attended and enthusiastic meeting, under the title of the Northwestern Electric Light Association.

The officers elected were: H. C. Higgins, of the Marinette Gas, Electric Light & Street Railway Co., as president; T. A. Pamperin, manager of the Citizens' Light & Fuel Co., and president of the Electric Manufacturing Co., of Oconto. Wis., as secretary; and Lewis Lusk, president of the Edison Electric Light Co., of Antigo, Wis., as treasurer. The directors, C. S. Leykom, Jas. R. Dee, F. B. Warren, A. A. Foreman and John F. Fitzpatrick, are gentlemen well known throughout the Northwest in the electrical business.

The object of the association will be the regulation, settlement and exchange of ideas concerning matters of mutual interest in the electrical business.

A number of honorary members were elected, including H. C. Hamilton, of Sault Ste. Marie, Canada; W. T. Sullivan, electrician of the Chicago Auditorium, and J. E. Bowers, president of the Crystal Falls board. After the adjournment of the meeting, the visitors, under the guidance and through the courtesy of President Higgins, inspected the well-equipped, well-regulated electric light plant and street railway under the management of that gentleman.

The next meeting will be held on October 12, at Oconto, Wis., at which full representation is looked for.

THE NEW YORK ELECTRIC CLUB.

After the period of nearly six months of depression, during which the board of managers have succeeded in liquidating the greater portion of the indebtedness of the club, it is a pleasure to notify the members that the restaurant and other full service of the club will be resumed on September 1.

A satisfactory arrangement has been made with Mr. W. V. Carter, caterer, who will undertake, from September 1, to supply members and their friends with meals, wines, liquors, cigars. etc., in quality and style of service equal to those of the best days of the club.

It is hoped that members will take an early opportunity to test the merits of the re-established restaurant; and that the opening night, September 1, will bring a houseful. Mr. Geo. F. Porter is now the assistant secretary and gives the club his close attention.

Mr. Joseph E. Lockwood, secretary of the Detroit Electrical Works, Detroit, Mich., spent a couple of days in Chicago last week. The works are very busy.

Letters to the Editor.

"CONTINUATOR" AND "PULSATOR."

I was greatly interested in the remarks by Mr. L. Gutmann, in your latest issue, concerning the expressions "continuous current generator" and "alternating current generator." Whenever they appear one is reminded of their wearisome length and simple meanings and of the want for something better.

However, the construction of substitutes is an important matter calling for considerable thought, and it is not easy to grasp just the right thing. The names "continuator" and "pulsator," as suggested by Mr. Gutmann, appear to me as hardly sufficient, inasmuch as they fail to convey the essential idea that the apparatus so named generates the currents pulsated or continuated. These names will equally as well refer to purely mechanical or non-generating devices—and there are several—which are used to pulsate a continuous current and to continuate a pulsating one. Of course, in this instance, it is absurd to designate the current as, in an electrical sense, nothing else can be pulsated or continuated.

Having appeared in The Electrical Engineer, Mr. Gutmann's excellent and timely article will be considered by every one in a position to do so, and it will, I hope, be the means of abandoning the old clumsy expressions referred to; but, giving him all due credit, I think something other than "pulsator" and "continuator" will be required to make a proper substitute.

Harry L. Tyler.

Corning, N. Y., Aug. 20, 1892.

Personal.

MR. NIKOLA TESLA.

This distinguished electrician has returned to New York, arriving by the "Augusta Victoria," from Hamburg, on August 27. Mr. Tesla sustained a severe bereavement while in Europe in the death of his mother, and was obliged to rest for some time. His magnificent reception at the hands of European electricians has become, like his inventions and researches, part of electrical history; and the honors conferred on him were such as to make Americans very proud of one who has chosen this country as his home.

Mr. R. S. Dobbie, fomerly with the Engineering Department of the Edison General Electric Company, has opened offices in the Times Building, New York. Mr. Dobbie will be glad to see his friends there and may be consulted in reference to new apparatus, inventions, designs, etc. As an old central station man, Mr. Dobbie is also ready to consult in regard to the construction and installation of new plants for lighting and power purposes.

Mr. Dobbie has had an intimate experience with United States, Thomson-Houston, Brush and Edison apparatus, and has made a particular study of designing and testing new apparatus. His card as consulting electrical engineer is to be found in our advertising pages.

Mr. F. A. Phelps, Jr., late mechanical engineer at the Schenectady Edison Works, has resigned that position to become associated with Mr. Edison more directly in the latter's various new enterprises, in which Mr. Phelps's ability will find abundant scope.

THE PLANT OF THE UNION POWER CO., PORTLAND, ORE.

Early in 1891 the Union Power Company was formed in Portland, Ore., for the sole purpose of furnishing power. In carrying out this purpose the company has adopted some devices which have been used before, but had also been obliged to do considerable pioneer work. It is the writer's purpose to speak of this latter more particularly. The revenue of the company is derived from the operation of two street railways, the City & Suburban Railway Co., and the Multnomah Street Railway Co., and from a large number of stationary motors.

The plant consists of one cross-compound condensing engine, Corliss type, of 1,200 h. p., one Buckeye engine of 500 h. p., a battery of ten boilers and seven 175 K. W. dynamos. In order to obtain cheap fuel a piece of ground was purchased, containing three acres, near a large sawmill, on which the plant was erected. The distance from sawmill to plant is 1,600 feet. The fuel used is sawdust and the edgings from the lath mill, which are previously broken up by a "hog." It was found that 1,600 feet was too long a distance to blow this refuse with economy; a carrier was therefore devised, similar to the ones used in mines, which receives the refuse, carries it to the stock house and there automatically dumps it. From this stock house another carrier takes the fuel across the tops of the boilers and dumps it into the fireboxes, as required by the attendant. The whole operation necessitates the employment of but two men on a watch, to care for the ten boilers. The power required for the conveyers is furnished by a 25 h. p. engine, which also pumps the water for the boilers into a tank from which the boiler pump takes it, passing it through a heater before forcing it into the boilers. The smallest estimate for blowing the amount of fuel required for this plant was 80 h. p.

There is nothing particularly novel about the steam plant but the transmission, both from engine to countershaft and from countershaft to dynamos is entirely by ropes on the Dodge system with single wrap. The double wrap was tried at first but was not entirely satisfactory and was changed to the single wrap. The system of transmission by ropes is now giving excellent results. One marked improvement is the almost entire absence of noise, a point spoken of by all who have had experience with belt-driven machinery. It is too early to give any definite figures as to depreciation and renewals but at present they are believed to be less than for belts.

The seven dynamos are connected, five to the large engine and two to the small one. The switchboard is arranged for the three-wire system or the two-wire system, as may be desired. Any dynamo may be thrown on either of the railways or on either side of the power circuit. The complete interchangeability of dynamos has proved of great benefit when occasion has arisen for stopping a dynamo from any cause. It is also possible to connect the dynamos so that the entire load may be thrown on both engines at the same time, by which an overload on either engine can be at once checked; necessity for this often arises on holidays. When running with load on both engines the voltage of dynamos on either engine can be held constant within one-half of 1 per cent or increased at will by over-compounding. This result is the more remarkable as one engine runs at 72 revolutions while the other runs at 130 revolutions per minute and no trouble is experienced in making each dynamo carry its proportion of the load and no more. All power is furnished on the three-wire system both to railroads and stationary motors, as the plant is three miles from the centre of distribution.

The results obtained have been very gratifying. The charges to the railroads are based on readings of Thomson wattmeters in each railroad circuit and are at a fixed price per horse power per month. These meters have given good satisfaction. A reading is taken daily and the meters have been found to respond accurately to any increase in load by addition of cars, or to extra load due to holidays. Ampere readings of circuits are taken hourly, from which it appears that the maximum load on street car lines is slightly more than twice the average load.

The stationary motor business has proved very satisfactory and the company has in addition to the usual motors running printing presses, fans, etc., installed a number of plants for operating hydraulic elevators using pumps and motors connected by belts. Formerly these elevators were operated from the city water mains but the cost was so great that the owners changed to electric means of working them, with a decreased cost to themselves and a much better service to the occupants of their buildings. These outfits have been furnished to pump into compression tanks and also to tanks on the roof. The cost to consumers has been found to be much less than for running steam pumps and the company has replaced several of these as well. The writer has made tests as to power consumed in operating different sizes of pumps under different pressures when pumps were operating elevators and finds them very satisfactory.

The company is also supplying power for running motors, operating generators, supplying light for large buildings and block lighting, to the extent of some 2,000 16 c. p. lights, and this from a plant operating some fifty cars at the same time on same engines and with perfect results as to uniform pressure. The plant was originally planned to run five dynamos but, while in operation about a year, it has been necessary to add two more of the same size and still the demand for power has about taken up the capacity of these latter machines.

H. E. C.

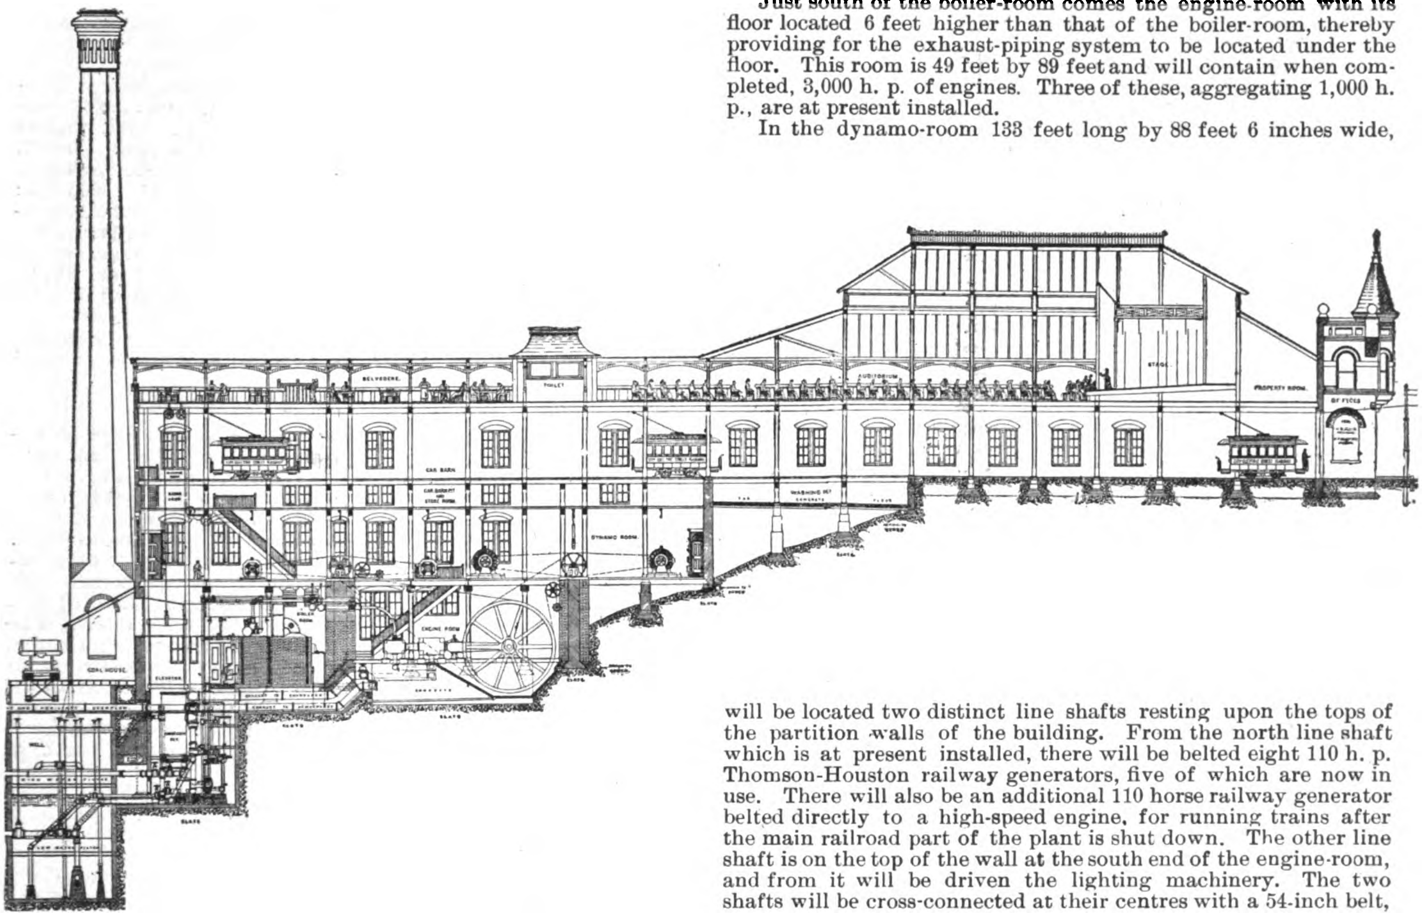
AN ELECTRIC GRAIN BIN INDICATOR.

An electrical device has recently been designed for the purpose of assisting men employed in elevators to tell when the bin is full. The apparatus comprises an electric battery, a bell and a diaphragm which is placed in the bin at a distance of about 18 inches from the top. This diaphragm is connected by wires to the battery and bell and when the bin is full the fact is indicated by the ringing of the bell, which continues till it is cut out by a switch provided for the purpose, the bin being also indicated by the number of the switch which corresponds to it or by a point annunciator. This device can also be applied to telling the amount of grain in the bin, which is now done by lowering a lighted lamp into the bin by a rope. Electric grain bin indicators have been placed in Armour & Co's. elevator, Chicago, by Mr. E. Sherlock, who is interested in the invention, with Newton & Co., of Aurora, Neb. This apparatus is worthy of investigation by elevator men and others as its introduction saves an immense amount of trouble and labor.

THE ELECTRIC STREET RAILWAY SYSTEM OF LITTLE ROCK, ARKANSAS.

On April 1, 1890, Mr. H. G. Allis, president of the First National Bank of Little Rock, Arkansas, to whom Little Rock is indebted for its electric street railway service, organized the Capital Street Railway Company, and secured authority from the city council to propel their cars by electricity. A short time later Mr. Allis secured control of the City Electric Street Railway Company and the other lines were then leased to this company. In October, 1891, the company closed a contract with the Thomson-Houston Electric Company to equip the system with electricity. The local company built its own power house, track and road-bed. Mr. H. P. Bradford, general manager of the company, personally superintended the construction of the road-bed and track. The Thomson-Houston Company's contract work, consisting of the overhead construction, and the installation of the electrical machinery was placed in charge of Mr. E. E. Downs, one of the constructing engineers of that company.

The engineering of the power station was placed in charge of Mr. B. J. Arnold, consulting engineer of the Chicago office of the Thomson-Houston Electric Company, who designed the plant and superintended its construction. Mr. Arnold was assisted by Messrs Rickon & Thompson, architects, of Little Rock, Arkansas. The road is now operating twenty 30 h. p. motor cars and six trailers and is using 12 tons of slack coal, costing $1.70 per ton, per day of 24 hours' run, or less than one-half ton of slack coal per car per day. The cars operate for 18 hours per day but the small electric light engine, running 18 arc lights for lighting the car barns and summer theatre, is run all night and this fuel consumption is included in the above amount.



Power House of the Little Rock Street Railway Company.

There are about 20 miles of track of 35-pound steel T-rail and 52-pound Johnson girder rail placed on chairs. The track is bonded throughout with No. 6 bond wire, joined to the rails with the Wheeler channel pins, and the ground wires are attached to old car wheels and other metal plates which are sunk in the old wells and ravines at suitable intervals along the road. About 20 miles of No. 0 hard-drawn copper wire was used for the trolley system or the road in addition to about 40,000 feet of No. 000 insulated wire for feeders. The trolleys and feeder systems are supported upon about 1,400 poles, 100 of which are Milliken latticed iron which are used through the business portion of the city. The thoroughness of the electrical work will be appreciated when it is known that the first time the current was sent out over the line not a ground was discovered or any defect in the electrical construction noticed.

The power house, a sectional elevation of which is shown in the accompanying illustration, is located on the Arkansas River on the site where the water-works plant formerly stood. The main line of the St. Louis, Iron Mountain and Southern Railway runs along the river bank in the rear of the building, enabling a side track to be built cheaply and fuel delivered directly into the coal house with but one handling. The boiler-room is 44 feet by 89 feet by 25 feet high. In it will be placed, when the plant is completed, eight 250 h p. water-tube boilers, three of which are at present installed. Over the top of these boilers is a sheet-iron breeching extending to the space between the centre row of columns where they join the main trunk breeching leading to the smokestack located outside the main building. The plant is at present operated from an iron stack 5 feet 6 inches in diameter and 180 feet high, set off to one side so that the permanent brick stack can be constructed in its proper position without interrupting the operation of the plant. The permanent stack will be built of brick and will be 84 inches in diameter by 180 feet high.

Just south of the boiler-room comes the engine-room with its floor located 6 feet higher than that of the boiler-room, thereby providing for the exhaust-piping system to be located under the floor. This room is 49 feet by 89 feet and will contain when completed, 3,000 h. p. of engines. Three of these, aggregating 1,000 h. p., are at present installed.

In the dynamo-room 133 feet long by 88 feet 6 inches wide, will be located two distinct line shafts resting upon the tops of the partition walls of the building. From the north line shaft which is at present installed, there will be belted eight 110 h. p. Thomson-Houston railway generators, five of which are now in use. There will also be an additional 110 horse railway generator belted directly to a high-speed engine, for running trains after the main railroad part of the plant is shut down. The other line shaft is on the top of the wall at the south end of the engine-room, and from it will be driven the lighting machinery. The two shafts will be cross-connected at their centres with a 54-inch belt, enabling any generator in the house to be driven from any engine in case of accident to any other engine. The railroad switchboard is at the north end of the building and the lighting switchboard in the south end so that the leads from dynamo to switchboard may be as short as possible, and also to keep the railway and lighting plants distinctly separate. Over each row of generators and the line shafting, extends an overhead single track railroad with the necessary differential pulleys, etc., for the lifting out of armature or box caps. This railway runs to the elevator shaft so that the heavy part may be delivered directly into the elevator and transferred to the machine shop above with but little labor.

On each side of the dynamo-room are stairways extending up to the pit-room above, placed there to provide for easy access to the motors and cars for making repairs at all times without necessitating the changing of position of the cars. Extending 50 feet south of this pit-room is the washing pit running the entire width of the building under all of the tracks so that cars from either track can be run over the pit, washed, drained and run back to their places without any transferring.

The car barn, 88 feet 6 inches wide by 297 feet long contains eight tracks 4 feet 8½-inch gauge and is capable of storing 96 motor cars, and on top of the car barn roof has been built a theatre and garden, capable of seating an audience of 1,000 people in the auditorium proper and about 400 around the tables and places of amusement in the belvedere.

STATION OF THE HULL ELECTRIC LIGHT AND POWER COMPANY, HULL, MASS.

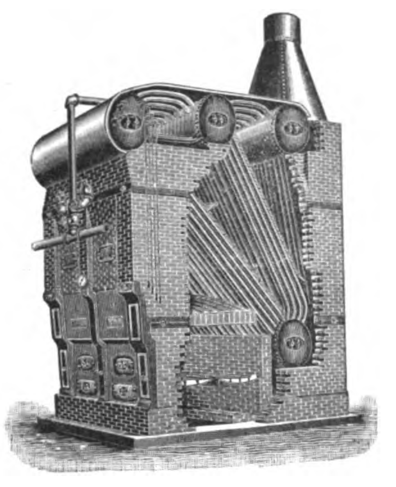


Fig. 1.—Stirling Boiler.

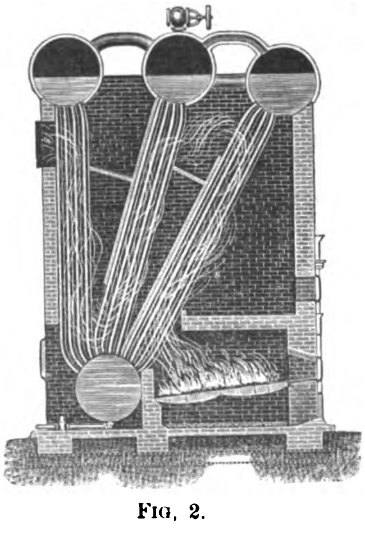
The Hull Electric Light and Power Company was organized about a year ago, but up to a very recent date, nothing was done in the way of construction, owing to various circumstances over which the company had no control. A few months ago, however, it was decided to proceed with the station, and there is now being built a short distance from Hull, a station which will be perfect in every detail, and which will possess some interesting new features. The company has the contract for lighting the town of Hull, with incandescent lights, and has besides many contracts for lighting the numerous hotels and private residences in Hull and along the shore to Nantasket, and it is their intention to make the station a model one in every respect. The engine-room, which is of wood, measures 40 feet by 50 feet, and will contain three Fitchburg cross-compound condensing engines, two being of 160 h. p., and one of 125 h. p. The larger engines will have fly-wheels 8 feet in diameter by 14-inch face, and the smaller one 66-inch diameter by 14-inch face, and there will be no countershafting, the engines belting direct onto the generators. Wainwright heaters will be used, and Deane steam pump and condensers. The generators will be at present two of the latest type Westinghouse alternating incandescent dynamos, one having a capacity of 1,000 lights, and one of 2,000. These generators will be equipped with the latest type of toothed armatures, and composite field winding, which will render them perfectly automatic, so that any number of lights can be turned off and on at will without affecting the others. The advantage of the toothed armature is that by this means the station is effectually protected from any complete shut-down of the plant, on account of the armature coils being easily removable in case of damage when they can be readily repaired by the employees of the company. The switchboard will be of the latest improved design and will contain the usual Westinghouse voltmeters and ammeters and other necessary apparatus. One of the most interesting features of the station is the boiler-room, which is built of brick 30 feet square, and which contains two 150 h. p. Stirling water tube safety boilers in one battery, which are worthy of a detailed description and of which two views are shown in Figs. 1 and 2. The Stirling boiler consists simply of two or more upper wrought steel drums connected with each other and with a lower or mud drum, also of steel, by tubes expanded directly into the drums. This comprises the whole boiler, not an ounce of cast iron or cast steel being used in its construction. The importance and value of this latter quality will be readily recognized and promptly conceded by all competent authorities, as it has been the aim of all boiler makers to eliminate cast iron from boilers for many years. As will be seen, the tubes sit in a nearly vertical position, thereby preventing any deposit on the inside of the tube or soot on the outside, and enabling the gas currents to pass around in such a manner as to utilize all their heat energy. The flame by means of brick partitions follows a tortuous passage up and down the length of the tubes, heating the water very rapidly through the thin tubes. Owing to its construction the Stirling boiler has a very large grate surface, a good draught, and perfect combustion is obtained, making it one of the most economical boilers on the market. Each tube is expanded directly into the circulating drums, furnishing its own outlet, allowing for expansion and contraction, and allowing a perfectly free circulation.



Fig, 2.

An additional precaution is also taken by making a bend on each tube in case of unequal expansion of any member in one group. The accessibility of these boilers for cleaning is also notable, as by opening one manhole in each drum, access is gained to every part of the interior of the steel plates and to both ends and the interior of every tube. These boilers, which are manufactured by the Stirling Company, of Chicago, and installed by their Eastern agent, Mr. J. Bradford Sargent, of 620 Atlantic avenue Boston, have already attained a high reputation, as being safe, highly economical, and satisfactory in every way. We append a list of a few electric stations in which they may be seen working to advantage: The Tiffin Illuminating Company, Tiffin, Ohio, 150 h. p.; American Water Works and Guarantee Company, Pittsburgh, Pa., 200 h. p.; Lyon, Clements & Greenleaf, Wauseon, Ohio, 150 h. p.; Bell Telephone Company, Philadelphia, Pa., 142 h. p.; Edison Electric Light Company, Altoona, Pa., 200 h. p.: Hughes & Gawthrop, Pittsburgh Pa., 60 h. p.; Second Avenue Electric Railway Company, Pittsburgh, Pa., 200 h. p.; Wilkinsburgh Electric Illuminating Company, 150 h. p., second order 450 h. p.; Jamestown Street Railway Company, Jamestown, N. Y., 300 h. p; Akron, Ohio, Electric Company, electric lighting, 600 h. p., second order 200 h. p.; Jones Bros. Electric Co, Cincinnati, Ohio, 300 h. p.; Auburn Mining Company, electric lighting, Auburn, Ind., 125 h. p.; San Francisco and San Mateo Electric Railway Company, San Francisco, Cal., 1,250 h. p.; Conneaut, Ohio, Electric Company, electric lighting, 160 h. p.; Los Angeles, Cal., Consolidated Electric Railway Company, 1,500 h. p; Indiana, Pa., Electric Company, 100 h. p.; C. S. Robinson, Princeton, N. J., 100 h. p.; Waco, Texas, Electric Co., 300 h p.; San Antonio Rapid Transit Street Railway Company, San Antonio, Texas, 200 h. p.; Edison Light Co., Grand Rapids, Mich., 400 h. p.; Minneapolis Street Railroad, Minneapolis, 575 h. p., second order 2.000 h. p.; Gray Electric Company, Highland Park, Ill., 75 h. p.; Grand Forks, N. D., Gas and Electric Company, 82 h. p.; Mahoning Electric Light Company, Youngstown, Ohio, 150 h. p.; Brush Electric Company, light and power, Cleveland, Ohio, 500 h. p.; Grand Rapids, Mich., Electric Company, 400 h. p.

ELECTRIC ILLUMINATIONS IN ST. LOUIS.

It has been customary for several years past to have an exceedingly elaborate series of fall festivities in St. Louis commencing September 1. This year one of the most important features will be the electric light pieces in some of the principal streets. This work has been placed in the hands of the Emerson Electric Manufacturing Co. who have handled it in the most able manner.

On 12th street between Market and Chestnut they have arranged a model of the vessel "Santa Maria" placed upon an arch across the street having a span of 60 feet and being about 30 feet in height and at least 60 feet to the topmasts of the vessel. The illumination of this piece is effected by 1,800 incandescent lamps of various colors, and a moving effect is given to the waves by an automatic switching device which cuts the lights in and out. Over the Grant statue on 12th street near Olive is erected a flag arch with the United States flag and the flag of Castile and Leon crossed above the statue and lighted by one thousand 16 c. p. lamps.

The most striking of the illuminations, however, is a display forming practically a panorama of the discovery of America. It comprises a globe upon a pedestal 125 feet high with the outlines of the New World clearly defined by incandescents and lines representing the equator, tropics and poles similarly illuminated; the former in white lights and the latter in arranged colored ones. By means of a commutating arrangement operated by a Meston alternating current motor, the outside circle of the globe is first lighted with the red, white and green lamps then the geographical lines. Next a small star appears at San Salvador, and simultaneously the date 1492. Gradually the march of discovery will be depicted by the lamps until the entire continent is outlined by myriads of lights, and the name St. Louis and date 1892 appear. More than 1,300 lights are used in this display.

There are also two additional electrical arches one on Olive street near 13th street, and the other at 17th street, the first a transparency of Columbus and the second a pyrotechnic arch with moving lighting effects. From 600 to 800 lights will be employed on each of these. Something like 600 to 800 h. p. will be required to furnish the current for all these lamps. Alternating current will be used and the little Meston alternating motors are here to be seen furnishing the power for the commutating cylinders. All the work has been carried out in the best and most artistic manner and reflects great credit on the Emerson Company both from the thorough way in which it has been done and the novelty and beauty of the effects produced.

ONE HUNDRED THREE TIMES.

One hundred new locomotives, one hundred new sleeping cars, and one hundred-pound steel rails, seems a rather trifling coincidence, but it is of great interest to patrons of the N. Y. C. & H. R. R. R.

THE CAR OF THE COMBINATION CAR COMPANY.

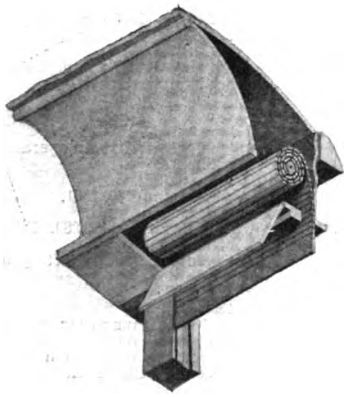


FIG. 1.—SECTION SHOWING AUTOMATIC ROLLER.

THE accompanying illustrations show the combination car which has been in constant service on the electric street railway between Newton and Waltham, Mass., and which has attracted wide attention among street railway men, owing to its many new and important features. Fig. 2 shows the full view of the car, from which it will be seen that it resembles in almost all respects an ordinary first-class eight-wheeled car, the only noticeable feature being the extra large size of the windows. The windows are patented, and, as will be seen, are divided horizontally in the middle, so that both halves can be readily let down into the pocket in the panel of the car. When the windows are thus let down the car has all the appearance of an open car, the sill of the window coming very low down and allowing a perfectly free circulation of air. Fig. 3 shows the inside of the car, and shows the seats, which are set across the car, like most open cars, instead of lengthwise, as in all closed cars. This is a most desirable feature, and has proved a wonderful attraction to many of the residents of Newton and Waltham. This view of the car also shows the slat roller blind, for use either when the sun proves too powerful for comfort, or in case of a moderate breeze or slight rain. Fig. 1 shows the automatic roller in section, from which it will be seen that the slat blind can be rolled up or down at the will of the passenger, much in the same way as an ordinary window shade. From the above description it will be readily seen that the combination car can be instantly transformed from a closed box car into an open summer car, and that in addition any degree of openness may be attained by manipulating the windows or the shades. The car has proved a remarkable success in every way, and is well worthy of inspection by electric railway companies, who can save a large amount of rolling stock by having those cars in place of two complete sets of closed and open cars. The patents on this car are owned by the Combination Car Company, of 23 Court street, Boston, who will gladly furnish any further information.

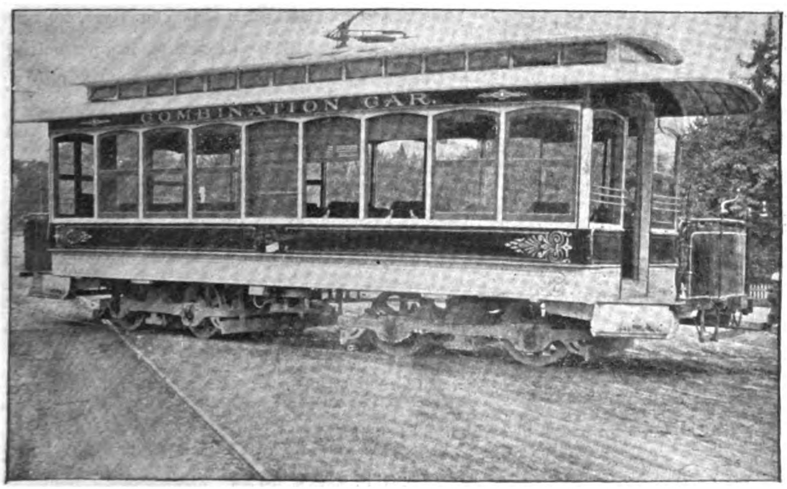

FIG. 2.—EXTERIOR OF COMBINATION CAR.

ELECTRIC TRACTION IN MONTREAL, CAN.

A SHORT time ago the Montreal city council invited tenders for the privilege of operating street railways by electricity in that city, in response to which tenders were received from several syndicates representing American and Canadian capitalists. After many meetings of the council and much virulent discussion of the merits of the different tenders, the contract was awarded to the Montreal Street Railway Co. on July 19th, their tender being considered the most advantageous. Considerable partisanship was manifested, and the mayor, who favored another tender, declared he would not sign the contract; but the company claim this can be dispensed with. This company, who at present operate the horse railway system in the city, will now have the exclusive right to propel cars by electricity on the principal thoroughfares for the next 30 years, in consideration of which they agree to the following conditions:

The company is to pay the city annually 4 per cent. of its gross earnings up to $1,000,000; 6 per cent. of its gross earnings from $1,000,000 to $1,500,000; 8 per cent. of its gross earnings from $1,500,000 to $2,000,000; 10 per cent. of its gross earnings from $2,000,000 to $2,500,000; 12 per cent. of its gross earnings from $2,500,000 to $3,000,000; 15 per cent. of its gross earnings above $3,000,000.

It is also to sell six tickets for 25 cents, 25 tickets for $1, and, to school children, 10 tickets for 25 cents. Tickets available between 6 and 8 a. m. and 5 and 7 p. m. to be sold at the rate of 8 tickets for 25 cents. Single fares to be five cents and transfers given to all routes without charge.

Mr. H. A. Everett, well known in connection with the Cleveland and Toronto electric railways, has been appointed managing director of the company and will have charge of the introduction of electric traction. In addition to the present routes, which will be relaid with English grooved rails, new routes will be established through other parts of the city. Work has already been commenced and it is expected that electric cars will be running on at least one of the routes by the end of September next.

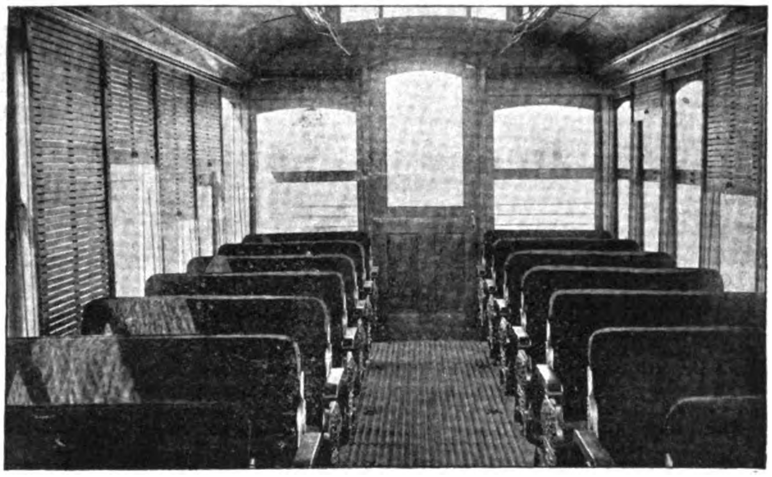

FIG. 3.—INTERIOR OF COMBINATION CAR.

The trolley system will be used, and the company estimate that it will cost $1,500,000 to introduce this system exclusive of any loss on the old equipment. The cars will be heated and lighted, and of the most improved type, and provided with single-reduction motors. As for nearly four months of the year the Montreal streets are covered with snow, often to a depth of two or three feet, the operation of the cars in winter is an important problem and has received careful consideration. In order to enable the electric cars to run all winter, the snow will be removed from the entire roadway of the streets on their routes, leaving a layer of sufficient depth for sleighing (say 8 or 10 inches) and the tracks will then be kept clear by the use of sweepers and plows. The city and company are to share in the expense of removing the snow which will be done after each snowfall of any depth, when it can be done most easily.

At present the horse cars run for about eight months of the year, and during the remaining time sleighs or stages are used; the stages being used when the streets are not in good condition for sleighing. At times, owing to the bad state of the streets, the stages or sleighs go at a speed but little faster than a walk, so that the citizens generally are much pleased at the prospect of having electric cars that will run all winter and give a rapid and reliable transit in spite of the snow or impassable condition of the streets.

Line and other material, including 80 cars, have already been ordered, which latter are to be equipped with two 25 h. p. motors each, in order to have ample power for ascending grades. These motors have been ordered of the Royal Electric Co., who have gotten up a single-reduction motor of their own design, embodying many improvements. For the present, this company (the Royal) will furnish the power for running the cars from their lighting station and are building eight 250 h. p. generators for this purpose.

The poles of the Bell Telephone Co. and those of the Royal Electric Co. are being used for the suspension of the trolley wire as far as possible. The work is being pushed forward rapidly; the Royal Electric Co. are working night and day in order to furnish the material ordered of them on time, and are using their new building, which is equipped with the most improved machinery.

L. M. P.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED AUG. 9, 1892.

Accumulators:—

Secondary Battery Plate, E. R. Knowles, 480,266 Filed Oct. 15, 1891

Composed of an alloy of lead, tin, antimony and arsenic.

Electric Acumulator, G. Gandini, 480,575, Filed April. 15, 1891.

Employs electrodes formed with a mixture of lead outside and small pieces of carbon having a thin top layer of lead outside, a porous partition separating the electrodes.

Alarms and Signals:—

Electric Bell, G. W. Conover, 480,319. Filed Oct. 31, 1891.

A bell or buzzer in which the operating bar is fastened to the cover and removable from the base.

Burglar-Alarm, F. H. Neal and J. R. Donnelly, 480,340. Filed March, 7, 1892.

Has for its object to limit the ringing of the alarm to the time during which the door or window is being opened and closed.

Block Signal Apparatus, T. H. Patenall, 480,411. Filed Feb. 10, 1892.

Consisting of electrical block signals for steam railways.

Electric Low-Water Alarm, E. Rothlisberger, 480,673. Filed April 18, 1892.

Conductors, Conduits and Insulators:—

Conduit for Electric Wires, S. H. Flagg, 480,573. Filed Jan. 26, 1889.

Conduit consisting of a metal pipe lined with glass.

Distribution:—

System of Electric Lighting, G. F. Myers, 480,372. Filed Dec. 15, 1891.

A system of electric lighting for use in connection with cable railway.

Electric Lighting System, C. Selden, 480,375. Filed April 9, 1892.

Employs a Wheatstone bridge interposed in the main line wire to supply a definite current to the translating devices connected in the bridge wire.

Galvanic and Thermo-Electric Batteries:—

Galvanic Battery, H. H. Dow, 480,384. Filed April 4, 1892.

Employs a zinc element, a bibulous sheet moistened with the electrolyte and a layer of finely pulverized carbon.

Electrolytic Cell. E. B. Cutten, 480,491. Filed Aug. 19, 1891.

Claim 2 follows:

The combination of an outer tank, an annode therein consisting of carbon pencils projecting from a carbon bar and a protecting trough enclosing said bar.

Lamps and Appurtenances:—

Incandescent Electric Lamp, P. Scharf, 480,284. Filed Aug. 7, 1891.

Has for its object to dispense with platinum leading-in wires.

Arc Lamp, C. Schmid, 480,285. Filed Dec. 7, 1883.

Claim 1 follows:

In electric arc lamps the combination with the carbon holder of the mechanically suspended retaining clamp and the trip-feed co-acting mechanically at determined intervals to release said clamp.

Supporting Device for Electric Arc Lamps, J. Maier, 480,470. Filed Dec. 11, 1891.

Electric Arc Lamp, E. A. Sperry, 480,525. Filed June 7, 1890.

Provides means for automatically re-establishing an arc which has been extinguished.

Support for Electric Arc Lamps, A. Wright, 480,539. Filed April 27, 1891.

Metal Working:—

Method of Electric Soldering, E. Thomson, 480,392. Filed Aug. 22, 1887.

Miscellaneous:—

Method of Electrical Regulation, H. E. Vineling, 480,393. Filed Feb. 23, 1892.

Employs a primary electric magnetic regulator and a supplementary regulator provided with adjustable means for varying the current supply which actuates the primary regulator.

Method of Electrolytically Producing Potassium Chlorate, E. B. Cutten, 480,492. Filed April 11, 1892.

Method of Electrolytically Producing Potassium Chlorate, E. B. Cutten, 480,493. Filed April 11, 1892.

Circuit Closing and Breaking Device for Railway Tracks, F. H. Pattenall, 480 507. Filed Oct. 20, 1891.

Employs a reciprocating plunger operated by the passing train and completing a circuit by engaging with two contact plates.

Automatic Mileage Recorder for Car Seats, H. S. Squires, 480,526. Filed Dec. 8, 1891.

Electric Door Opener, L. Bates, 480,546. Filed Aug. 13, 1891.

Method of Apparatus for Testing Circuits for Electric Time Systems, W. F. Gardner, 480,576. Filed Jan. 7, 1891.

Clock Synchronizing Device and System, W. F. Gardner, 480,577. Filed Dec. 13, 1888.

Electric Fuse Box, G. W. Baumhoff, 480,651. Filed Dec. 16, 1891.

Consists in interposing pieces of non-fusible between the fuse and the means of attachment.

Dental Engine, C. W. Thomas, 480,678. Filed Oct. 21. 1890.

Electrical Spool, S. S. Wheeler, 480,681. Filed Dec. 30, 1891.

A sleeve or spool for an electromagnet.

Electric Push, J. F. Wollensak, 480,683. Filed May 10, 1892.

Railways and Appliances:—

Closed Conduit for Electric Railways, A. L. Lineff, 480,409. Filed June 30, 1891.

Employs a series of separate supports for the conductor provided with downardly projecting annular lips and a continuous series of tiles serving as a base for said supports and provided with oil troughs into which the annular lips enter.

Electric Railway, F. B. Badt, 480,543. Filed Dec. 19, 1891.

Relates to means of supplying current from underground conductors to the moving car on the surface.

Switches and Cut-Outs:—

Time Cut-Out for Electric-Service Systems, S. R. Linville, 480,369. Filed March 29, 1892.

Consists of a time-controlled switch for automatically short-circuiting or breaking a lamp, motor, etc., at a required time.

Electric Switch, J. S. Gibbs, 480,694. Filed Feb. 27, 1892.

Employs fixed and movable poles supported upon a base, a handle connected with the movable pole through a train of multiplying gears.

Telegraphs:—

Telegraph-Key, A. E. McClaren, 480,475. Filed Apr. 9, 1892.

A key designed for use in connection with all the wires that an operator can handle dispensing with a multiplicity of instruments.

Duplex Telegraph, T. A. Edison, 480,467. Filed Sept. 1, 1874.

Telegraph-Transmitter, C. Willoughby, 480,644. Filed June 30, 1891.

Employs a bank of keys one for each letter or character desired.

Automatic Circuit-Closer for Telegraph-Keys, C. W. Bradford, 480,669. Filed May 31, 1892.

Has for its object to prevent the circuit from being accidently left open.

Telephones and Apparatus:—

Telephone, J. A. Christy, 480,656. Filed Dec. 1, 1890.

Employs a wire gauze screen over the mouth of the transmitter, an insulating washer resting on the screen, a diaphragm resting on the washer, a metal washer set upon the diaphragm having electrical connection with the exterior of the case and an insulating washer set upon the metal washer

---

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED AUGUST 16, 1892.

Accumulators:—

Storage Battery, E. P. Usher, 480,883. Filed Aug. 22, 1891.

Employs a flexible wrapper for the series of plates having inwardly projecting inclined lips to hold the separator sheets and lead plates in proper alternate position,

Storage Battery, E. P. Usher, 480,885. Filed Feb. 19, 1892.

Employs separator plates of kiln-dried wood applied directly to the face of the positive plates, while an open space is left between the separator and the negative plates.

Battery Plate, E. P. Usher, 480,886. Filed Feb. 19, 1892.

Consists of a tablet of lead oxide or its equivalent formed of a wrapper of lead foil, and a filling of dry powder with a conducting strip embedded therein and protruding therefrom.

Battery Plate, E. P. Usher, 480,887. Filed Feb. 19, 1892.

Employs a marginal frame with open interior spaces and one or more cross-bars, one side of the frame and bars being coa'ed with an adhesive substance to which adheres a leaf of lead foil. The spaces are then filled with powdered oxide of lead and another leaf of foil similarly fastened to the other side of the frame.

Alarms and Signals:—

Electrical Drop Annunciator, T. W. Lane, 480,729. Filed Dec. 19, 1891.

Electric Train Signal, G. Merritt, 481,042. Filed April 18, 1892.

An electric cord signal system for steam railways.

Conductors, Conduits, and Insulators:—

Insulator, W. J. Bowen, 481,132. Filed May 2, 1891.

Consists of a hollow shell containing an insulating material and having an eye extending through the shell, to which the conductor is connected.

Distribution:—

Electric Lighting System, M. J. Quirk and C. Bach, Jr., 480,782. Filed Oct. 29, 1891.

A concealed system of switches for operating lights in large buildings.

Dynamos and Motors:—

Armature Conductor and Means for Insulating the same, E. Kolben, 480,727. Filed Feb. 8, 1892.

A conducting bar serving as a commutator bar and having a continuous sheet of insulation on its two sides and rear edge.

Ring Armature, E. Kolben, 480,728. Filed Feb. 8, 1892.

An armature having a conductor comprising its coil bare on two opposite sides of the armature, whereby either side may be employed as a commutator surface.

Commutator for Electromagnetic Machines, H. F. Parshall, 480,73). Filed Dec. 11, 1891.

Employs conductors connecting separate segments of the commutator, each of said conductors having sections in separate parallel planes.

Armature for Dynamo-Electric Machines, H. F. Parshall, 480,740. Filed Dec. 11, 1891.

Claim 2 follows:

An armature core built up of alternating sections of notched and perforated plates.

Ventilated Brush for Dyanmos, H. H. Cherry and S. D. Younglove, 480,769. Filed Oct. 2, 1891.

A ventilated brush consisting of a perforated core enclosed in a perforated wrapper and a clasp connected to the brush body.

Commutator for Ring Armatures, G. Pfannkuche, 480,780. Filed July 8, 1890.

Claim 1 follows:

A commutator having the sections provided with transverse recesses and arranged so that said recesses in adjacent sections overlap.

Galvanic and Thermo-Electric Batteries:—

Battery Cell, E. P. Usher, 480,881. Filed Feb. 19, 1892.

Employs a lining of acid-proof gum and a thin shell embedded in the gum and coated externally and internally therewith.

Electric Battery, P. Steins, 481,(75. Filed Apr. 20, 1892.

A system of filling and emptying battery cells from some one convenient point.

Lamps and Appurtenances:

Holder for Arc Lamps and Similar Globes, Frederick D'A. Gould, 480,720. Filed Dec. 5, 1891.

Electric Arc Lamp, F. D'A. Gould. Filed Dec. 5, 1891.

Employs tilting mechanism for forming the arc and feeding the carbon.

Electric Light Fixture, J. T. Robb, 480,745. Filed Aug. 31, 1891.

A hanging fixture having a universal joint at the socket so that the lamp will always hang vertically.

Standard, L. T. Stanley, 480,749 Filed May 15, 1891.

Combined Gas and Electric Light Fixture, A. T. Enos, 480,818. Filed Oct. 31, 1889.

Incandescent Electric Lamp, G. F. Melick, 480,954. Filed March 4, 1892.

Has several filaments connected in series and a short-circuiting switch mounted on a metal sleeve on the base of the lamp.

Electric Arc Lamp, R. Schefbauer, 480,968. Filed Nov. 24, 1891.

Employs a differential solenoid and suction core, a carbon carrying rod passing into said core and a magnetic friction device, one part of which is connected to the core and another part geared to the carbon carrying rod.

Adapter for Incandescent Lamp Sockets, H. P. Ball, 480,968. Filed May 7, 1892.

Consists of a sleeve having inwardly extending flange at its base and an insulating disc in the end of the sleeve having a central screw-threaded hole for the purpose of connecting with Edison or Thomson-Houston lamps with equal facility.

Incandescent Electric Lamp and Lamp Socket, B. Ford, 481,019. Filed Nov. 27, 1891.

Has for its object a construction in which the short-circuiting fusible plug is arranged in the lamp proper instead of the socket.

Incandescent Electric Light, E. McOnat, 461, 047. Filed July 9, 1891.

Has for its object to lessen the length of platinum wire required to mount the filaments.

Measurement :—

Electrical Measuring Instrument, E. Weston, 480,888. Filed March 11, 1891.

Claim 1 follows:

In an electrical measuring instrument a movable index arm and a body of diamagnetic material, in plain or disc form, disposed transversely the lines of a field of force aud connected to, and operating to retard or oppose the oscillatory motion of, said index.

Apparatus for Retarding or Dampening the Motion of Moving Bodies in Electrical Instruments, E. Weston, 480,889. Filed March 11, 1891.

Employs a coil mechanically connected and moving bodily in an axial direction in the field of force.

Electric Time Indicating Apparatus, E. Weston, 480,890. Filed June 4, 1891.

A loop conductor vibrating in a field of force on the passage of a current and a device for showing the number of its vibrations.

Temperature Regulating Device for Electrical Circuits, E. Weston, 480,891. Filed June 4, 1891.

Employs a coil formed of an electrical conductor, the resistance of which increases with augmented temperature, a conductor connected in series with said coil, the resistance of which decreases with augmented temperature, the latter conductor being so proportioned as to render the combined resistance of the two substantially constant.

Electrical Measuring Instrument, E. Weston, 480,894. Filed Jan. 8, 1892.

Relates to means for causing augmented deflections on the index of an electrical measuring instrument for equal increments of moving force thereto applied.

Electrical Measuring Instrument, E. Weston, 480,895. Filed Jan. 14, 1892

Employs a flexible body of conducting material in a main circuit, means of applying strain at an angle to said body and an index and scale showing the displacement of the body under strain.

Electrical Measuring Instrument, E. Weston, 480,896. Filed Jan. 14, 1892.

Similar to No. 480,895.

Electrical Measuring Instrument, E. Weston, 480,897. Filed Jan. 14, 1892.

Depends upon the principle that a wire when heated by a current passing through it will become elongated relatively to the current strength.

Electrical Measuring Instrument,, E. Weston, 480,898. Filed Feb. 17, 1892.

Claim 1 follows:

In an electrical measuring instrument an enclosing case, having a portion of one of its walls detachable, and a scale upon said portion.

Electrical Measuring Instrument, E. Weston, 480,899. Filed Feb. 19, 1892.

Employs a magnet having concentric poles and movable coils extending through the inner pole and through the space between the two poles.

Electrical Pressure Indicator, J. W. Howell, 480,947. Filed Jan. 2, 1892.

Employs a resistance sensitive to changes of current and having another resistance reserved as a test, and a switch adapted to throw either one in circuit as desired.

Metal-Working :—

Arc Welding and Heating Apparatus, P. I. Unwin and H. Howard, 480,794. Filed June 14, 1892.

Has for its object the economy of power when a number of circuits are being employed intermittently so that all, a few or none may be in use.

Method of Electric Welding, H. Howard, 481,080. Filed May 31, 1892.

Miscellaneous :—

Injector or Inspirator for the Larynx, etc., W. Scott, 480,787. Filed March 14, 1892.

Has a hollow handle holding a small battery furnishing current to a lamp at the extremity of the instrument.

Electric Dispatch System, A. Bryson, Jr., 480,804. Filed Oct. 15, 1891

Employs a motor, a carrier, a guide located at each of the branches of the track, means for allowing the sender to engage automatically with a predetermined guide and a continuous conductor for supplying current to the motor.

Electric Elevator, F. E. Herdman, 480,845. Filed Oct. 20, 1891.

Has for its object to regulate the speed of an elevator proportionately to the load.

Electric Elevator, F. E. Herdman, 480,846. Filed Dec. 22, 1891.

Similar in its object to 480,845.

Rheostat, E. Weston, 480,892. Filed Dec. 5, 1891.

Employs two suspended bodies of conducting material in juxtaposition and a means positively acting upon both to force them into more or less close contact.

Rheostat, E. Weston, 480,893. Filed Dec. 10, 1891.

Employs two series of contact plates opposite one another on the circumference of a circle, and resistances interposed between them.

Process for Recovering Tin from Tin-Plate, M. R. Garcia, 480,920. Filed Dec. 24, 1890.

An electrolytic process for separating the tin from the plate to which it adheres.

Joint for Electric Wires, W. E. Harrington, 481,025. Filed Aug. 28, 1890.

A sleeve joint for trolley wires, etc.

Railways and Appliances :—

Guide for Replacing Electric Trolleys, C. Fortin, 480,766. Filed April 11, 1892.

A bifurcated lever arm pivotally secured to the trolley pole and having its upwardly extending members inclined outwardly for the purpose of guiding the trolley wheel to the wire in case of displacement.

Electric Railway, R. M. Hunter, 480,850. Filed May 28, 1887.

Has for its object to provide means for supplying current from a surface conductor which shall be cut out of circuit except when the vehicle is passing over it.

Electric Locomotive, R. Eickemeyer, 480,918. Filed Dec. 21, 1859.

Employs a construction by which the motor is pendant from the truck frame and has its armature shaft substantially in the horizontal plane occupied by the axle.

Electric Control of Railway Trains, R. C. Sayer, 481,062. Filed March 10, 1892.

Has for its object to control the motion of the train automatically by electrical means, the power being led to the motor through a valve switch or other means as circumstances require.

Switches and Cut-Outs :—

Snap Switch, F. d'A. Gould, 480,722. Filed Mar. 26, 1892.

A snap switch in which the switch arm remains stationary in both its open and closed positions until a spring suddenly operates to close it.

Electric Fuse, O. T. Blathy, 480,802. Filed May 8, 1890.

Employs one or more dics threading the fuse wire for the purpose of absolutely preventing the formation of an arc after the wire has blown.

Adapter or Plug for Incandescent Lamp Circuits, E. Weston, 480,900. Filed Mar. 21. 1892.

Rosette for Electric Lighting, E. W. Buffinton, 480,915. Filed May 27, 1892.

Snap Switch, J. Hutchinson, 480,948 Filed Jan. 12, 1891.

Has a circular track with a series of double inclines and contact plates in the alternate depressions formed by said inclines, one end of each contact plate being in the form of a spring.

Telegraph :—

Combined Telegraph Key and Circuit Closer, W. F. Lott, 481,114. Filed April 26, 1892.

Telephones and Apparatus :—

Microphone, E. Noriega, 481,048. Filed June 11, 1891.

A carbon for microphones formed of charcoal, graphite, boric acid and water.

Telephone, E. Noriega, 481,049. Filed June 11, 1891.

Employs a pole-piece formed of a series of round rods of different diameters attached to the pole of a permanent magnet and forming a core to receive the bobbins.

Microphone, E. Noriega, 481,050. Filed May 7, 1892.

Employs a vibratory carbon plate, a fixed carbon plate and a mass of carbon filaments between the two.

Electric Annunciator, F. A. Pickernell, 481,120. Filed April 16, 1892.

A combined annunciator and reset for telephone systems.

Telephone, F. H. Brown, 481,138. Filed Mar. 23, 1891.

Employs a permanent magnet, one pole of which is movable in close proximity to the other pole, a diaphragm and a connection between the diaphragm and the movable pole of the magnet.

CARPENTER ENAMEL RHEOSTAT COMPANY.

THE CARPENTER ENAMEL RHEOSTAT COMPANY, now have their works at Bridgeport, Connecticut, in full operation. The extreme cheapness and evident advantages of this rheostat have been the cause of an unexpectedly large business, although the works have only been in operation a short time. Orders have already been received from over 50 different concerns, one order alone being for 1,000 rheostats.

The capital stock of the company is 100,000 fully paid. The officers of the company are H. Ward Leonard, president; Geo. H. Finn, vice-president; Charles E. Carpenter, secretary and treasurer. Several prominent and wealthy New York gentlemen are financially interested.

The manufacture of the rheostat involves a great many trade secrets, which, together with several strong patents and extremely low prices and a progressive business policy, seem likely to soon make the coiled wire rheostat a thing of the past. The company promises some startling developments in the patent situation at an early date.

THE WIGHTMAN ELECTRIC MANUFACTURING COMPANY.

THIS active concern, at Scranton, Pa., has enjoyed a busy summer and looks forward to a rushing fall trade in its railway motors and specialties. A number of improvements have lately been made in the motor, one of which is to shift the commutator to the side of the armature furthest from the gear. This is much better mechanically, and enables the motor to give an increased output for the same input. The casing to protect the motor has also been made more complete, yet the motor is much easier to get at and to repair, if necessary. The new type gives excellent results.

The company has recently undergone change in its management, and the following is now the list of officers: Oscar T. Crosby, president; R. E. Dunston, general manager; Merle J. Wightman, vice-president and electrician; H. E. Hand, secretary and treasurer. The new superintendent is Mr. T. V. Bolan, a useful importation from the Lynn factories. Mr. Bolan is a graduate of the Massachusetts Institute of Technology, and has paid considerable attention to railway motor work.

ANNUAL STATISTICS OF THE PATENT OFFICE.

THE annual report of W. E. Simonds, Commissioner of Patents, to the Secretary of the Interior, shows that during the fiscal year ended June 30, 1892, applications for patents and caveats were received as follows: Letters patent, 39,987; design patents, 983; reissue patents, 114; registration of trade marks, 1,919; registration of labels, 541; caveats, 2,401; total, 45,945.

There were during that period 23,626 patents granted, including reissues and designs, and 1,563 trade marks and six labels registered; 12,427 patents expired during the year. The receipts from all sources during the year were $1,268,727; expenditures, $1,114,134; leaving a surplus for the year of $154,593. Since its establishment the Patent Office has turned into the Treasury $4,102,441 above its expenditures.

The number of applications awaiting action on the part of the office on June 30th was 9,447.

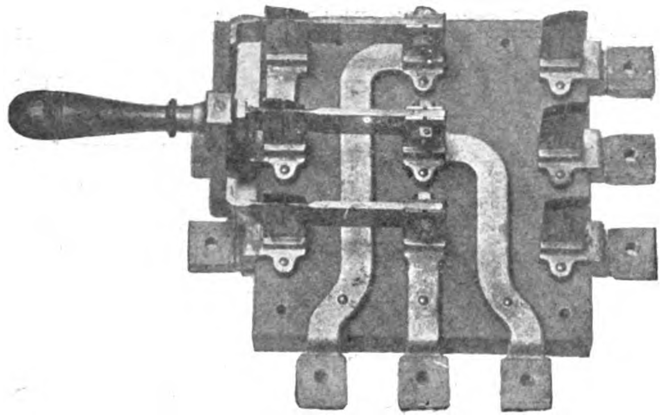
THE GENERAL ELECTRIC CHANGEOVER SWITCH.

To meet a demand created by the increasing adoption of electricity for lighting purposes, the switch shown in the accompanying illustration has been devised by the General Electric Company. This is constructed for use as a main switch on installations, provided with independent or isolated dynamos, and at the same time connected with the street service. The switch is mounted upon a slate base. Three connecting wires are arranged crosswise between the two sets of side contact clips. To these bars are hinged three switch blades having a common handle, which can be thrown into either set of contact clips. Two of the clips on one side are connected, and it is on this side that connection is made with the main wires of the isolated plant, which must be wired according to the three wire system. It is necessary that the neutral wire which is brought to the central connecting bar of the switch should be of larger sectional area than usual. When the lights are being run from their own isolated plant the neutral wire acts as the positive conductor, the two outside wires serving as the negative. Thus, when the isolated plant is shut down and the street service thrown on, the building is lighted on a true three-wire system.



General Electric Changeover Switch.

The advantageous uses to which this switch can be put are numerous. In factories having isolated electric plants, the operation of the boilers, engines and dynamos after whistle-blow, when part of the force is working overtime would be extremely costly. Connection with the street service is therefore made, the switch illustrated thrown over from the isolated service, and the factory lighted on an economical basis. The switch can also be used as an emergency or break-down switch in case of injury to the isolated plant. In theatres and other public institutions, where a sudden extinction of light would be apt to cause a panic, it is a moment's work only to switch on the current from the street and avert disaster.

CENTRAL ELECTRIC CO.

The Central Electric Company report that the ten-story Lakota Building in Chicago is to be wired throughout with Okonite. Interior Conduit will also be used. They also report having secured an order for some ten miles of No. 6 Acme lead covered cable, tested for 5,000-volt circuit. The company's sales for Gladiator dry batteries have been so large for the past few weeks that their stock is completely exhausted. They are, however, receiving a large consignment, and will be in a position to again fill their orders promptly.

President W. H. McKinlock has been cruising on the Southern Massachusetts coast, and reports delightful weather and excellent fishing. He has been touching the principal watering places and has been having a thoroughly enjoyable time. His brother, Dr. John McKinlock, of the Central Electric Company, has been spending a few weeks with his family at Mackinac Island, and no doubt will return with renewed vigor for the winter's campaign.

Mr. Romaine Mace, the representative of the Interior Conduit & Insulation Company, has been spending a few days with the Central Electric Company, consulting with them regarding the best methods to pursue in pushing the sales of the Interior Conduit Company's specialties, and taking care of the large business which they are securing. The Central Electric Company report flattering prospects for a heavy trade the coming fall on these now essential devices.

THE "TWIN CONDUCTOR" AND HOTEL OVERCHARGES.

The following letter to Mr. E. W. Little, general manager of the Interior Conduit & Insulation Co., gives striking proof of the merits of the twin conductor and the brass conduit tubes:

Philadelphia, Pa., Aug. 12, 1892.

Mr. E. W. Little, General Manager,
42 Broad street, New York.

Dear Sir:—Thinking it would be of interest to you to have a testimonial relating to the performance of your standard twin conductor at the New Neversink Mountain Hotel, Reading, Pa., during the recent and very severe electrical storm, I being an eye witness, and Walker & Kepler the contractors, it was very gratifying to see the results; we have tubed the entire hotel with about 30,000 feet of the brass conduit tube, and have placed the twin wire throughout the entire building.

The lightning was said to be the most severe ever seen in Reading even by the oldest inhabitants of that place, and seen to play around and through the building in every direction, but did not affect our lines in any manner, not even so much as to blow the smallest fuses.

During the storm several of the lamps were broken by the overcharged lines, the glass being blackened as though they had been painted with black paint on the inside.

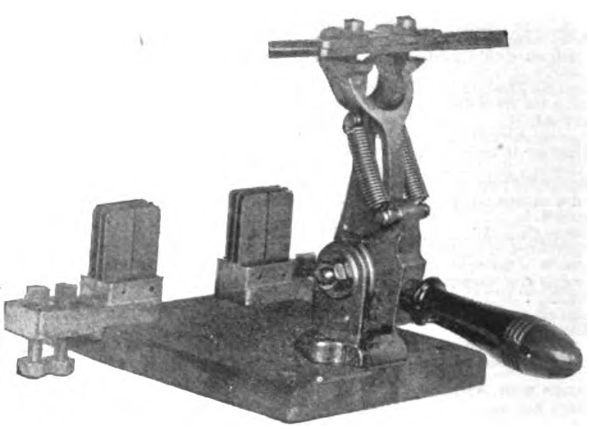
Some were burst, and cracked like little pistols when they went off. The building gets its current from the Reading Electric Light Co., whose plant is located 9,500 feet from the hotel. It is an overhead system, and therefore the overcharge in such a storm would be very heavy.

Hoping that this testimonial will be of some benefit to you, I remain,

Yours respectfully,
(Signed) I. C. Walker.

THE CROSS-BAR INSTANTANEOUS SWITCH.

The "Cross-Bar" instantaneous switch, shown in the accompanying illustration, is the invention of the General Electric Company, and is the latest high voltage instantaneous switch to appear upon the market. As its name indicates, it is a switch having its contact blade at right angles to the actuating lever. The terminal clips are placed opposite to each other, but widely separated, and the circuit closes as soon as the cross-bar simultaneously enters both clips. This cross-bar is loosely supported in the pawl of the lever by two steel pins, and a small steel spring serves to press the bar against the lever so that it will enter the clips truly, and make full and easy contact with both inside faces. Practical use has shown that this flexible method of mounting the cross-bar increases the durability of the switch, the alignment of the parts being rendered less liable to destruction by violent or careless handling. The snap, or instantaneous, action is obtained by means of two strong helical springs, which are attached both to the handle and the lever. The downward movement of the handle distends the springs to that point of tension which compels the obedience of the lever, and the cross-bar flies out from the clips, breaking the circuit at two points and reducing the possibility of arcing to a minimum. When the switch is fully opened, a catch-spring retains it in position, and an accidental closing of the circuit is rendered impossible; this small spring also serves to give a snap action to the switch when the circuit is made.



Cross-Bar Instantaneous Switch.

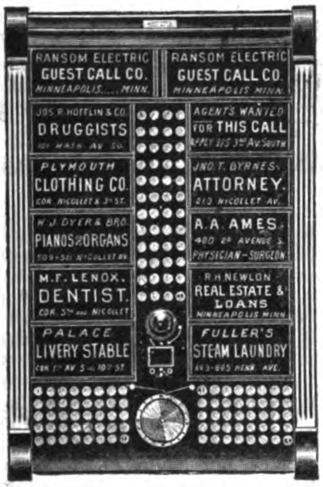
The principal novel points claimed for this switch are: Considerable distance between the clips; an absolutely instantaneous breaking of the circuit and a perfect flexible and frictional contact. The smaller sizes have the cross-bar in a single piece, while those of larger capacity are provided with a double parallel bar as shown in the engraving.

THE ELECTRIC GUEST CALL.

The accompanying illustration shows a new hotel annunciator, introduced by the Electric Guest Call Company, of Minneapolis, Minn., the operation of which will be readily understood.

The electrial dial has 48 pins in the edge of the rim corresponding to the quarter hours. The operation is as follows: "A," room 18, informs the clerk that he wishes to be called at 7.30 a. m., the check hanging on hook 18 is hung on the 7.30 hook above and the pin in the dial marked 7.30 pushed in. "B," room 22, is to be called at 8 a. m.; No. 22 check is hung on 8 o'clock hook above and 8 o'clock pin pushed in. "C" also wants to be called at 7.30, his check is also hung on the 7.30 o'clock hook; the pin on the dial having been pushed in for "A" need not be touched. It will be seen at a glance that no guest should be missed as all of the rooms to be called at a given time hang on the same hook and one ring answers for all. No further attention need be paid to the matter until the electric bell rings, which will be at the different hours it may be set for. The bell will ring several minutes or can be stopped at once. The wires do not run to the rooms in the hotel as the guest call is complete in itself. The clock is a good Seth Thomas time-piece.

The whole device is very simple in action and cannot readily get out of order. In an instant the dial can be set to ring each 15 minutes during the night and can be used during the entire day to remind the clerk of wants at specified times, etc. The bell is on the outside of the case, which is 26 inches wide, 8 inches deep and 40 inches high, and can be hung against the wall. It is sent ready to hang up and does not need an expert, but can be set up by any one. The two top signs measure 5 x 11 inches and the 10 side ones 5 x 9 inches and are tastefully executed, the whole making an ornamental as well as extremely useful device.



Electric Guest Call.

THE CARDEW VOLTMETER FOR ALTERNATING CURRENTS.

The Cardew Voltmeter is recognized as a standard switchboard instrument for alternating currents, while an essential feature is its equal correctness when used on continuous circuits. Queen & Co., of Philadelphia, who own the American patents, are making these voltmeters in quantities to supply the demand, and have also reduced the prices considerably, which announcement is of importance to intending purchasers. The merits of the Cardew instruments are fully set forth in price list No. 290, which can be obtained from the makers for the asking.

AN IMPORTANT ELECTRIC RAILWAY PLANT IN NEW YORK STATE.

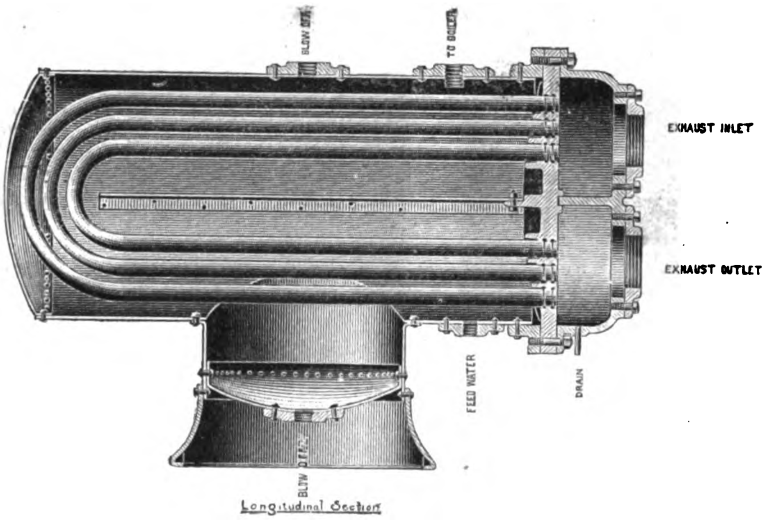
Perhaps the most important and novel electric railway work recently undertaken is that of the Cayadutta Electric Railway, connecting Fonda, Johnstown and Gloversville, N. Y. It will parallel a steam road, and electric locomotives will for the first time be in direct competition with steam locomotives for freight as well as passengers. The complete construction has been undertaken by H. Ward Leonard & Company, including grading, roadbed, building, steam plant, electric generators, electric overhead work, cars, etc. The road will be in operation about December 1. This important contract forcibly illustrates the desire on the part of owners to deal with one contractor for the entire work, and especially with a contractor who is entirely independent of so-called "systems," and hence able to procure for such a plant the best and most recent developments in this rapidly changing industry.

STILWELL'S CLOSE HEATER—ITS SUPERIOR POINTS.

For more than a quarter of a century the Stilwell & Bierce Mfg. Co., of Dayton, Ohio, have made a specialty of manufacturing devices for heating and purifying the feed-water for steam boilers. Their latest contribution to that branch of industry is the Stilwell patent close heater, herewith illustrated, for which the following points of superiority are claimed: The heating tubes are seamless brass, U shape, and so fastened into the tube-sheet as to be absolutely tight. The base on which the heater stands serves also as a mud-well or settling chamber for the deposit of impurities, which can be readily blown off. Deposits of impurities in this settling chamber do not diminish the power of the heater. The cold feed-water enters the heater near to the steam-exit end of the tubes, thus offering the most favorable conditions for extracting the most heat from the exhaust steam.

The diaphragm which separates the shell into two equal sections, compels the feed-water to traverse the entire length of the heating tubes, and its exit from the heater is made at a point in close proximity to the incoming exhaust steam, thus insuring the highest possible temperature of the feed-water. The construction of the heater admits of its being taken apart, if necessary, for cleaning. The tubes and tube-sheet can be readily removed from the shell for that purpose.

Those interested can obtain further particulars by addressing the manufacturers as above.



Stilwell's Close Heater.

THE TICHENOR BATTERY AT YORK, PA.

It may interest some people to know that "Prof." A. C. Tichenor, of primary battery fame, has opened up once more, this time at York, Pa., where he is delighting and dazzling the natives with a fine exhibit "Over Free's Liquor Store." The juxtaposition between the store and exhibit may, perhaps, account for the eloquence of the descriptive article appearing in the *York Daily*, which devotes a column to the subject of "Prof." Tichenor's great inventions.

THE ENTERPRISE ELECTRIC CO.

An announcement that will be of great interest to the electrical trade in general is that made by the Enterprise Electric Co., of Chicago, of which Mr. W. C. McKinlock is president and treasurer, to the effect that they have secured the general Western agency for a special rubber wire manufactured by the National India Rubber Co., of Bristol, R. I. Futher details will be awaited with a good deal of interest and curiosity.

The Columbia Phonograph Company have prepared a number of cylinders of campaign songs with piano accompaniment, which they are ready to furnish in any quantity and for which they anticipate a ready sale.

INTERESTING RESULTS WITH FUSE WIRES.

THE accompanying cuts of fuse strips, made from two different alloys, show, in an interesting way, the difference in the manner

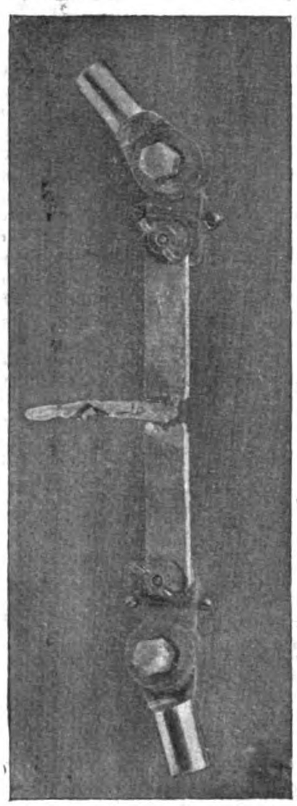


FIG. 1.

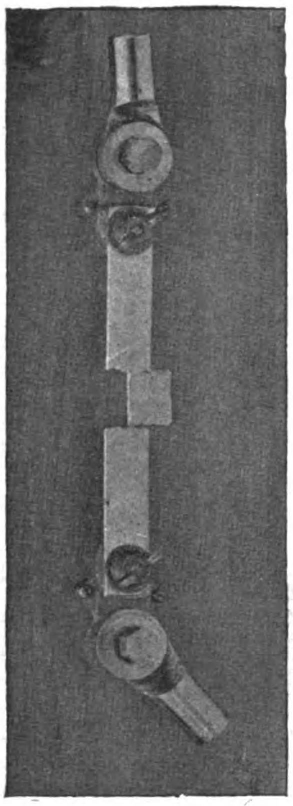

FIG. 2.

of fusing. Fig. 1 shows a strip made from the metal in common use. Under the action of the heat a crust of oxide apparently forms on the surface, preventing the fuse from breaking at once, but causing it to run and bubble in the interior until the molten metal breaks through this outer skin. It will readily be seen that such a fuse will open the circuit awkwardly—scattering the hot metal and causing much arcing. Fig. 2 shows a strip made from the special alloy used by the Shawmut Fuse Wire Co. in their tested fuse wire. In this the fuse remains solid until a certain point is reached, when, as will be seen, a part of the metal drops out bodily, making a quick and clean break of the circuit and thus preventing, to a large extent, the destructive effects on terminals and fuse blocks.

PROSPERITY OF THE FIELD ENGINEERING COMPANY.

THE FIELD ENGINEERING COMPANY report that they have had the contracts for all the railway work in Philadelphia for the last six months They helped all through the controversy last spring in obtaining franchises, etc., having charge of the expert part of the matter. They have had franchise for a year and a half for going ahead with all the roads in West Philadelphia, though the controversy which came up last spring in obtaining the franchise for the main part of the city delayed them in starting the work on these roads. The franchises were all obtained and work ready to go ahead with, except for the defect which developed on an application for an injunction. This has been denied on several of the lines, and they are now going ahead with this work in the main part of the city, and expect to have cars running before frost. This fall and winter and next summer the obstacles will probably be removed, so that the main part of the roads can be gone ahead with. They will approximate 150 miles, which it is proposed to equip with the trolley system. All that money and engineering skill can do will be done to make the equipment in all respects the best that has been done in the country, and all feeder wires will be put under ground.

The power plant which is being erected at present is a small one, only about 1,500 h. p. for operating the lines which are being equipped at present. The first main power station will be eight or ten thousand horse power. Construction work is very active with the Field Engineering Company on all their other contracts as well. They have four or five contracts on hand at Buffalo, including the main contract with the Buffalo Railway Co. They have already in operation there about sixty miles of road, the last part being started up a few weeks ago, and have 2,500 h. p. in the power station. The balance of this equipment, up to 5,500 h. p., and 250 cars, will probably be finished this winter.

The Newark and South Orange road at Newark is being rapidly equipped for the new company that has recently purchased it. It is expected that this road will be in operation early in the fall. It is one of the best paying roads for its length in the country, and was purchased recently for a million and a half of dollars from Mr. Radell, who paid about sixty thousand for it eighteen years ago.

At Trenton part of the system is in operation with the Short single-reduction motors. There will be an additional line started very shortly.

TOLEDO, OHIO, NOTES.

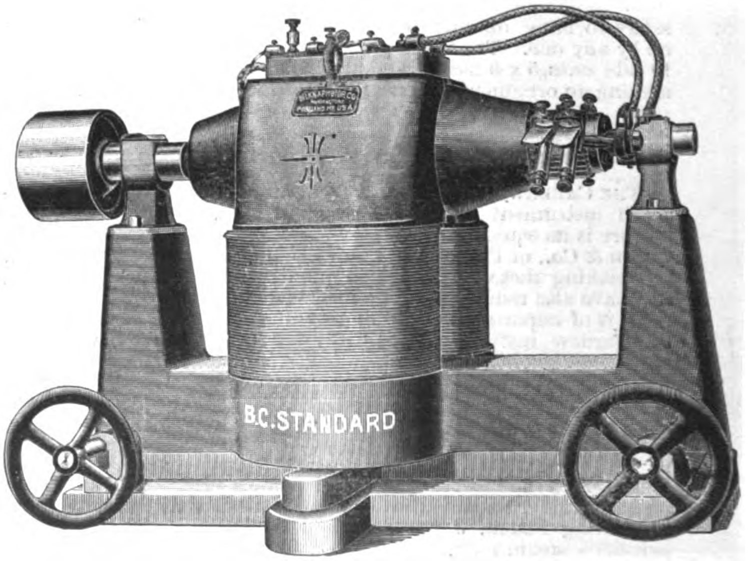
THE CONSOLIDATED STREET RAILWAY CO., of Toledo, Ohio, are equipping all their lines with electricity. Four large new T.-H. generators have just been added in the station. The new Belt Line is now completed and proving very popular. The company have had a number of banners made to put on cars which are being chartered every pleasant evening by parties who enjoy a whirl around the city.

THE TOLEDO ELECTRIC LIGHT STATION was destroyed by fire on July 30, with a loss of $75,000, insured for $61,500. New dynamos have already been ordered, and are being put in. Power will be furnished by the street railways and other companies until the new station can be built and equipped. The new plant will cost about $150,000.

THE TOLEDO ELECTRIC STREET RAILWAY CO. have recently made an excursion line of the Asylum line, running open cars through from Manhattan to the Asylum, every afternoon and evening and all day Sundays. The distance is eight miles, and it is one of the most interesting and attractive rides in the city.

THE B. C. STANDARD ELECTRIC MOTOR AND DYNAMO.

WE illustrate in the accompanying engraving the most recent form of the B. C. Standard electric motor and dynamo, manufactured by the Belknap Motor Co., of Portland, Me., who are also large manufacturers of water motors for various purposes. The B. C. dynamo or motor is compound wound, and therefore self-regulating, the field magnets being of the horseshoe type, the bed plate forming the yoke of the magnet. The wire of the field is wound on separate spools made of brass with leatheroid heads, which can easily be replaced. The armature is laminated, the sheets being all keyed to the shaft by one spline, and pressed firmly together by a nut at one end. The depth of the winding on the armature is very small, and this, together with the large quantity of iron in the field magnets produces a magnet circuit of low resistance and consequently a high inductive capacity for every foot of wire on the armature. The commutators are made of pure tempered copper, and spring brush holders are used, so made that the friction on the commutator is reduced to a minimum.



B. C. STANDARD ELECTRIC MOTOR AND DYNAMO.

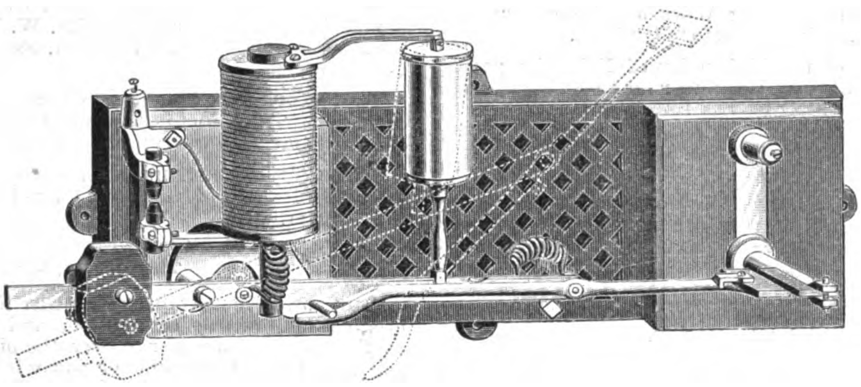
BOILER PITTING CURED BY GRAPHITE AND OIL.

In the *American Machinist* of July 28, Mr. T. T. Parker has a very interesting column article regarding pitting in boilers. Besides some clever theories, he has this to say from a practical point of view: "A boiler of the porcupine persuasion, pitting was found in the mud drum. Acting under advice, the drum was cleaned and scraped, after which it was painted with graphite mixed with cylinder oil. Measurements of the depths of the pits were taken, and six months after they were found no deeper, and no new ones had shown up. Other parties have since tried this experiment in mud drums, but it is too early as yet to give the result. However, knowing the character of plumbago, if the interior of a boiler could be painted with it in such a way that it would stay it may be this would prove a remedy. I am satisfied also that the person doing so would kill two birds with one stone, as the scale could be easily detached. In a pair of cylindrical boilers 42x28, occasional applications of cylinder oil (mineral) and plumbago have kept back corrosion on a trial of six months. Boilers were new when plumbago was used. The boilers which the new ones replaced were thrown out rotten from corrosion. The feed was mine water, as nothing else could be had."

To Mr. Parker's remarks, we may add that Messrs. Harig, Koop & Co., Louisville, Ky., after experimenting more or less trouble from rust and scale in the mud drums of their boilers, applied with great success graphited oil, purchased from the Joseph Dixon Crucible Company, Jersey City. The mud drums were cleaned out and the graphited oil applied with swab, brush, or anything handy to the joints and parts where the water enters the drums. Every four or six weeks this process is repeated with the most gratifying results.

THE COLUMBIAN LIGHTNING ARRESTER.

A reliable lightning arrester that will always operate is of the utmost importance to central station men and others, and to meet the requirement, the Interstate Complete Electric Construction Co., of St. Louis, have lately brought out a new form shown in the accompanying illustration which combines many new features. Is exceedingly simple and has proved its reliability under all conditions of service. The arrester comprises a solenoidal magnet operated by the main current, which opens automatically the path to ground taken by the lightning in the event of the dynamo current tending to follow over. This magnet is provided with a special dash-pot which allows a rapid movement upward with a slow return. One pair of carbon points in addition to the carbons at the point of break, and in series with them, are provided in case of an abnormal discharge, thereby always protecting the solenoid. As a further precaution, a special break-arm lever is used, giving additional distance and rapidity to the break. This arrester has already been put out in large numbers and under the most severe tests has never failed to operate; and its extreme simplicity, there being nothing to get out of order, recommends it at once.



Columbian Lightning Arrester.

The Collins Park and Belt Railroad Co., of Atlanta, Ga., is now in successful operation with two 150 h. p. generators and ten Brill cars, equipped with 20 h. p. single-reduction motors, all of which apparatus was furnished by the Short Electric Railway Company, of Cleveland, Ohio. The company are operating the two ends of their system, not having as yet been able to complete the line through a part of the city. The road has had unusual success from the start, and both ends are very much more than paying expenses. It is thought that it will be but a few weeks before passengers can be carried from one extreme of the city to the other.

WESTERN NOTES.

The Pabst Brewing Co., of Milwaukee, Wis., have placed their order with the Siemens & Halske Electric Co., of America, for their new 1,000-light incandescent central station. This installation will consist at first of two 250 h. p. dynamos, and one 90 h. p. dynamo. These machines will be of the well-known Siemens & Halske direct coupled type, the armature being placed on the end of the shaft. The Lake Erie Engineering Works have the order for the engines. The ultimate capacity of this plant will be in the neighborhood of 40,000 lights, and by means of the Siemens & Halske generators and Lake Erie engines, the space occupied will be very small. The electrical work is being done under the supervision of Mr. Geo. W. Gibbs, M. E., and the steam engineering under the supervision of the Osborn Engineering Company.

Messrs. Reed & Gross are exhibiting a cycloramic scene upon a magnificent scale of the Chicago fire of '71. The effects obtained by a large number of incandescent lamps, used to illuminate the scene, are exceedingly striking, and the work is highly truthful and realistic. Two large sized Crocker-Wheeler fan motors of the gyratory pattern which distribute the breeze from all points of the compass in turn, are used by these enterprising gentlemen to temper the warm evenings when the lake breeze is lacking. The Cyclorama, which is located at No. 129-131 Michigan avenue, is well worth a visit.

Clark & Marshall, of the Rookery, are to be congratulated on having secured the exclusive agency for the "Cope Automatic Come Along" and other specialties manufactured by T. J. Cope, of Philadelphia. They have also secured the agency for the "Arnold Flexible Bracket" for the states of Illinois, Wisconsin, Minnesota, Iowa, Missouri and Indiana. This bracket is manufactured by the Arnold Novelty Co., of Tacoma, Wash. They will have these goods on the market about September 1st. These goods can be seen at their office, and the trade is invited to call and examine same.

The New Athletic Building.—A recent visit to the new Athletic Building, on Michigan Avenue, gave us an opportunity to thoroughly examine the excellent work which Mr. L. K. Comstock, the electrical engineer, whose office is in the Monadnock Building, has recently done in connection with the wiring of the building, and the use throughout of Interior Conduit tube. Mr. Mace, the expert of the Interior Conduit and Insulation Company, on examining it, stated that it was as perfect and complete a piece of work as he had ever seen, and reflects great credit upon Mr. Comstock's able corps of assistants. The conduit for this building was furnished by the Central Electric Company.

The Electric Appliance Company are doing a splendid business on Packard lamps since the extension of their territory, and although it is still early in the season for lamp business, the outlook is certainly encouraging for an immense business during the coming fall and winter. The sales of the Paranite wire are also increasing daily and splendid results are being secured in every direction.

Mr. J. R Burdick, the traveling agent for the electrical and steam railroad department of the H. W. Johns Mfg. Co., was in Chicago last week having returned from an extended Western trip. Mr. Burdick reports business as excellent, and the sales in molded mica insulation as exceedingly large. Mr. Burdick favored the Western office of the Engineer with a call.

In the article by Mr. Fred. A. Scheffler on "The New Electric Cranes at the Brush Electric Co's. Works," which appeared in our issue of July 20, the author omitted to state that these cranes were manufactured by the Morgan Engineering Co., of Alliance, Ohio. This refers both to the traveling crane in the erecting shop and to the 15-ton pillar crane in the yard.

Mr. F. A. Pamperin, of "Brilliant" lamp fame, was a Chicago visitor last week. He spent several days in the interest of the Electric Mfg. Co., of Oconto, Wis., of which concern he is the general manager. The Chicago office of the company is located at No. 239 La Salle street; Wm. Hood & Co., managers.

Mr. A. A. Forman, manager of the Iron Mountain Electric Light and Power Co., Iron Mountain, Mich., spent a few days in Chicago during the past week.

TO LIGHT THE METROPOLITAN MUSEUM OF ART.

The New York Park Commissioners will on September 7, open bids for furnishing an electric plant and wiring and lighting the north wing of the Museum of Art. They will at the same time open bids for the construction of a boiler house for the use of this museum.

NEW YORK NOTES.

Among the contracts closed by H. Ward Leonard & Co., as bulk electrical contractors, during the past thirty days are the following:

Port Richmond Prohibition Park Railway, Port Richmond, S. I.; J. S. Kennedy's residence, Bar Harbor, Me.; New Netherlands Hotel, New York, City; Racquet and Tennis Club, New York City; Delaware, Lackawanna and Western Building, New York City; the Betz Building, Philadelphia, Pa.; the Havemeyer Building, New York City; the Continental Corset Company Building, Newark, N. J.; I. N. P. Stokes' residence, New York City; the Broadway Power House, New York City; the Cayadutta Electric Railway, Gloversville, N. Y.

The business secured by this concern during the past thirty days exceeds $400,000.

Mr. Ernest H. Heinrichs, who has charge of the Intelligence Department of the Westinghouse Electric and Mfg. Co., was in the city last week. He reports that the company is crowded with work entirely aside from its big World's Fair contract, and that it is now greatly increasing its factory facilities.

Prof. R. B. Owens, of the University of Nebraska, passed through New York on his way West to resume work after his summer vacation, during which he has been seeking coolness in the interiors of electric light stations. He has mapped out some very interesting work for the coming term.

The Engineering Equipment Company have become the sole Eastern representatives of the Railway Equipment Co., of Chicago. The Engineering Equipment Company are having an unusually good trade, and their orders on steel poles are behind in shipments at all times.

NEW ENGLAND NOTES.

C. S. Knowles, of Boston, have undoubtedly filled a want in their "Tenax" tape and splicing compound, judging by the large orders they constantly receive. A rubber tape, to be good, requires to be always sticky, and not easily dried up. The Tenax seems to possess this quality in a marked degree, and can be used at all times for making water-tight joints of high insulating capacity without the use of heat, a somewhat novel feature in such material. That the Tenax tape sticks may be easily proved by trying the experiment which is illustrated this week in our advertising columns. The following postal card which Mr. Knowles received a few days is amusing, as showing the curious places where electrical supplies may sometimes reach, and is at the same time convincing of the adhesive qualities of the compound. "Dear Sir: Your sample of Tenax splicing compound came duly to hand: I have used it upon a pneumatic tire and find there is no doubt about its holding."

Smith & Wallace, of No. 8 Oliver street, Boston, are announcing to their friends in the electrical trade that they have formed a copartnership under the above firm name, and are prepared to furnish all supplies needed in the equipping of electric railways. Mr. A. Otis Smith was for two years treasurer of the Eastern Electrical Supply Company, of Boston, and Mr. J. Edward Wallace was formerly connected with the same house as salesman, where he formed a wide connection with electric railway companies. Smith & Wallace will act as manufacturers' agents, or commission merchants, and their large connection among electrical men will undoubtedly enable them to do a large business.

Mr. F. A. Magee, who has been for the past year Eastern agent, in Boston, for the Underwood Manufacturing Company, of Tolland, Conn., has resigned his position with that company and returned to New York to accept a position with The E. S. Greeley & Company of that city. Mr. Magee is identified with the railway supply department and will handle a new line of electric railway material controlled by The E. S. Greeley & Company. Mr. Magee was formerly connected with this company, having been with them for over four years, and has a wide circle of friends in New York City, who will be glad to see him once more among them.

The Eddy Electric Manufacturing Company, of Windsor, Conn., through their Boston office, of which Mr. E. R. Gilbert is manager, report the following sales: A 400-light dynamo to H. H. McKay, Devonshire street, Boston, for use in the Old Provincial Gold Mines, in Nova Scotia; a 750-light dynamo to the Holtzer-Cabot Electric Company for Washington parties; a 80 h. p. motor and a 300-light dynamo for the new Lyceum Theatre on Washington street; and a 3,000 ampere generator for the American Lead Company, of Salem, Mass.

The C. & C. Electric Motor Company, of New York, through their Boston office, has been awarded by the city architect of Boston, the contract for the electric lighting plant of the city institutions on Long Island, in Boston Harbor.

Mr. W. H. Cole, electrical engineer, has just installed for the Colombian Government, an electric lighting plant for the city of Cartagena, Republic of Colombia, South America. American apparatus was used throughout.

PHILADELPHIA NOTES.

Queen & Co. have laid in a big stock of Deprez-Carpentier ammeters and voltmeters. These instruments are strictly dead beat, so that readings can be taken very quickly, and the scales are graduated from zero up. Being mounted in compact nickel-plated metal cases, they are adapted for portable testing as well as for switchboards. The prices are very moderate, and a considerable number have already been sold.

Mr. T J. Cope, of the Cope Pilot Line Co. has returned from a business trip West Mr. Cope gave exhibitions of their machine for running pilot line through conduits, and several large electric light companies in the West have adopted their use.

Mr. E. Ward Wilkins, of the Partrick & Carter Co., accompanied by his brother-in-law, Mr. W. W. Winship, are off on a sea trip on the yacht "Lizzie H. Partrick" under the care of Capt. John Meyers.

The Partrick & Carter Co. have a new automatic set back annunciator, a marvel in the line of annunciators, for which this company have a world-wide reputation.

The Commonwealth Co. are having a large run on small motors for fans, and have been obliged to refuse large orders during August.

TROY, N. Y., NOTES.

The power house of the Troy City Railroad on River street is progressing towards completion, and tracks are laid into the north house for cars to run over the pits for inspection and repair purposes. At present the power is received from the Division street power house of the T. & L. R. R., and so far has been amply sufficient to supply current for both roads. At Albia some changes in the car house have' been required, but these have had temporary attention only, owing to the unavoidable necessity for caring for the road-bed which has been almost entirely relaid and reballasted, since the changes involved by city improvements were inaugurated. That this has been done without serious delay is a matter of congratulation to the directory.

ST. LOUIS NOTES.

The St. Louis Electrical Supply Company will make a comprehensive, and elaborate exhibit of their specialties, among which they control many novel and valuable devices at the forthcoming St. Louis Annual Exhibition. A prominent feature of their display will be a number of electrical cooking and heating devices, and also a display of large Packard incandescent lamps for which they are agents, ranging from 200 to 500 c. p.

W. I. Brook reports the closing of a contract with the Burlington, Iowa, Electric Light and Power Company for one 22 x 48 improved Corliss engine built by the Sioux City Engine Works.

Days "**Kerite**" reports among recent sales an order from San Francisco, Cal., of four miles of seven conductor submarine cable; also another, one mile in length to cross the Mississippi at New Orleans. The factories of the Kerite Co. are rushed to the fullest capacity.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

THE
Electrical Engineer.

Vol. XIV. SEPTEMBER 7, 1892. No. 227.

RECENT IMPROVEMENTS IN TELEPHONE ENGINEERING.

BY

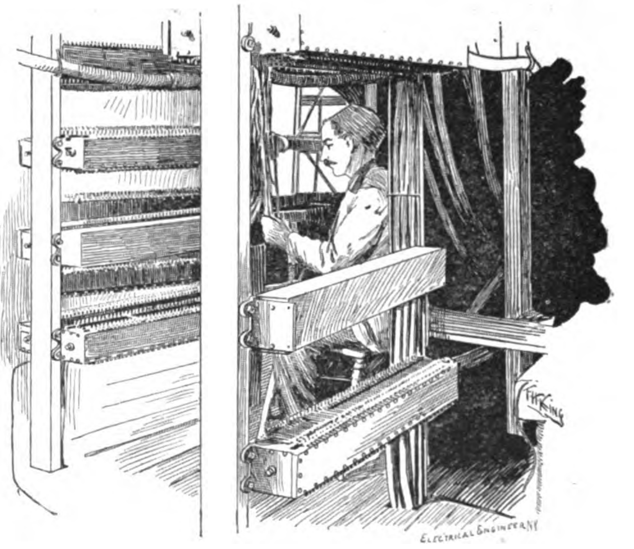
Herbert Laws Webb

GRADUALLY, steadily, and without stint of money, the telephone systems of large cities have undergone a remarkable process of reorganization and reconstruction during the last few years in answer to the demands for better service and for the abolition of overhead wires from city streets. Not very many years ago it was generally considered that "anything was good enough for telephone work," and badly constructed lines, poorly equipped central offices, and rusty, dirty, inefficient instruments were the rule rather than the exception. I remember once being told by a gentlemen who had done a good deal of telephone construction work, and done it very badly, that the insulation of a telephone line was quite immaterial and that he would guarantee good conversation over a bare wire laid along the ground! Such lax notions have quite disappeared now and instead of considering that anything is "good enough," most telephone men think that scarcely anything is too good for telephone work. The closest attention is now paid to details which before were almost entirely ignored, and any little point which may contribute to the efficiency of the system as a whole is most thoroughly investigated.

With the disappearance of the old networks of overhead wires and the crowded cupolas which formerly ornamented the top of telephone exchange buildings, and the introduction of underground cables, has come about the greatest change in telephone engineering proper. The adoption of the telephone cable brought with it a host of problems, both electrical and mechanical, and entirely disarranged the established order of things. Almost every portion of the telephonic system has been more or less upset, modified and changed by the underground cable.

When it became necessary to place the telephone wires underground very few people had had any experience with underground telephone wires. Where such wires had been used they were entirely unsuitable for systems that had to be planned out on a large scale, because they were both electrically and mechanically deficient and too expensive; therefore it was necessary to strike out in entirely new lines. When we have to strike out in entirely new lines we generally learn a good deal by experience in a comparatively short time, and with telephone cables this is particularly true; the experience gained in their manufacture and use during the past few years has been very valuable; and it certainly ought to be very valuable because it has assuredly cost a great deal.

The telephone cable of to-day generally contains one hundred separately insulated copper conductors, enclosed in a leaden pipe about two inches in diameter. Sometimes a larger number of conductors is used, one hundred and twenty, one hundred and sixty and even two hundred, but the hundred-wire cable is the standard type in most general use. The wires are twisted together in pairs, each pair forming a metallic circuit for a single line, therefore a hundred-conductor cable accommodates fifty subscribers. The insulating material used is generally cotton or paper, as india-rubber, gutta-percha, or any of the rubber compounds are debarred on account of their high inductive capacity—the greatest enemy to telephonic transmission. At first the insulating covering on the wires was impregnated with paraffine or some resinous compound to prevent too rapid absorption of moisture in case of rupture of the lead covering, but to reduce still further the inductive capacity the paraffin or compound filling has been abolished and the paper or cotton covering is left untreated. The telephone cable of to-day is more than fifty per cent. better, electrically, than that of two or three years ago. Its chief disadvantage, but one of course inseparable from the use of a non-waterproof insulating material, is that the insulation of the whole cable is dependent on the continuity of the lead covering. If the lead should be punctured or cracked so as to admit air, the covering of the wires will quickly absorb sufficient moisture to destroy the insulation and break down the whole cable. This risk seems more



A Corner in the Terminal Room.

important than it really is, because such accidents are quite infrequent; when they have occurred they have nearly always been traceable to some mechanical injury to the lead of a preventable nature. It may be argued that most of the cables in use are comparatively new and have yet to stand the test of time and long continued service; but then we know that lead is a most durable metal, if properly handled and safeguarded, and it is fair to assume that cables of this type ought to have a long life if they are carefully protected from external injury. So much for the telephone cable itself. Now let us see what changes it has brought about in the telephonic system generally.

For one thing it has had a certain moral influence which has made itself very distinctly felt. There is nothing very delicate about an overhead wire, and overhead construction in this country is generally carried out in a very slack manner. The wires are strung up anyhow and forever after left to their own devices, except when repairs are absolutely necessary, and then the last state of those wires is considerably worse than the first. Nobody ever thinks of testing an overhead wire, except perhaps some of the electric light companies, and these, when they do test their overhead circuits are particularly anxious to say as little as possible about the results. The general slackness of overhead construction is apt to spread to other parts of the work, and bad lines out of doors will be accompanied by poor inside wiring, joints and connections. With underground cables, however, things are quite different. They cost a good deal of money and are made to meet a rigid specification; their electrical conditions are carefully tested at first and watched afterwards to see that the insulation keeps up to, and the capacity below, the mark. The rest of the work naturally takes the key from this; refined methods and high standards must not be relaxed directly the terminals of the cable are passed; good insulation and careful work are required in the connecting wires, and gradually all the construction work is tuned up to concert pitch to be in harmony with the underground cable.

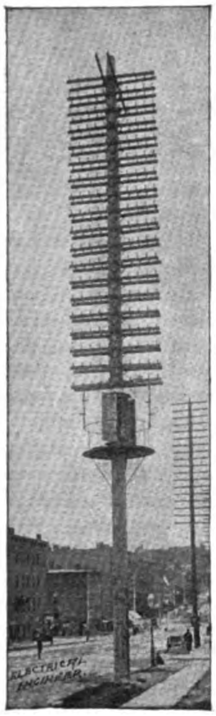
The actual changes in telephone engineering brought about by the extensive use of underground cables, are chiefly confined to the exchanges and terminal or distribution points; with the subways we need not concern ourselves here. It is readily apparent that the conditions under which the wires must be handled are entirely different where underground cables are concerned from what they were with overhead lines. The greatest difference is felt of course in the exchange, although it extends to the outside arrangements as well. With overhead wires each line is separate along the entire route, it is accessible at any point for repairs or alterations, can be led off in any direction required, and can be terminated wherever desirable or necessary. With underground cables, on the contrary, a large group of one hundred wires is inaccessible except at two fixed points, the terminals of the cable; from the outer terminal wires can be led off in different directions to subscribers' stations and with the inner terminal all the connections leading to the switching apparatus must be made. This inflexibility of the underground telephone cable makes it necessary to carefully calculate beforehand the best points for outside terminals in order to place them where a large group of subscribers shall be easily reached, so that each cable may be worked to the best of its capacity. In the New York down-town districts this difficulty is materially simplified by the large office buildings, many of which contain a sufficient number of subscribers to fill up one or more cables.

In the exchange building the problem of properly dealing with the large number of cables that naturally converges there has now been pretty thoroughly solved, both from a mechanical and electrical point of view. Probably the next few years will see still further changes and advances in the methods of handling underground cables at the exchanges, but the present system has been worked out very carefully and does not seem to be susceptible of much further modification, unless some startling improvements in the art should be introduced which would necessitate a complete revolution of existing methods.

The ends of the cables are enclosed in air-tight terminal heads of iron or hard rubber, provided with as many brass binding posts as there are conductors in the cable. The conductors are attached to these binding posts on the inside before the cover of the head is screwed on, and connecting wires can afterwards be attached to them on the outside whenever it is necessary to obtain connection with any conductor in the cable. The problem in the exchange is to lead in the cables in regular order so that any one of them can be traced out among the others, be accessible for repairs or alterations, and if necessary be drawn out and replaced by a new one; further, to arrange the terminal heads compactly so as to economize space, and in such position that the work of attaching the connecting wires, and detaching them whenever tests have to be made of the lines, may be easily done; further, to provide a systematic method of handling the immense mass of wires required in a large exchange to make the connections between the fixed terminals of the underground cables and the fixed terminals of the cables in the switchboard, so that every line shall be available for inspection at connecting points and readily traced out, and with provision for changing the connection between a given cable conductor and a given number in the switchboard at any moment; further, to provide efficient protection against lightning and other foreign currents at some point between the terminals of the underground cables and the switchboard apparatus. The problem, it is evident, is a formidable and a complex one, and it is interesting to see how the solution has been arrived at.

A fifty-pair telephone cable weighs about five pounds to the foot. A large exchange might need between one and two hundred of these cables to reach all the subscribers in its district, and it is readily apparent that to deal successfully with such a number of cables and cable heads and with such a weight of material, so as to economize space and secure all the conditions enumerated above is a task of electrical engineering by no means to be lightly attacked. It was at first thought that owing to the extreme weight of the cables, their inflexibility and liability to suffer damage if much handled, the best plan would be to terminate them at as short a distance from the subway vault as possible. The terminal room was therefore placed in the basement or cellar, and the cables were led in straight from the vault at the end of the subways under a false flooring and headed up in long rows, the terminal heads being attached in a vertical position to an iron framework. The connections with the switchboard on the top story were made by means of cables made up of large numbers of rubber insulated wires which ran up the building through a shaft or through ducts let into the walls. It was soon found that this system led to confusion. All changes in the connections between the switchboard wires and the underground cables are necessarily made in the terminal room, and also the tests on lines which are reported to be in "trouble." The operating department and the terminal room being so far apart, concentrated supervision of this important part of the work was impossible, and mistakes and delays were of frequent occurrence. Then, too, the frequent changes of connections among such a large mass of wires concentrated in a comparatively small space led to great confusion, involving much loss of time in testing out circuits.

This evil was attacked first, and the remedy was devised by Mr. A. S. Hibbard, general superintendent of the American Telephone and Telegraph Company. He constructed a cross-connecting or distributing board (everything to which a number of wires connect is called a "board" in telephone language, wehther it be made of wood or brass, hard rubber or iron) to form an intermediate link between the underground cable terminals and the terminals of the



Cable Tower on Terminal Pole.

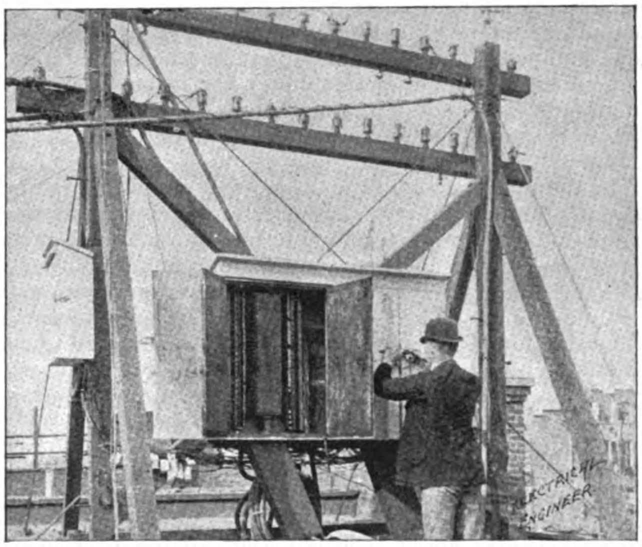
switchboard cables. This cross-connecting board is an iron framework or cage, made up of iron rods and tubing combined so as to form a number of vertical and horizontal grids. It is generally about three feet wide and eight or nine feet high, the length depending on the number of cables for which accommodation is required. On either side of the framework, at regular intervals, are fixed long strips of hard rubber carrying double rows of little metal ears or plates; to each of these ears two wires can be soldered. At one side wires leading from the underground cables are terminated, at the others the wires from the switchboard. This arrangement brings the wires of the underground system and those of the switchboard, all arranged in regular order, to fixed terminals within a few feet of each other. To connect them together all that is necessary is to solder a pair of wires to the metal ears on one side of the board, run them through the framework and solder them to the required ears on the other side. In this manner all risk of error in making connections is done away with, the switchboard wires on one side and the cable wires on the other all being numbered and connected in regular order, and there is no confused mass of loose wires to deal with. In a large telephone exchange many connections have to be made every day between the cables and the switchboard owing to the addition of new subscribers, changes of location among existing ones, and so on. The cross-connecting board reduces this work, which was formerly slow and uncertain, to a system which is at once both simple and expeditious.

When a new exchange is being equipped, as soon as the switchboard is in place cables are extended to one side of the distributing board and the wires are all connected up in numerical order. As the underground cables are put in, similar cables to those used for switchboard work are connected to their terminals and run to the distributing board, where they are all connected in place on the cable side of the board. The wires used for connecting across between the two terminal points are rubber insulated and twisted in pairs so that the anti-inductive arrangement of the underground and switchboard cables shall be maintained throughout the circuit. The wires follow definite courses through the framework, certain spaces being allotted to horizontal runs and certain others to vertical runs; the grid construction of the framework and the arrangement of the runs prevent large numbers of wires being massed together, so that it is easy to draw out any pair when it becomes necessary to change the connection between a pair of cable conductors and the switchboard. The distributing board has one other advantage besides those already named, which is that it allows of, in fact it demands, soldered connections at the points where the continuity of the circuit is broken; this is an important point electrically, as soldered connections are far safer than those afforded by any form of binding post.

ELECTRICAL ENGINEER.

Drawing in Telephone Cables.

The cross-connecting board having satisfactorily provided a method of making the connections between the cable terminals and switchboard, the next point which arose was the best situation of the terminal room in the telephone exchange. The work of making and inspecting the connections between the mass of wires in the operating department and the cable terminals involves numerous little details requiring careful and constant supervision, and ready communication between those in charge of the different branches of the system. Careful supervision and prompt communication were obviously best attainable by placing the operating department and the terminal room as near together as possible. The operating-room is placed always on the top floor to secure the best conditions of light, ventilation and freedom from the dust and noise of the street. These considerations precluding its removal to any other part of the building, the terminal room had to mount up from the basement to the top floor or to the floor immediatly below. The cables, then, instead of being terminated in a room immediately adjoining the subway vault had to be led up to the top of the building—no slight job when one considers the weight of the cables and the number necessary even in an exchange of only moderate size.



Underground Cable Terminal on Roof Fixture.

The very weight of the cable, however, has in some cases been a help rather than a hindrance, as the method has been adopted of taking the drums of cable to the top floor and paying out the cable down the shaft, a gang of men then taking charge of it and leading it through the basement to the subway vault. From one exchange in New York sections of cable five hundred feet long have been drawn from the drum in the terminal room through the shaft, basement and subway to the nearest street manhole half a block away.

The cables now, instead of being terminated in the basement, are supported there on a framework of iron bars mounted in stout wooden uprights; over the iron bars are placed wooden pulleys on which the cables rest and which prevent any injury to the lead covering during the operations of drawing in or out. The supports are placed close together to distribute the weight of the mass of cables and to prevent them from sagging, and they are so arranged that any cable is easily accessible for inspection or repairs, and can be drawn in or out without disturbing its neighbors. From the basement to the terminal room the cables follow a shaft built specially for the purpose. At first these shafts were threaded with iron pipes, in fact they were made like a vertical subway, a separate pipe being provided for each cable. An open shaft is now considered better, being cheaper and having the advantage that the cables are easily accessible at all points. The cables are attached by means of iron clamps to beams let into the sides of the shaft, clamps being placed at every floor, a door being provided at each floor to give access to the shaft. This method of supporting the cables is found to be entirely satisfactory; the strain is all in a vertical direction and is taken off by the clamp at about every eight or ten feet, therefore there is no chance for the cables to get out of place, nor for any heavy strain to be thrown upon one spot in a cable. At the top of the shaft, where the cables curve out to enter the terminal room, radial beams are placed intersecting the arc of the curve and the cables are clamped at close intervals to these beams. It is, of course, highly necessary to support the cables thoroughly at this point, as any strain thrown on the bend would probably result in buckling and cracking the lead covering.

In the terminal room the cable heads are arranged horizontally on upright iron frameworks. Placed horizontally a greater number of terminal heads can be arranged in a given space than if they are set vertically, and they are also more easily accessible for making connections, testing out lines, etc. Where possible, the framework carrying the cable heads is placed immediately opposite to the distributing board, making the connecting link as short as possible, and bringing all the operations of making connections and tests in one department. The work of making connections and tests is carried on by a staff of inside wiremen attached to the exchange and an inspector or wire chief, under whose directions the work is carried on. This official is provided with a desk equipped with a telephone set and instruments for making tests; wires run from the desk to various parts of the switchboard, and, by means of special lines, the instruments can be connected to a subscriber's circuit for the purpose of testing it out and discovering the location of any trouble that may be reported.

The provisions required for the distant terminals of the underground cables do not involve the engineering questions and careful design and calculation incident to the disposition of the cables and their terminals at the exchanges. It is comparatively seldom that more than one or two cables terminate at a given point. When possible, the terminals are placed in boxes in the basement of a building, insulated wires being run through the building to the rooms occupied by the different subscribers. Where subscribers are more scattered the cable is terminated on a roof fixture and connected by means of insulated bridle wires to the aerial lines attached to the insulators on the cross-arms above. On the terminal pole of an important overhead line, the wires of which have to be led underground from a certain point to the exchange, a cable tower is placed. This tower has enclosed protection capable of accommodating several cable heads, and a circular platform is fixed at a height of twenty or thirty feet above the ground so that the men can carry out the work of connecting up the cables in perfect security and comfort.

There are many other improvements in telephone engineering that are worthy of comment and description, but this article has already reached its limit and attained its object—a sketch of the changes brought about in telephone central office construction and equipment by the introduction of underground cables.

A FEW PRACTICAL OBSERVATIONS ON COVERED WIRE MAKING AND USING.

BY

Frederic A.C. Perrine

A GREAT deal has been said and written about "hay scales wire" and so few have been found to say a good word for this "weatherproof" wire of which most of our pole lines are constructed that the unfortunate superintendent whose company will not allow him to expend the money for a taped and braided rubber insulation feels ashamed of what he has done and answers under his breath "weatherproof" when asked his out-of-door insulation.

Are we really then so remiss in our regard for public safety in this country, and have we really no engineers brave enough to stand out for first-class construction in our central station installations? Across the water this opinion seems to prevail, and who can wonder when the men using such construction are so ready to acknowledge an inferiority in comparison with European work. In one case I know of, an American at a foreign exposition in charge of a telephone exhibit, which was surmounted by a great red cross-arm, green glass insulator, pole, etc., would tell all comers that it was intended as an illustration of our beautiful climate which would allow such *poor* construction. I do not think that such strictures on our engineering ability in this country are justifiable, or that the exceptions to our methods of construction are well taken. Rather it is one of those cases where the witless general average has drawn a better conclusion than the long-headed individual; or better it is a case in which a certain few well-informed engineers have taken the lead and been followed by the mass of constructors without the latter understanding the reason for their perfectly rational action.

I do not wish to be understood as advocating any work being done in an imperfect manner, nor do I wish to claim that weatherproof wire has as high an insulation resistance as a high grade rubber. But I do not consider that the *unattainable perfect* is engineering in its true sense; on the contrary I hold that the engineer should, with such means as are at his disposal, attain the best possible results as regards efficiency of plant, public safety and dividend payment by his company; and I do not consider that high insulation is the only consideration in all electrical installations.

Taking the latter point first, let us consider what are these wires which are called by the trade weatherproof, and taped and braided rubber, or as they have been nicknamed, "hay scales wire," and the "ites and shaws wire."

In the "ites and the shaws," our rubber manufacturers with the aid of the electricians have devoted their best energies, some to produce the most lasting insulation mechanically, some to produce the highest insulation resistance, and others to turn out the cheapest wire, and have used about every available compound of rubber and its substitutes. Except the last, of producing a cheap wire, these problems have been found to be very baffling, and although there are many different brands of rubber wire on the market, it is hardly possible to secure one which in the sun, the wind and the rain will maintain either its electrical or its mechanical qualities. A reason that this should be, may perhaps be known to that fortunate man who thoroughly understands the nature and cause of "blooming" in rubber goods. To be sure, this failure is not so complete that the insulation falls from the wire or that the galvanometer will show expensive leaks along the pole line, but it is serious enough to make the high insulation of a rubber wire line delusive, and to render contact with the wire possibly dangerous, if carrying high potentials in wet weather. While, as to the cheap shoddy rubbers which are sometimes used, and which make a very handsome wire to sell, as good and safe an insulation could be obtained by surrounding the wire with sponge.

Turning now to our "weatherproof wire," what is it? How should it be manufactured? And by what qualities is it suitable for pole lines?

A few years after the introduction of "underwriters'" wire, which was intended to fill the rules of the New York Board of Fire Underwriters for 1882, it was recognized that although an excellent insulation in dry buildings, it could not be relied upon in any way for out-of-door construction, and Mr. A. A. Knudson devised for Holmes, Booth & Haydens a compound having more waterproof qualities and intended to be applied to a braided wire as the underwriters had required. This compound of paraffine, cresine and asphaltum was a decided advance but was actually a long way behind the compounds used in the same manner and bearing the same names which are at present in use.

Almost every manufacturer has to-day a slightly different compound and different means of applying it, and not a few neglect the essential features of their product in order to obtain a handsome appearance and consequently easy sales to uninstructed purchasers. For the best results the insulating compound should be one which is applied to the wire after it has been rendered thoroughly liquid by heat, and which when so applied is not softened so much as to run when subjected in the open air to the warmth of the summer's sun, and which will not crack and open by swaying to the wind under the influence of frosts. The component parts should make with each other a true compound and not merely a mechanical mixture capable of being separated by the filtering action of the capillary fibres of the yarn. The yarn itself should be considered as a carrier and protector of the compound, and, for this reason, so proportioned as to be a minimum except in the outside braiding, where the strength is needed for protection against mechanical abrasion.

To manufacture such a wire as is described above is far more difficult than may be at first apparent, and the best results are often obtained in a product which has less the appearance of so doing than a more faulty wire. Perhaps the handsomest external appearance can be obtained by the application to a wire braided dry with a black dyed yarn of a well-made compound dissolved in bisulphide of carbon or coal tar naphtha; but although almost perfect in apperance, such a wire has almost all the undesirable elements. The yarn which has been applied to the wire in a dry state will always lie closely to its surface, and by its powerful capillary attraction will make a good contact communicating with the surface of the insulation from the conductor wherever the least moisture is absorbed; and the compound itself on delivering up its solvent maintains a slight porosity to aid in such an absorption, while the dye on the yarn fills the pores and renders it less capable of absorbing the heavy insulating compound, as well as offering little resistance to the absorption of water.

On the other hand if the wire is passed through a hot compound of very liquid and rather soft nature and immediately into the braiding machines where a single braid of a soft yarn is put on, and then again through the same insulation, and a couple of braids, one soft and open and the finishing braid close and hard, and is then again passed through a harder compound capable of being rubbed down into the crevices between the yarns, leaving a smooth surface for a finish, the essential features for a serviceable weatherproof wire are obtained.

With this method of manufacture it is impossible to make a wire which is perfectly uniform in every foot, or even for that matter, in every mile, so that the practice of selling by the foot which is perfectly satisfactory to both purchaser and manufacturer, in the case of a rubber covering is obviously unfair to both in this weatherproof, while the very cheapening of the product by increase of the insulation compound in proportion to the cotton yarn enhances the value of the covering as an insulation.

However perfectly manufactured, this wire is not and cannot be said to be insulated against a continued immersion in water, for the reason that no compound so saturates the fibres of a yarn as to altogether exclude a further absorption of water, and the only value of an immersion test is a comparative one of the rapidity with which the different grades will absorb water and fall to some arbitrarily determined low limit of insulation resistance. This being the case, weatherproof wire should not be used where it is not capable of continued inspection by the eye. For concealed work whether done between floors on cleats or porcelain insulators, or for wires imbedded in plaster, it is obviously unsuited, while even for tube work there is continually present a certain amount of risk, although these tubes if properly installed should be watertight and sealed, and its use under such conditions is not necessarily dangerous.

On a pole line, however, this wire is not only satisfactory, but for many reasons is the best possible, provided only it is chosen for care and correct principles in its manufacture, and not simply for the external appearance. The external surface of a hard yarn and polished compound is not only a protective against destruction through abrasion, but also leaves no projecting irregularities for the accumulation of rime and the lodgment of moisture. Internally the softness of the compound of itself repairs any minute cracks which may be made when stringing the wire in cold weather, and as time goes on it saturates more and more thoroughly the yarn which thus holds it in position, while its known nature will guard against the careless handling of live wires by the workmen; though accidental contact is not by any means attended with disastrous consequences.

It is in view of these qualities of weatherproof wire that it has been so universally adopted in this country, and by our best engineers. By allowing satisfactory construction at a moderate expenditure of capital, it has extended the privileges of the electric light universally throughout our country, while the more cautious but not more careful practice abroad has restricted the light to the largest and most wealthy centres of population.

THEORETICAL ELEMENTS OF ELECTRO-DYNAMIC MACHINERY[1]—XII.

BY

A. E. Kennelly

STRESS DISTRIBUTIONS—(*Continued.*)

As a consequence of the tendency exerted by an active conducting loop or coil, to move from a position of lesser to one of greater flux enclosure, the force urging it any instant along its path to its goal of maximum contents, will be the space rate of adding new flux at that moment to the flux already encircled. The coil will advance in such a such a manner that this rate of addition shall be the greatest rendered possible by the flux distribution, under the conditions imposed by the form of the coil and its geometrical freedom. The journey will thus be performed in the least time and by the shortest route that the system will permit.

We may observe this in the simplest case of two equal and coaxial circles of conducting wire maintained at radius distance, as represented in projection by Fig. 31. If unit current flows round circle A it will generate a M. M. F. of 4π which will force a total flux of, say, F C. G. S. lines through the circuit; or in other words, F will be the surface integral of flux through A. A certain share of F (in the case represented by the figure, numerically, $0.8958\, r$), will pass through circle D, and the total flux so intercepted—the surface integral of flux from *A* over *D*'s area—may be called *m*. This quantity *m* will be zero when the axial distance between the rings is infinite, will increase with their proximity, and in the ideal case of filamentary circles will numerically equal *F* when A and D coincide. Practically, the thickness of the wires forming the circles will limit their approach, so that *m* can never equal *F*. It is evident that when A's unit current is altered in strength to c_1 units, the M. M. F. will be altered in like proportion, changing both *F* and *m* to c_1 *F* and c_1 *m* respectively, but leaving the ratio $\frac{m}{F}$ of the total fluxes through D and A unchanged.

---

[1] *Copyrighted, 1892, by A. E. Kennelly.*

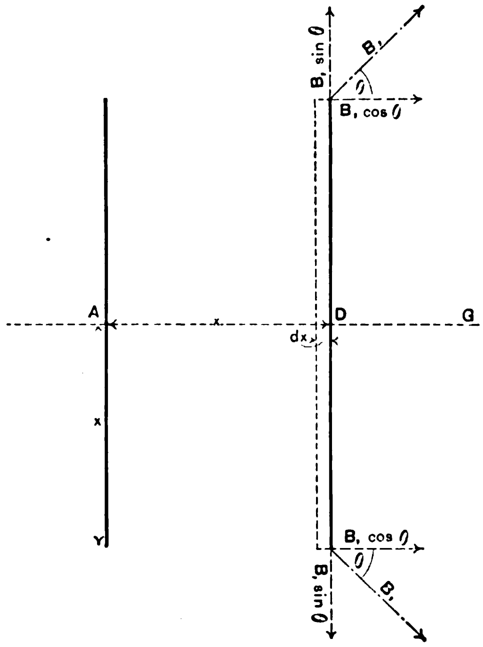


FIG. 31.

Round the circumference of circle D, the intensity due to the M. M. F. of c_1 will be, by symmetry, uniform in strength and in inclination θ with the axis A D, and its value may be denoted by B_1. As represented in the figure, this inclination will be almost exactly 45° or, $\frac{\pi}{4}$ in this instance, and equal to 1.61 $c_1 \div r$ C. G. S. lines per sq. cm. Resolved into components this becomes $B_1 \sin \theta$, in the plane of the circle, radially outwards in all directions from the axis, and $B_1 \cos \theta$ cutting the circumference parallel to the axis. In the case before us these components happen to be each 1.14 $c_1 \div r$, the current *c* being supposed to circulate positively, or counter-clockwise as viewed from G. The circle D is now filled with flux aggregating to c_1 *m* lines, terminated at the margin with these component intensities.

Next, suppose that a steady current of c_2 units is established in D, also counter-clockwise, as viewed from G. The stress distribution due to the combined flux systems will be represented by the vector product of $B_1 \sin \theta$ in the plane of D, upon c_2 round the circumference, urging D bodily towards A; also the corresponding vector product of $B \cos \theta$ on c_2 tending to expand the circle D radially, which force its rigidity will hold in check and which may therefore be dismissed from consideration. The summation of B_1 sin $c_2\ r\ d\ \theta$ round D is

$$P = 2\ \pi\ r\ B_1\ c_2 \sin \theta;\ \text{or}\ P = O\ B_1\ \ c_2 \sin \theta,$$

where *O* is the circumference of the circle, and *P* will be the force of attraction between them. If c_1 and c_2 circulate in opposite directions the same force *P* will be exerted in repulsion.

As a numerical illustration, applicable to Fig. 31, let the radius *r* and axial distance *x* between the circles be 5 cms.; $c_1 = 3$, or 30 amperes; $c_2 = 4$, or 40 amperes. B_1 then, becomes $1.64 \times \frac{3}{5} = 0.966$ at the circumference of D, and the local components $B_1 \sin \theta$ and $B_1 \cos \theta = 1.14 \times \frac{3}{5} = 0.684$ radially outward, and through the ring. The force of attraction between the circles will then be $P = 0.684 \times 2\ \pi \times 5 \times 4 = 85.96$ dynes.

This result can be expressed in terms of *m*; for if while c_1 and c_2 are flowing, the circle D is given a displacement *dx* along the axis, as shown, so small that B_1 does not appreciably alter within the range, *m* will increase by the motion and the total flux from A threading D will rise from $c_1\ m$ to $c_1\ m + 2\ \pi\ r\ dx\ B_1 \sin \theta$; for the surface integral of A's fluxes over D in its new position will, by the results of Part I, be equal to the surface integral over D in its previous position plus that over the cylinder *dx* generated by the circumference during the small displacement. This latter must be the intensity normal to the cylindric surface, namely, $B_1 \sin \theta$ into the area of that surface, or $O\ dx$, making $O B_1 \sin \theta\ dx$ in this instance numerically

$$1.14 \frac{c_1}{r} \cdot 2\ \pi\ r\ dx = 2.28\ \pi\ c_1\ dx,$$

and this will be the increase in D's share of A's flux for a small excursion *dx* of D. If this rate of increase were to continue unaltered for one centimetre of displacement, the increment would amount to $c_1\ B_1 \sin \theta\ O$ total lines, representing an increase in the value of *m* to the amount of $B_1 \sin \theta\ O$, and since $P = c_2\ B_1 \sin \theta\ O$ it follows that the attractive force between the circles is the product of the two current strengths and the rate at which *m* increases per cm. of advance, as gauged from a small displacement; or in symbols

$$P = c_1\ c_2\ \frac{dm}{dx}.$$

If *P* attains the negative sign in this formula, the pull will be exerted in the direction opposite to that of the infinitesimal displacement *dx*.

The share intercepted by A of flux due to unit current in D, must by symmetry be equal to D's interception of A's flux from unit current; that is to say *m* has *a* mutually reciprocal value between the circles. Again, if instead of being coaxial, A and D be removed to any distance and set at any inclination θ to each other, *m* will still be reciprocally equal. For, viewed from the centre of cirle A, D will be seen at distance *l*, say, and under inclination θ. On shifting the standpoint to the centre of D, A's distance and aspect must be relatively the same.

Further, we may remove the remaining limitations of equality and form, by proving that *m* will be mutual between any two circuits under any fixed geometrical conditions whatsoever. For in Fig. 32 let A, D, and F, be three equal squares fixed in space, D and F having one common side. If unit current flows round the contours of these squares, then the flux from A intercepted by F, say A_F must be equal by the above reasoning to the flux from F intercepted by A or F_A. Similarly $A_D = D_A$. Summing these two equalities, the flux in F and in D together, due to A, must be equal to that in A due to D and F coincidently, or $A_{D+F} = D_A + F_A$. The currents in the common side *k l* of D and F oppose and neutralize, so that *k l* may be removed without influencing this result. When this is done, the flux intercepted by A from unit current round *m k o p l n*,

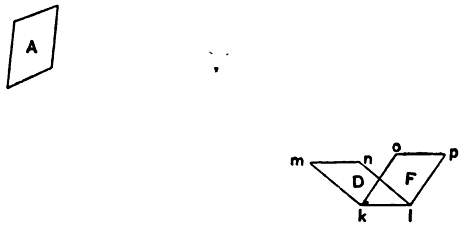

FIG. 32.

will be equal to the flux intercepted by $mkopln$ from that due to unit excitation in A. Continuing this process, any loops or series of loops can be constructed, having any sizes or shapes, and it will be evident that they have mutual and reciprocal values of *m*. This quantity *m* is called the mutual inductance of the two circuits. The proposition only holds good for non-magnetic media, and the introduction of iron into the system induces more or less deviation from the rule.

For a complex system of conducting loops, such as a pair of coils with many turns, situated in given relative positions, we might proceed to find *m* by establishing unit current in one coil, and then determining the flux due to this M. M. F. that is intercepted by each turn of the other coil, taken separately, and as though existing alone. Let m_1, m_2, m_3, ... m_n, be the separate interceptions of the *n* turns in the recipient coils, then the mutual inductance of the two coils will be the sum of these terms, or $\Sigma\, m$.

If an active coil made up of any arrangement of turns, be placed in a uniform prime flux due to an external M. M. F., it is clear that no motion of translation can alter *m*, although a rotatory dispacement will in general do so. The force tending to rotate the system coil round any axis will have a moment

$$t = c_1\, c_2 \frac{dm}{d\theta};$$

where $\frac{dm}{d\theta}$ is the rate of increase in the mutual inductance per radian or unit of angular displacement round this axis. The coil, if free, will rotate round that axis which possesses the greatest values of $\frac{dm}{d\theta}$ and *t*. If its freedom be restricted to motion round special axes or in certain planes, the coil will still select that axis of rotation left free which has the greatest value of *t*. The moving forces will vanish so soon as *m* attains a maximum, but frequently, the momentum acquired by the moving system in its rotation to this position will carry it beyond, against opposing forces, and set up an oscillation about the position of ultimate repose. This is the recognized general behavior of active coils and of magnets, their prototypes, when suspended in prime fluxes that are practically uniform.

When the prime flux is not uniform, a translatory motion will, in all but exceptional cases, increase the mutual inductance of the systems, and the moving forces will in general consist of a resultant force accompanied by a couple. The motion of the system will be that translation and rotation consistent with geometrical freedom, that will increase the mutual inductance most rapidly in space and time.

HYSTERESIS AND TEMPERATURE.

An abstract in the *Journal* of the London I. E. E. mentions some interesting experiments by W. Kunz on the effect of temperature on hysteresis. With equal maximum induction the hysteresis loss distinctly diminishes with increase of temperature. In a piece of soft iron the loss per cubic centimetre was 23,490 ergs when cold, 19,180 ergs at 530 degrees C. (dull red), and 21,640 when cold again. Steel showed a diminution of hysteresis of about 20 per cent. raised to 100 degrees.

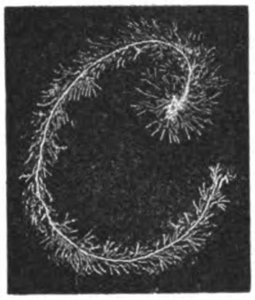
BERLIN ELECTRIC RAILWAY.

The proposal for the electric underground railway in Berlin is making progress. The line is to be equipped by the Allgemeine Company, and will be 30 miles long. There will be two generating stations connected together by mains, and using 500 volts. There will be 48 trains, each with three carriages, running at one time, the fare for any distance being 2½ cents. The trains will run on a three minutes' service.

DIRECTION OF ELECTRIC MOVEMENT.

BY

Philip Atkinson.



CURRENT is a word more freely used than understood. The instantaneous movement of electricity renders it impossible to determine by ordinary observation the direction in which it moves. A current will traverse a coil of wire hundreds of miles in length, with such rapidity that there is no appreciable difference of time between the closing of the circuit at one end and the click of the instrument at the other. A discharge of lightning is visible at the same instant throughout its entire length, which may be three to five miles, and the same is true of the spark discharge between the poles of a static machine, which is often six to eight inches in length. Any apparent movement of the lightning or the spark in a given direction rather than in the opposite is illusory; just as a horizontal discharge between two clouds may, from the effect of perspective, appear vertical, so that we imagine it to be from the cloud to the earth.

But we are not without evidence in regard to the direction of electric movement, and that evidence is in support of the theory that it is from a point where there is an accumulation of electric energy to a point where it is relatively less; so that the terms positive and negative, which represent these relative conditions, should not be regarded as mere conventionalisms, adopted for convenience, but as representatives of physical facts.

If a Töpler-Holtz machine be constructed with a wooden base, and a switch between the Leyden jars, by which the metallic electric connection between their outer coatings may be opened, the spark discharge is changed to a brush discharge; the passage of electric energy between the outer coatings taking place comparatively slowly through the insulating wood, and producing a corresponding slow discharge between the knobs of the discharging rods connected with the inner coatings. This brush discharge can be seen best in the dark, and is always far more prominent at the positive than at the negative pole. In the rapid spark discharge a single line of air becomes heated to incandescence for an instant only while it is traversed by the electric energy, but in this slow discharge the electrified air is continuously visible, so that the movement of electric energy which it represents can be studied; the electrified molecules repelling each other and producing the brush, that from the positive pole branching out into long forked red tongues, surrounded by a brush of whitish light, which passes over and becomes concentrated in a short brush of violet light on the negative pole, indicating in a very remarkable manner the movement of electric energy from positive to negative employing the air as its medium. This movement is indicated by the color of the discharge as well as its form; the change from bright red to violet showing decrease of energy in proportion to the work performed in overcoming the resistance of the air, just as variation of energy is shown by variation of brilliancy in the lighting of an incandescent lamp or the heating of an iron bar.

If the poles of a Töpler-Holtz machine be separated a little more than sparking distance, the discharge may be produced by bringing a conductor near enough to the negative pole to draw a short spark from it, thus reducing its electric energy and therefore increasing the potential difference between the poles. But if a spark be drawn in a similar manner from the positive pole, reducing its electric energy, the potential difference is proportionally equalized and no discharge produced, indicating that the positive and negative conditions are due respectively to an excess of energy in the positive and a corresponding lack of it in the negative, and that the discharge is a transfer of energy from positive to negative to restore the equilibrium.

Herewith is shown as an initial letter, an electric tracing of the letter C, reproduced from a photograph. I made the tracing with the knob of a charged Leyden jar on a plate of glass varnished with shellac, dusted sulphur on it, which adhered to the electrified lines, and removed the surplus sulphur by tapping the glass; the tracing is therefore a perfect reproduction of the work done by the electric charge. It was made just as one would make it with a pen, beginning at the dot of the C and moving the knob rapidly round to the opposite terminal of the curve, where it was lifted from the glass without stopping.

This tracing shows a broad fringe on both sides of the line traced by the knob, which consists of fine lines branching out from the main line with numerous subdivisions, all of which turn in the direction in which the knob was moved, while at the dot of the C, where the knob first touched the glass, they radiate from a common centre.

Assuming that the inner coating of the jar was positively charged, this shows that the electric energy moved from the higher potential of the main line to the lower potential on either side, radiating at first from the dot of the C, and that it was under the influence of two forces, one acting at right angles to the main line and the other parallel to it, by which it was turned forward diagonally in the direction in which the knob was moved. The electric energy acting inductively through the insulating shellac, produced a negative surface on each side, toward which it moved; but as the lines shot out at right angles, the inductive force from the knob, moving in advance of them, turned them forward diagonally.

If it be assumed that the inner coating of the jar was negatively charged, the movement of electric energy must have occurred in reverse order, but still from higher to lower potential as before; moving towards the dot of the C, and towards the negatively charged line and advancing knob from the adjacent surface charged positively by induction; so that this experiment shows only the relative direction of electric movement from positive to negative, and not its absolute direction. Its chief value lies in the fact that there is no movement of electrified matter, as in other experiments, which is liable to be mistaken for the transference of electric energy; the fringe being a permanent record left by the energy itself in the fixed shellac surface.

In the figure of the letter G shown by Lichtenberg, who was the first to observe this phenomenon, we find precisely the same indications, but the fringe lines are heavy and coarse, and he had not the advantage of photographic reproduction which I had, so that the electric work may have lost something of its original value in the hands of the engraver.

When the arc light is produced by the direct current, the positive carbon is consumed much more rapidly than the negative, while, when produced by the alternating current the consumption is equal in each. This warrants the conclusion that the relative consumption is in proportion to the relative electric energy expended, and hence that, with the direct current, the energy is much greater on the positive than on the negative side; and that the direction in which this energy moves is from positive to negative, so that in passing through the arc a large proportion of it is expended in overcoming the high resistance, which accounts for the relatively smaller consumption of the negative carbon.

Difference of potential is, of course, no evidence of the relative direction of electric movement in a conductor, and the common expression of "fall of potential from positive to negative" must be regarded as a mere conventionalism, unless it can be proved in some such manner as above that the potential called positive is higher than that called negative.

The theory of the dual nature of electricity, and of the simultaneous movement of the two kinds in opposite directions in the same conductor must be rejected as unsustained, inconsistent with the theory of difference of potential and contrary to the observed movement of kindred forms of physical energy, as light and heat. The movement of light and heat from higher to lower potential is verified by common observation, and the negative conditions of darkness and cold are known to be due to a lack of the energy which produces the positive conditions; hence, reasoning from analogy, we may infer the existence of similar physical conditions in electrified bodies, and a similar movement of energy; and recognizing each of these manifestations of energy as different kinds of molecular movement, each having its own special phase, there is no valid reason for attributing to electricity a different direction of movement from that which we find in light and heat.

AURORAL AND EARTH CURRENTS.

BY

D. B. Grandy

It is unfortunate for the cause of science that the excellent facilities for the study of auroral storms, such as those of July 16 and August 12, afforded by the network of telegraph wires extending over the country, have never, as yet, been utilized on a systematic and comprehensive plan. That they have not is due, not to any lack of willingness on the part of the companies, nor of zeal on the part of the electricians and wire chiefs in their employ, but to the fact that the time and attention of telegraph officials is wholly occupied during periods of auroral activity in devising methods to neutralize its effect and prevent a total suspension of business on their wires.

It would seem that if these officials would enlist the interest of the operators who work the wires in this subject, satisfactory results might be achieved. With a little instruction any operator of ordinary intelligence would be able to note the time an auroral current appeared on his wire, its polarity, approximate strength and time of disappearance. To illustrate: The polar relays in multiplex apparatus are arranged to close their "local" circuits and record a signal on a current of a certain polarity arriving from the distant terminal. Let us say that St. Louis relay closes on a positive current from Kansas City. When the receiving operator finds the signals growing "heavier" and his relay finally "closes," he will know, if properly instructed, that the cause is an auroral current of positive polarity, while, if the signals become "light" and his relay finally remains "open," the extra current is negative. On wires worked "single" from a + pole the neutralizing of the home current and opening of the relay would indicate an auroral + current, while an increase of strength and sparking at the key would indicate that the extra current was —. The operator could judge the approximate strength of the auroral current by its effect on the relay.

Such a record by the operators at each terminal of wires in use during auroral disturbances, properly tabulated and revised by the local electricians of the telegraph companies, would afford data for intelligent theorizing on the nature and effects of auroral phenomena more complete and reliable than we now have. If it served no other purpose, it would at least answer the question whether these currents are local and erratic in their character and due to constantly changing and reversing differences of potential between certain sections of earth and atmosphere, or have their origin in solar influences which sweep across the earth's surface like shadows of summer clouds, and give rise to vast waves of electrical energy, uniform in direction and polarity at any given time, wherever felt on the surface of our planet.

Further opportunity will possibly be afforded during the ensuing months of 1892 for study and experiment on this subject. During the last period of auroral activity, in 1882, the phenomena occurred with more or less frequency and energy, from January until September. If preparation be made at once to obtain a record of the effects of future phenomena which may occur, in the manner suggested, something definite and valuable in the way of results may be obtained during the present period of auroral activity.

The employees of the telegraph companies are a very intelligent body of men and women, to whom the idea of assisting science in solving the mysteries of nature would appeal with peculiar strength and fascination.

INSULATED ELECTRIC CONDUCTORS.—IX.

BY

James Bowstead Williams M.A.

Copal.—Copal includes several varieties of resins which are found in widely separated portions of the globe, the principal being the African, West Indian and New Zealand copals. That imported from Zanzibar is considered the best. The resins which are the hardened exudations of trees long extinct are hard and lustrous, and vary from an almost colorless transparent mass to a bright yellow brown. The true or fossil copal is mined from the earth, and is undoubtedly the best for insulating purposes.

Copal is a valuable insulating material although but little used in practice, probably on account of its cost and the lack of knowledge concerning it. Like amber, it is one of the most permanent resins known. It remains unchanged for years in air and stands comparatively high temperatures without injury. Chemical agents which dissolve or destroy other resins have little or no effect upon it. It is too brittle to be used alone, and must therefore be used in combination with elastic or flexible substances. It readily combines with most of the resins, and paraffine, when heated, and when used in suitable proportions, but not with asphaltum.

Linseed oil is its proper solvent, although a small amount of it can be dissolved in a large quantity of volatile solvents. Copal requires a special treatment before it is fit for the best solutions, and even then care and practice are necessary to dissolve it. If first combined with rosin, the solution is easier effected but the product is not so durable. Many formulæ for the use of copal are published in books and journals but are nearly all worthless. This statement will apply to the majority of published formulæ, and recipes for paints, varnishes and chemical mixtures generally. The writer has recorded scores of failures caused by placing confidence in such; hence this word of caution.

Copal is a very slow-drying resin when used in paints, but this can be remedied by baking or otherwise heating the painted articles. When combined with rubber, by means of linseed oil, it makes an excellent insulating paint. When used as an ingredient of paints it should be dissolved separately and then added to the other ingredients in solution. This should also be done when it is used as an ingredient of melted compounds; otherwise it is apt to separate from the other ingredients upon the addition of the oil which is added to impart the requisite flexibility to the compounds.

Copal and amber varnishes are commonly adulterated with cheaper resins; therefore, the safest plan is for the electrician to make his own solutions. Full directions for making these will be given later.

Animé.—This resin is a variety of copal. It derives its name from the presence of insects which were imprisoned in the oleo-resin as it exuded from the trees, and which remained embedded in the mass when hardened.

Kowrie.—This resin is considered to be a variety of copal. It is the hardened exudation of fossil trees which grew principally in New Zealand. It is dug from the earth the same as the African copal. It is easier to use than the Zanzibar copal. When used with camphor it assists the union of sulphur and rubber in vulcanized compounds.

Amber.—This is the hardened exudation of extinct conifers, and is found along the shores of the Baltic sea and other parts of Russia. It is probably the most permanent resin known and is a most valuable ingredient for insulating paints. Like copal, it is a very slow-drying resin, but the drying can be accelerated by heat.

Much of the amber sold is an adulteration, the pure resin being scarce and expensive. For insulating purposes its place can well be supplied with copal, which is practically inexhaustible, if the statements of recent African travelers are to be believed.

Solutions of amber in linseed oil are effected in the same manner as copal solutions.

Turpentine.—Turpentines are exudations from incisions in pines, larches and firs, and consist of resin combined with essential oils. The principal turpentines used for insulating material are the white or gum turpentine, Venice turpentine and Canada balsam. When they first exude they are viscid like honey but by exposure to the air gradually become harder until, in time, they become brittle. This change is due to the oxidization of the essential oils and evaporation of the volatile constituents. If heated to boiling the volatile matters are quickly eliminated, and if the heat be continued for a few minutes the turpentines are changed to brittle resins. Hence they are not suitable for compounds which require a high temperature for their production and application. If used in low-melting compounds or in paints they impart flexibility at first, but if the compounds are exposed this flexibility gradually disappears.

When pure, Venice turpentine can be combined with beeswax to form "preservative material" for vulcanized compounds. This turpentine is imported from Switzerland and is the product of the European larch; but what is often sold as Venice turpentine is made by dissolving rosin in oil of turpentine. The imported turpentine is nearly transparent, with a yellowish or greenish tint, but the manufactured material has a brown color.

Pitch.—This is obtained by distilling pine tar, and, when pure, consists of the resin of the pine unchanged. It unites with most of the resins, paraffine and asphaltum. It absorbs moisture when exposed and partially dissolves in water. This is probably owing to the presence of small quantities of tar which have not been removed by the distillation. Combining it with paraffine does not prevent the absorption of moisture when used with fibre and exposed to a damp atmosphere.

Sandarac, dammar and mastic are used in varnishes and are not suitable for melted compounds. All contain more or less moisture which should be removed by powdering and then drying in a current of warm, dry air before they are used.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, SEPTEMBER 7, 1892. No. 226.

Science is a growth of time, and though man's cultivation of the field is an essential condition of that growth, the development steadily progresses, independently of any individual investigator, however great his mental power.—Josiah Parsons Cooke.

ELECTRICAL SCIENCE AND THE SCIENTIFIC AMATEUR.

IF we read aright the comments on the successive meetings of the British Association there appears be an opinion gaining ground that this world-renowned body is losing prestige and that its meetings have latterly resolved themselves into junkets which give its members opportunity to come together to have a good time, the papers read being a mere incident to the occasion. As a result it has been suggested that the Association be reconstructed upon a different plan if it is to continue to carry out the object for which it was organized. The work done by the British Association in the past, and especially in the domain of electrical science, demonstrates sufficiently that there is need of an organization, under whatever name it may be known, in which all those interested in a common object can meet on equal ground. The papers read this year before the Mathematical and Physical Section, which includes electricity, and some of which we have printed elsewhere, though not of that broad and general nature which characterizes those brought before the more specialized electrical societies, nevertheless have a value of their own which it would be folly to ignore.

But the British Association, as well as the American Association for the Advancement of Science, presents opportunities for the encouragement and even for the fostering of a class of men to whom Prof. Arthur Schuster alluded in his presidential address before the Mathematical and Physical Section at the Edinburgh B. A. meeting, namely, the "scientific amateurs." In defining this term Prof. Schuster does not necessarily mean a man who has other occupations and only takes up science in his leisure hours, but rather one who has had no academical training, at any rate in that branch of knowledge which he finally selects for study. He has probably been brought up for some profession unconnected with science and only begins his study when his mind is sufficiently developed to form an entirely unbiased opinion. We might best define an amateur as one who learns his science as he wants it and when he wants it; and in the light of this definition, Prof. Schuster would call Faraday and Joule amateurs! Prof. Schuster lays special stress on the danger we now run of losing such scientific amateurs, who constitute one great and necessary factor in the origination of scientific ideas, and the danger is to be looked for in the methods of education now in vogue. He goes so far even as to maintain that at present a knowledge of scientific theories tends to kill all knowledge of scientific fact. He considers the highly specialized entrance examinations to the scientific departments of universities a curse to all sound school education, and thinks that they will prove a still more fatal curse to the progress of scientific knowledge. Prof. Schuster, however, notwithstanding his recognition of the scientific amateur or unprofessional scientist, has done well to draw attention to the damage they are likely to do themselves and the cause of science when they overstep their legitimate boundaries, especially when they seek popular support for their theories, which have not received the approval of those competent to judge. We take it that in this lay intolerance of the judgment of the professional scientists lies the barrier which has so long separated many workers for a common end. There is much food for thought in the utterances of Prof. Schuster which are specially applicable to the domain of electrical science, now so actively cultivated in all quarters, and it is to be hoped that the science of pedagogics will advance at a rate commensurate with that of the physical sciences so as to give the beginner all the advantages which a properly trained mind has over the untrained.

THE ELECTRICAL UTILIZATION OF GARBAGE.

IT may be that the electrical sterilization of water, freeing it from the poison of such things as cholera germs, may be still in its experimental stages, though more than hopeful; but it would seem that electricity can meantime do much in the way of helping great municipalities to dispose of their garbage. New York at the present time is sadly in need of improved methods of garbage disposal, and is using its beautiful bay as a dust bin, with the result that all bathing beaches and the ocean, too, are bestrewn with the disgusting refuse of the city. The idea is that the garbage is towed out far to sea, but as a matter of fact that only happens when a storm chances to carry the barges out despite the opposition of their captains.

Prof. George Forbes, the distinguished electrical engineer who is now in this country to give personal attention to the great work at Niagara, has been interviewed by city papers on the subject of garbage destructors, and we print this week a synopsis of his recent paper before the British Association, in which he sets forth the same facts that have now been brought to the notice of the citizens of New York. His figures should be studied by all public authorities, for they certainly suggest a means for abolishing a great evil that must increase with every city's growth. Even if the garbage were merely burned up, the gain in public health and comfort would be enormous; but there is, as pointed out, the further opportunity of generating steam for large electric light and power plants.

LOW TENSION STREET ARC LIGHTING.

The growing popularity of low tension, or multiple arc lighting must have impressed every one who has watched the tendencies of electric lighting. When we see local incandescent companies and electric railway companies running hundreds and hundreds of such lights on their regular circuits, it is plain that a new and important factor in street lighting must be taken into account. As a matter of fact, a great many of these constant potential arc lamps are used on the streets, but it is still a novel thing that they should be used from end to end of an important thoroughfare. This departure has been taken, however, in the contract made last week by the New York City Gas Commission with the local Edison Company for the lighting of Fifth avenue from Washington Square all the way to Fifty-ninth street. The lights will be in pairs at street intersections, and, of course, will be supplied from the Edison underground mains without the necessity of any overhead wires. A brilliant illumination of this fine avenue is expected in place of the feeble flicker of the old gas lamps, and the experiment will be very closely watched. The influence of its success upon the lighting of leading thoroughfares in large cities must be obvious to all.

COVERED OVERHEAD WIRES.

The methods of construction adopted by electric lighting companies in this country have been made the subject of attack by most foreign electricians who have visited these shores; and it has, indeed, become the fashion even among some of our own electrical engineers to rail against the apparent backward state of the art of line construction in the United States. So far as the criticisms refer to the actual character of the workmanship, independent of the material, no one will deny the truth of much that has been laid at our door, but ought the indictment to be so sweeping, especially with regard to that most important detail, the line wire? For the objects of the present discussion, we may leave out of consideration the old "underwriters'" wire, and confine ourselves on the one hand to rubber-covered and on the other to what is known in the trade as "weatherproof" wire. That the latter can never form a complete substitute for the former goes without saying but in analyzing on another page the conditions as they exist in this country to-day, Dr. F. A. C. Perrine concludes that weather proof wire has a *raison d'être* and that with proper methods of manufacture it may creditably occupy a position of usefulness. The enormous extent to which this class of wire is employed to-day is a certain indication that it meets the wants of central station managers and that they will continue to use it as long as the higher cost of rubber-covered wire places the latter beyond their reach. But we are not advocating the employment of an inferior material of construction. It must be clear that the results which can be obtained with weatherproof wire of good quality depend largely upon the manner in which it is handled, just as in the case of rubber-covered wire. Its very hardness has been one of the causes which has led to its abuse; and care in erection has been the exception rather than the rule. It is this laxity or poorness of workmanship that vitiates many of the benefits which could be obtained with inferior materials and which often makes the very best the only safe thing to use.

Cables in Telephony.

The enforced adoption of cables by many telephone companies has had a most marked influence not only on the methods of operation heretofore in vogue, but also upon the art of cable making and using. The changes in the methods of insulation to reduce the inductive capacity of the cables have already been alluded to at length in our columns, but the influence of their introduction in the working of exchanges had still remained to be told. It is this aspect of the subject which Mr. H. Laws Webb takes up in this issue. He gives the reader a glimpse of the manner in which the cable has led to successive modifications and improvements in exchange work.

LIQUEFIED AIR AND OXYGEN.

Prof. Dewar gave a very interesting lecture at the Royal Institution recently, on liquefied oxygen and liquefied air. He produced both liquefied oxygen and liquefied air, the oxygen in pints; and even the liquefied air was handed round in claret glasses. Liquid oxygen boils in air at —182° Centigrade. The liquid oxygen placed between the poles of Faraday's great magnet behaved like a metal, leaping up to the poles and clinging to them till it disappeared as gas. But liquid oxygen, though so strongly magnetic, is a very bad conductor of electricity. It is a non-conducting magnet. He showed too, that so far as chemists can judge, there is probably no oxygen in the sun—the oxygen of the earth's atmosphere accounting for all the oxygen lines in the solar spectrum. The boiling point of liquid air is —192° Centigrade, or 10 degrees lower than that of oxygen. It is not true, as had been supposed, that the oxygen in the air liquefies before the other elements in air; on the contrary, the air liquefies as air, and is not resolved into its elements before liquefying. If this globe were cooled down to 200° below the zero of Centrigrade, it would be covered with a sea of liquefied gas thirty-five feet deep, of which about seven feet would be liquid oxygen.

INSTALLATION EFFICIENCY.

Careful experiments have been carried out with the electric plant at the Argenteuil railway station by the French Edison Company. The boilers are two of Weyher and Richmond's, engines slow speed (85 revolutions), 35 h. p. to 50 h. p., by same makers, driving Edison dynamos, 115 volts and 240 amperes at 950 revolutions. The lamps comprise 30 arcs of 6 to 12 amperes, and 95 incandescents of 10 c. p. and 16 c. p. The two extreme arcs are three-quarters of a mile apart. The test with all lamps and an added resistance gave a total of 26,400 watts absorbed. The output was 460 watt hours per kilogramme of coal, or 209 watt-hours per pound, equal practically to 5 lbs. of coal per supply unit. This was 30 per cent. better than specification, and is a result that may be regarded as very satisfactory.

NOTE ON SOME EXPERIMENTS WITH ALTERNATING CURRENTS.[1]

BY DR. LOUIS DUNCAN,

Assisted by Mr. E. R. Carichoff and Messrs. R. H. and G. E. Hutton.

THE first real representation of an alternating current curve was made by Joubert, who employed a contact piece rotating with the armature of a dynamo, touching a fixed brush at a point of the revolution determined by the position of the brush with relation to the dynamo poles. He obtained a curve for current which was approximately a sine curve. Later, in 1888, Messrs. Wilkes, Hutchinson and myself modified the method to obtain the curves for E. M. F. and current in the primaries and secondaries of induction coils. This modification was used afterwards at Cornell, where Professor Ryan and others made valuable experiments, and it has been more or less generally employed. The principal difficulties lie in the fact that with a single commutating arrangement but one curve can be taken at a time, and as an experiment involving four curves takes something like 45 minutes, the condition may seriously change; while the whole voltage of the dynamo is at times on the commutator. It is at best rather a tedious method. In our work referred to above, and in the work at Cornell, E. M. F's, were measured by an electrometer, and currents were obtained by getting potential differences at the terminals of a non-inductive resistance through which the current passed. Lately, in France, two commutating arrangements have been used to give two curves at once, with a condenser charged through the contact and discharged through a d'Arsonval galvanometer.

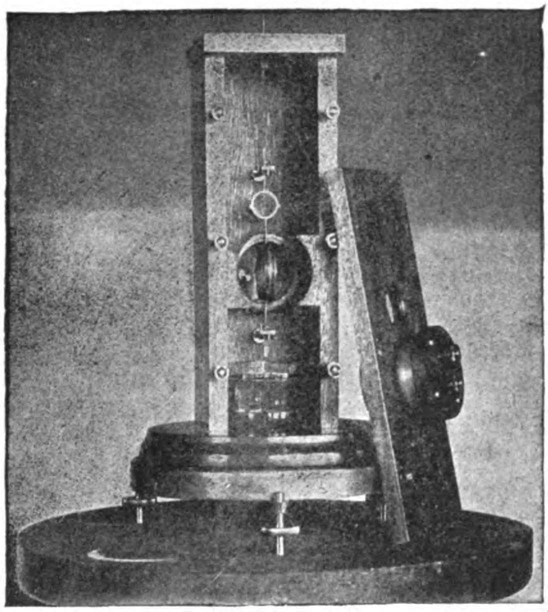

FIG. 1.—ELECTRODYNAMOMETER.

By the method which I described last fall any number of curves may be obtained simultaneously, with only a few volts on the commutator and with a rapidity and accuracy much greater than by the other methods. Briefly, a number of dynamometers are used, equal to the number of simultaneous curves to be obtained. These dynamometers are very cheap and convenient. The first ones used were made by Mr. Carichoff and myself, and were quite satisfactory, but experience having suggested some improvement, and our time being fully occupied, Messrs. E. S. Ritchie & Sons made four of them, such as shown in Fig. 1.

The four dynamometers have their stationary coils wound for—say—primary current, primary E. M. F., secondary current and secondary E. M. F. The movable coils are wound with fine wire, and are all connected in series. The E. M. F. instruments are made exceedingly sensitive so their self-induction may be made a minimum, and in series with them is placed a large non-inductive resistance, the relation of the self-induction and resistance being made such that the former may be neglected. The circuit of the movable coils is through a battery of a few storage cells to a brush which may be moved by hand through the arc of a circle, and which touches a contact-piece on the dynamo shaft once every revolution. The other end of the circuit being joined by a sliding connection with the contact-piece, the circuit is closed through the cells and coils for a short period once every revolution. The instant of closing this circuit is determined by the position of the movable brush with respect to the dynamo poles. Now, suppose an alternating current is sent through the stationary coil of one of the dynamometers. If an instantaneous current be sent through the movable coil, an impulse will be given it dependent on the value of its current and on the instantaneous value of the current in the stationary coil; as the period of the coil is great compared with the period of the dynamo, we will get a steady deflection dependent on this product. If now we move our contact brush, the instantaneous current will pass at some other point on the alternating current wave, and our deflection will be proportional to the value of the current at this point; by moving the brush through an angle corresponding to a complete wave we can plot the wave exactly, providing we have properly calibrated our dynamometer.

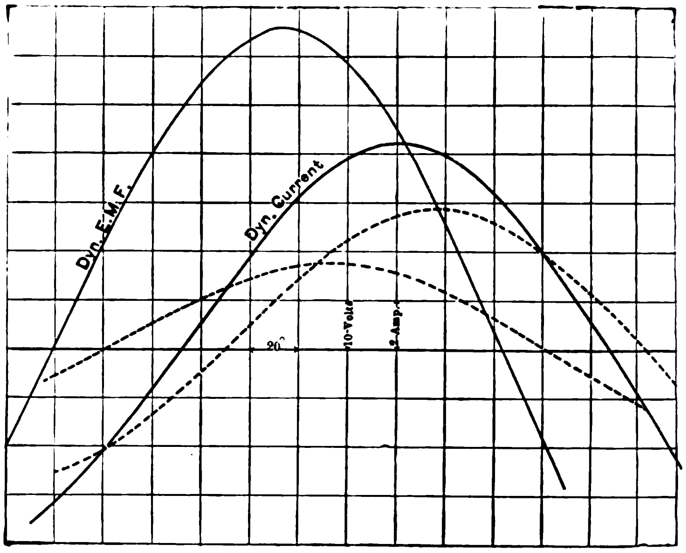

FIG. 2.—Tesla Fan Motor. Period $\frac{1}{140}$.

It is apparent that in order to attain accuracy our instantaneous current must be very brief and very steady, and its value must be the same in actual work as in calibrating. A d'Arsonval galvanometer in the circuit allows us to judge the two last points, and we found that when a high resistance was used in the circuit so that any variation in the contact resistance was eliminated, almost absolute steadiness was obtained. It was also assured by using a condenser charged during part of the revolution and then discharged by the contact brush through the circuit. To give an idea of the current in this circuit, an ordinary arrangement, when the condenser was not used, was 12 volts through 1,000 ohms, and it must be remembered that this current only passes an exceedingly small part of the time.

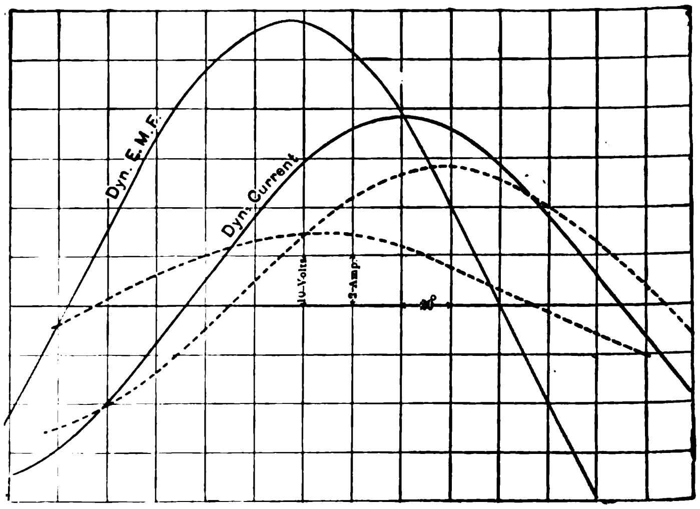

FIG. 2A.—Tesla Fan Motor—Held. Period $\frac{1}{140}$ second.

Dynamometers.—The dynamometers were made of wood, mounted on a revolving base, so they could be adjusted with respect to the meridian. It will be seen on looking at the picture that one side is made removable to facilitate adjustments. The fixed coils are wound in two cylinders which move in and out through holes in the sides, and whose distance apart is adjusted when the instrument is calibrated, so the scale divisions read directly in volts or amperes, or fractions of them. The movable coil is suspended by a silk fibre, which gives it no directive force but which sustains it. Directive force is given the coil and current is introduced to it through two palladium hair springs which are fastened to stiff brass wires, which serve as the axis of the coil. A vane in a beaker filled with glycerine damps the swinging and makes the instrument absolutely aperiodic. I have rarely used instruments which give more satisfactory results; the zero is invariable; readings may be taken with great ease and rapidity, while a reversal of the current gives equal readings on the two sides of the zero. To show the rapidity of the readings, six curves, representing different quantities in a step-up-and-down transmission were taken in a little over five minutes, and in this case two instruments were used for four curves—those at the sending and receiving ends of the plant—and therefore had to be switched from one side to the other at every reading. Twenty points were usually taken for each wave.

---

[1] Abstract of a paper read at the general meeting of the American Institute of Electrical Engineers, Chicago.

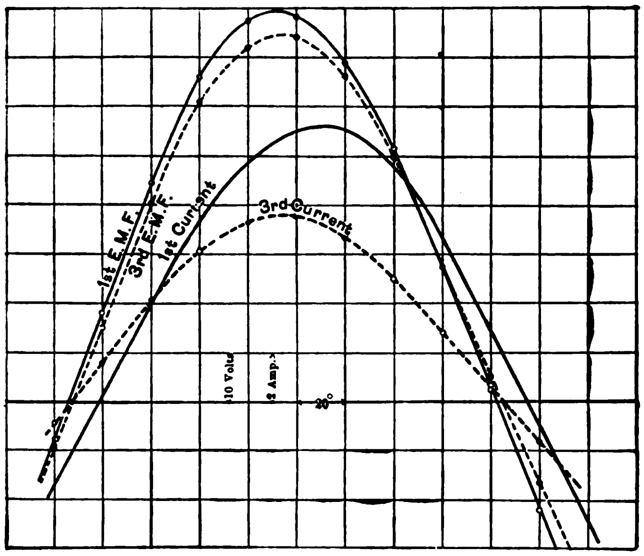

FIG. 3.

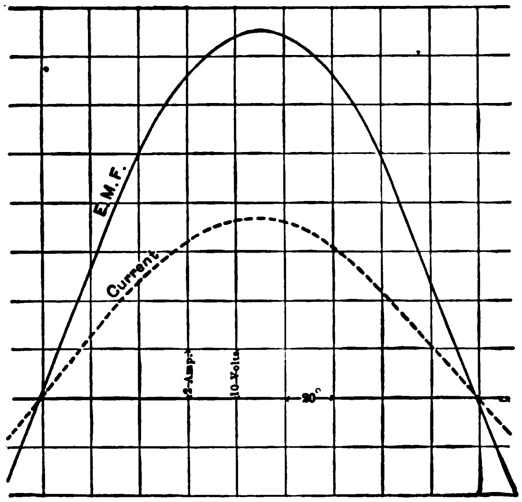

FIG. 4.—Dynamo Direct on Lamps.

The curves could of course be photographed instead of observed, but the latter is so much simpler and more satisfactory that—especially in a laboratory where there are plenty of observers—I much prefer it.

The results of our work will have to be another story. I will simply give a few to illustrate the method.

We have a small Tesla fan motor intended to work on an ordinary incandescent circuit. There are eight poles, the alternate ones having their windings in different circuits,—one set of poles having a few turns of coarse wire, the others having a greater number of fine wire turns. The curves in Fig. 2 show the condition of affairs when the motor was working; in Fig. 2A where the armature was held. In the second case the energy represented corresponds, of course, only to the losses. It seems to be the general impression, by the way, that a rotating field motor starts up with the same torque as a corresponding continuous current machine. I have shown, however, that a two-phase motor corresponds exactly to a converter—or rather two converters—in which the secondary has an outside resistance of $\frac{p^1}{p-p^1}$, where p^1 is the angular velocity of the armature and p that of the field.

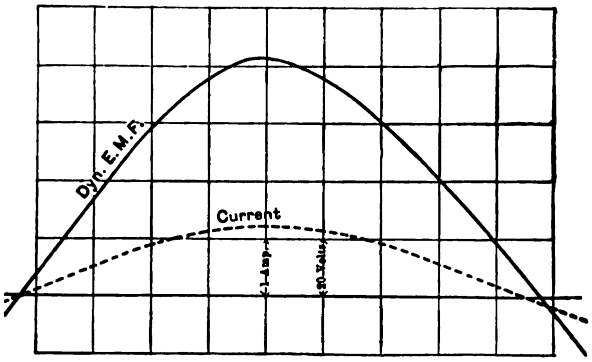

FIG. 5.—Copper Condenser with Coils.
Cap. 1.35 M. F.'S. Wire Core.

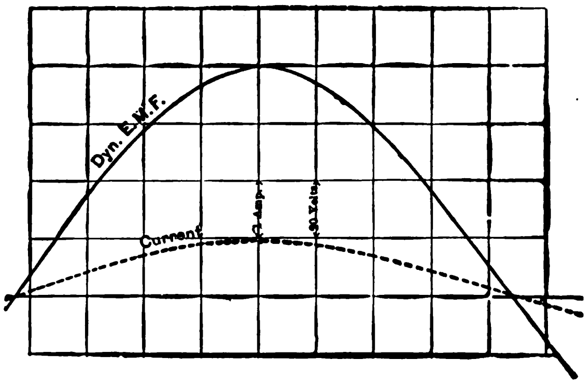

FIG. 6.—Tinfoil Condenser with Coils.
Cap. 1.38 M. F.'S. Wire Core.

When p^1 is 0—that is when the motor is at rest—it will be seen that the current is in the worst possible condition for starting and the torque for a given current is small. It is like starting a continuous current motor with the brushes almost ninety degrees from the proper position.

But most of our work has been with circuits in which both self-induction and capacity have been introduced. It is a well-known fact that circuits carrying alternating currents may be given the same period of vibration as the current, or to put it another way, circuits may be so arranged that with currents of a given period the sum of the energies stored up in the circuit and given out by

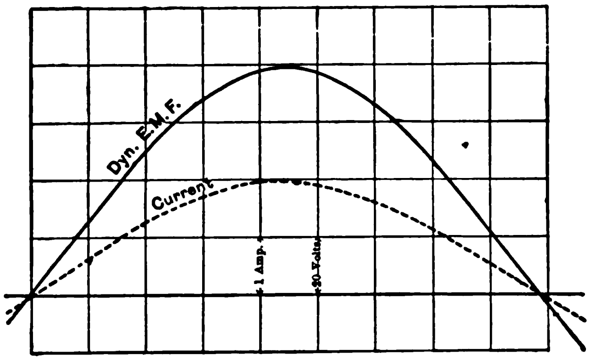

FIG. 7.—Tinfoil in Parallel with Copper Condenser with Coils.
Cap. 2.675 M. F.'S. Wire Core.

it, is zero. With a condenser and self-induction properly adjusted, if energy from the current is being stored up in the condenser an equal quantity is being given to the current by virtue of the self-induction. That is, we can neutralize our self-induction by a capacity. I can hardly think of any fact more likely to play an important part in the future of alternating current work. For instance, if a circuit has in it a periodic current consisting of a number of sine curves of different periods—one-third, one-fifth, one-seventh, etc., the period of the fundamental wave; then if we put in inductive relation to this circuit another circuit whose period is, say, one-third that of the fundamental wave, this current will pick out the one-third period waves in the primary.

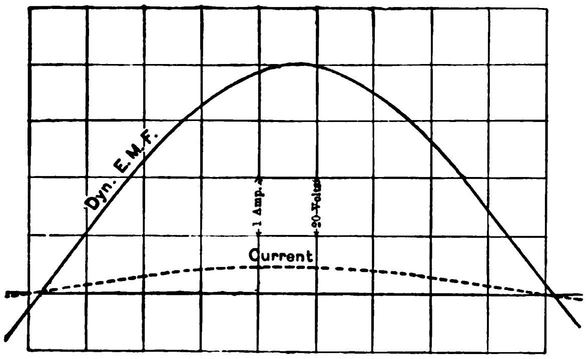

FIG. 8.—Tinfoil in Parallel with Copper Condenser with Coils. Cap. 2.675 M. F.'s. Solid 1¾" Iron Core. Resistance of Circuit, 20.3 ω.

An ordinary sine curve E. M. F. may be made to give a periodic current wave with these higher harmonics in several ways—by having in the circuit a self-induction coil whose iron core is saturated when the current nears a maximum, or by using the same coil with a capacity which neutralizes one of the value of the varying self-induction; so we can produce these higher harmonics and we can pick them out. But it is a complex subject not to be treated here. In all such experiments, however, there are several points which must be carefully attended to, or there will be very unsatisfactory results. If the iron core of the induction coil—provided such a core is used—is not properly laminated and annealed, or if there are considerable losses in the condenser, the results will be disappointing. Take the case, for example, where there are eddy currents in the core and there is loss in the condenser. The first effect corresponds to a short-circuited secondary near the coil; the loss in the dielectric of the condenser means that energy is taken from the current, and this energy must be represented by the product of the current into the E. M. F., *e* corresponding to the transfer of energy, or it is $e.\ i$. The value of *e* is a maximum when the displacement is greatest—that is when the current is greatest, and for a given current and dielectric varies as $\frac{1}{c}$. If we represent these effects by a revolving diagram, as is ordinarily done, and suppose we have neutralized the self-induction by a capacity, we get something like Fig. 10. The result is that the relation between R. I. and E. instead of being 1 to 1, as would be the case were there no disturbing causes, is 1 to 1 +. That is, for a given E. M. F. the current is less than it should be, and a glance at the figure will show that it is thrown ahead of the E. M. F. No possible change in our self-induction and capacity can remedy this decrease in the current, although we may, of course, make the phase anglo zero if we wish.

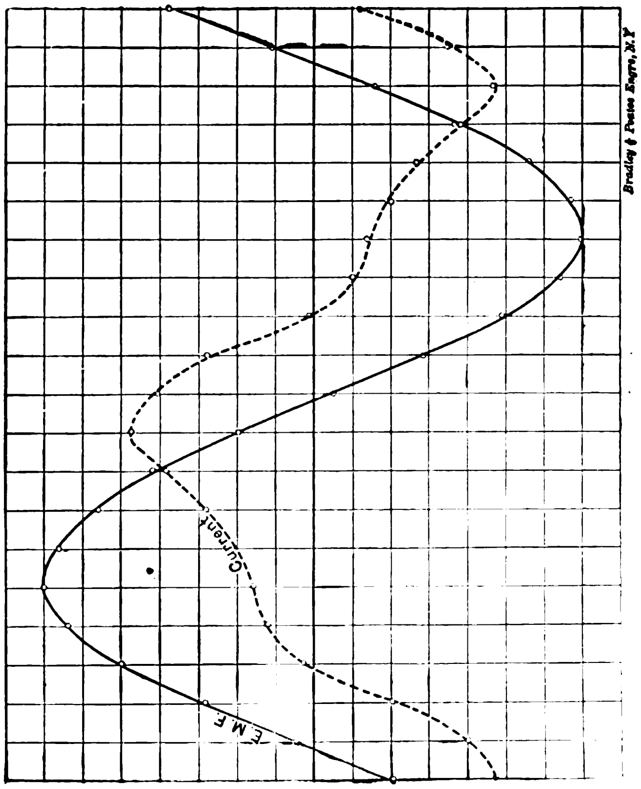

FIG. 9.—Siemens Dynamo on Transformer; Secondary Open. Curves Taken with Experimental Dynamometers.

An excellent way to make an iron core, by the way, is to shellac fine, well annealed wires, spread them along a piece of thin paper, brush them over with shellac and then roll the mat so formed into a cylinder. The losses in a condenser are usually small. They are discussed in a paper of Messrs. Hutin and Leblanc, published last spring in *La Lumiere Electrique*. We find, however, that if the condenser is made of very thin tinfoil and has a large area, then for heavy currents it may considerably decrease in capacity and offer a definite resistance to the current.

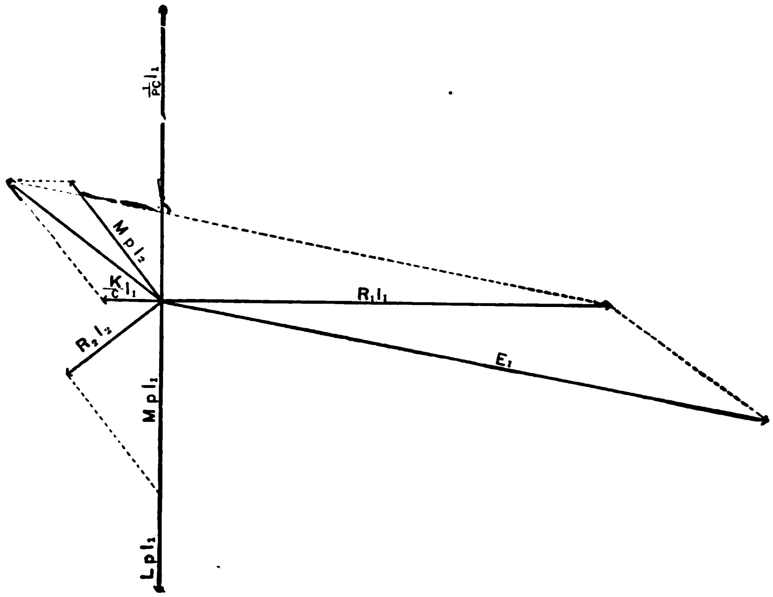

FIG. 10.

The curves given have been selected almost at random from a mass of data. We have not the time to discuss the results which are hardly within the scope of this paper. Fig. 3 gives the curves at the two ends of a transmission plant where the voltage was raised from 50 to 1,000 volts and reduced again. Fig. 4 gives the curves for the dynamo directly on the same lamps. It is seen that the transmission decreases the E. M. F. and current, and increases the lag of the dynamo current.

Figs. 5, 6, 7 and 8 give curves taken from the dynamo circuit when self-induction and capacities were inserted. In Fig. 5 the core of the induction coil was only fairly well laminated; and a condenser with copper sheets between paraffined paper was used. The maximum current is a little over 1.2 amperes, while it should have been about four amperes if there were no losses in the circuit. The second point of crossing is thrown out by a change of speed of the dynamo. Fig. 6 shows the result of substituting a tinfoil condenser of the same capacity in place of the copper one. In Fig. 7 both condensers were used and a considerable part of the wire core was withdrawn. In Fig. 8 with the same two condensers, a solid iron bar was used as the core of the induction coil.

Fig. 9 gives the curves obtained in the circuit of a dynamo connected to a transformer whose secondary circuit was open.

MR. JOHN R. MARKLE, the well-known fuel, gas and electrical expert, of Detroit, Mich., called at the Western office of THE ELECTRICAL ENGINEER during a visit to Chicago on special business pertaining to electrical matters.

APPLICATION OF DESTRUCTORS, PARTICULARLY TO THE ELECTRIC LIGHTING OF EDINBURGH.[1]

BY PROF. GEORGE FORBES, F. R. S.

THE object of this paper, said the author, was to enable the citizens of Edinburgh to see the enormous natural advantages which exist in their city with relation to electric lighting. The advantages were such as would enable the people of Edinburgh to obtain the electric light at a price lower than gas, which could hardly be considered possible in any other town. First, as to the use of destructors, that was, the use of furnaces for burning the city ash bin refuse, which was recognized as the best way of geting rid of refuse, and the means of using these destructors for fuel to generate steam. Referring to any load diagram of an ordinary central station, they would find that during the greater part of the day the machinery and boilers were lying idle; for two hours only were they working at their maximum. To have these dynamos and engines standing without earning any money was very serious, but there was another serious result, and that was that the boilers required to be fired up for simply a two hours' run. Every engineer knew what a low efficiency there would be from coal used in that manner. The only cure for this difficulty was some system of storage. The president of the section had referred to the storage by means of hydraulic accumulators, which Lord Armstrong has so largely introduced; he has also alluded to storage—hydraulic storage in reservoirs—both at Geneva and Zurich. It was exactly following out those ideas that the author would suggest how the difficulty of storage should be overcome in Edinburgh. The reason why Edinburgh was peculiarly well situated was, that there was very high land in the immediate neighborhood of the town—he referred specially to Arthur's Seat.

The author's first notion was to use Dunsapie Loch as a reservoir, the idea being that a steam engine should be used at the lower level, continually pumping water up to the high level, and at the lowest part of this, pipes and turbines should be attached for driving dynamos; this arrangement was exactly the same as that employed at Zurich. A further examination and consideration of the locality showed that by a slight additional expense they gained enormous advantages. Looking from the summit of Arthur's Seat, in the direction of Portobello, there was a gully which, by means of a very short dam, would enable them to make a reservoir which would not be in the least unsightly to the neighborhood of Edinburgh, and, in fact, would be invisible save from the Portobello side of the hill. If such a dam were built, the pipe line would then be taken down to Lochend, nearly a mile distant. The height of the reservoir would be 725 feet, and the height of Lochend 83 feet; they might also use Dunsapie Loch and St. Margaret Loch—in fact there were several ways of doing the work. If Dunsapie were deepened to 10 feet, it would contain a million and a quarter cubic feet of water; but by building a dam near the summit of Arthur's Seat they got a quantity of water equal to 28,000 h. p. working for an hour, that is, on the assumption of 75 per cent. efficiency on the turbines and pipes. The cost of the pipes carried from the summit of Arthur's Loch came out at the rate of £1 per horse power. They would be able to see what could be done with this horse power. The Berlin load curves showed that the maximum demand on a mid-winter day was four times the mean; secondly, if engines were constantly supplying power, storing what was not wanted, the storage capacity must be equal to maximum output working for about two hours; thirdly, the maximum output at any moment in the year was about six times the mean output of the whole year. Working from these facts, the author found that there can be obtained from the 28,800 h. p. hours available in the reservoir, a maximum output in the central station of 12,500 h. p., and that 3,000 h. p, continually working in the form of steam engines, would make a total of 15,500 h. p. There is by this means saved the cost of 12,000 h. p. boilers and engines which would probably cost £200,000, replacing it by pipes and turbines, pumps and reservoir, probably costing not more than £35,000 altogether. Pumping engines and turbines were now so perfect that it would be possible to get a horse power delivered from 3 lbs. of Welsh coal. Experience showed that, including the coal wasted in getting up steam and banking fires, even when using the best appliances of the modern central station, 5 lbs. of coal at least was required for every horse power. There was then a saving of about 2 lb. of coal per horse power by keeping the engines working at their maximum. The maximum demand in winter was six times the mean of the year; thus, with a maximum of 15,625 h. p., there was a mean output of 2,600 h. p. all the year round. A saving of 2 lbs. of coal per horse power hour amounted to 20,000 tons, which at £1 per ton meant a saving of £20,000 per year. These facts illustrated very clearly the enormous advantage of storage, which could be so easily gained by utilizing the natural anvantages of the city of Edinburgh.

The author then dwelt on the advantages of the use of destructors. There was no doubt that the use of destructors for getting rid of refuse, and for getting up steam for electric lighting purposes, would play an important part in the future, but in most towns it would be impossible to get the full advantage from the destructors, because they must be burning refuse day and night, whereas for electric lighting purposes, or the distribution of power, it was only during certain times of the day that there was a demand, so that the heat from the destructors was wasted for the greater part of the day; but by the hydraulic storage in Edinburgh they would be able to use destructors with the greatest advantage. After a reference to the destructor at Leeds, the author said that steam had not been largely used at Leeds, but at Southampton and one or two other places it had been largely used. At Southampton the boilers (locomotive) were simply placed in the main flues, without any attempt to drive the products of combustion through the flues, with the consequence that there was a very bad economy, and it required 75 lbs. of ash bin refuse to give a horse power for one hour. The author had made numerous experiments on the heating properties of ash bin refuse, and there was not the slightest doubt that in the great majority of towns the ordinary ash bin refuse as a heat-producing power would mean that 10 lbs. would equal 1 lb. of ordinary coal.

ON THE DIELECTRIC OF CONDENSERS.[1][2]

BY W. H. PREECE, F. R. S.

ARTIFICIAL cables are very useful adjuncts to the laboratory of the telegraph engineer. They not only enable him to experiment at his leisure, but they form very useful means to test and compare high speed and delicate telegraph apparatus, and especially telephones. I have one, made some years ago, which has been in incessant use; composed of 54 inductionless coils of insulated copper wire, each giving 33 ohms resistance, and having a condenser of 1 microfarad capacity at the juncture of each pair of coils. This represented a circuit of a total capacity (K) of 54 microfarads and of a total resistance (R) of 1,188 ohms. The K R being 64,152. This was equivalent to an ordinary submarine cable of 162 nauts length. It was not sufficient for our growing wants, and another precisely similar set was recently made of the same dimensions and materials and in the same way. But it did not give the same results. The resistances were exactly the same, but the individual capacities differed so much that the total capacity for the same surface of foil was 60 microfarads instead of 54, so that the K R was 71,280. This difference, of nearly 11 per cent was, of itself, of no practical consequence for the particular purpose for which the cable was constructed, but on carefully comparing the two "cables" with telephones, it was found that with the same nominal K R the new one gave 30 per cent. better results than the old one; that is, with the same nominal K R and the same telephone speech would be 30 per cent. clearer on the new "cable" than on the old one. The limiting distance of speech would also be 30 per cent greater on the new one. This was a surprising and unexpected result. I thought it might be due to inductance, but none, neither *self* nor *mutual*, could be detected.

The insulation, taken after one minute's electrification of each, was:

Old cable 172.8 megohms per naut.
New " 82.8 " " "

so that the difference was in favor of the old one. But the electrification of the new one was much superior to that of the old one. The difference in the resistance reading between the beginning and ending of the first minute on the former was $\frac{1}{10}$ of that of the latter.

Each cable was then rapidly charged and discharged 1,200 times, at varying rates, with an E. M. F. of 40 volts, and the cumulative remaining charge in each case read by reflection on a Thomson galvanometer. This was done by passing a 10-foot length of perforated slip through a Wheatstone automatic transmitter. The following are the results:

Number of discharges per second.	Discharge.		Percentage difference.
	New.	Old.	
20	46	28	39
40	86	55	36
80	151	100	33
120	200	136	32
160	237	168	29

This clearly shows that the effect is due to absorption. Electrification, polarization and absorption are phases of electrolytic work done by the current upon the dielectric. The material is slightly decomposed by the leakage current, a counter E. M. F. is set up, which reduces the apparent resistance (electrification); it gives a current of discharge reverse to that of charge (polarization); it absorbs a quantity of electricity, the undissipated part of which is recovered as a discharge current. The condenser acts, in fact, like a secondary cell.

---

[1] Abstract of a paper read before the British Association, Edinburgh.

[1] Lord Kelvin proposes to call this useful instrument a "Leyden," because the term "condenser" is applied to other more appropriate mechanical and physical apparatus.

[2] A paper read at the B. A. meeting, Edinburgh.

We are now using better paper than formerly—that made from the best linen rags, thinner tinfoil and better wax—the best refined unadulterated white paraffine, having a melting point of from 125° to 128° Fahr. Resin was formerly mixed with the wax, and when hot and liquid, it was painted on the paper with a brush. The paper is now thoroughly dried, and well saturated with wax, by soaking under pressure, so as to get rid of all the moisture. Hence there is less electrification and less absorption, and consequently less retardation, and hence the superiority of the new "cable." In the old type of condenser we observed a variation of capacity, due to temperature; but in the new type this has disappeared. This effect of absorption on the effective capacity of the condensers, and of insulated conductors, is new to me, and as it may be new to many others, I have thought it to be of sufficient interest to bring it before the section.

It is a new term to be added to the question of energy of compound circuits, and it has evidently a material influence upon the retardation of signals in long submarine cables. It has an equally important influence on the efficiency of telephone circuits, and it accounts partially for the great difference in my K R law between the observed effects of aerial and those of subterranean or submarine conductors. The former are always much superior to the latter. This would be due to the absence of polarization in air as well as to other electromagnetic and electrostatic causes. No work would be done on the molecules of air, no energy would therefore be absorbed, and no retardation of currents from this cause would ensue. An air dielectric is clearly the "Holy Grail" of the electrician.

POWER TRANSMISSION BY ALTERNATING CURRENT.[1]

BY GISBERT KAPP.

SOME two years ago the municipal authorities of Cassel, in Germany, determined to become purveyors of electric light and to place the generating station on the site of the water-works pumping station, which is situated on the River Fulda about four miles from the town. The object in choosing this site was partly to bring both undertakings under the same management, and so reduce administrative expenses, but chiefly to utilize an existing turbine plant which had been erected for driving pumps to augment the natural supply of water by gravitation, which was found in the hot summer months to be scarcely sufficient for the requirements of Cassel. The gravitation supply being abundant during the rest of the year, the turbine plant and an auxiliary steam engine erected as a stand-by to the turbines represented so much idle capital during all the time that motive power was not required for pumping. It was thus obviously good policy to put the central electric station on the site occupied by the waterworks, using for motive power the turbine plant and stand-by engine already existing, and this the more so as the two services, namely, water and light supply, do scarcely, if at all, overlap. In summer when the greater part of the power obtainable from the turbines is required for pumping, the demand for light is a minimum, whilst in winter when the whole of the turbine power is required for lighting the pumps need not be worked, the water supply by gravitation being, as already stated, amply sufficient.

The problem was solved in a very successful manner by a German engineer, Herr Oskar von Miller, who had been called in by the Municipality to carry out the work. The plan adopted by von Miller was briefly this: He determined to transmit power by single phase alternating current from the generating station to a sub-station or rather to two sub-stations in Cassel, and to use this power for the supply of direct current on the three-wire system. At one of the sub-stations he established a battery which is charged during the hours of light load, and assists the dynamos during the hours of heavy load, so that the maximum power available shall suffice for 3,500 16 c. p. lamps wired.

The general arrangement of this installation is shown in the accompanying diagram. A_1 A_2, are two 60 K. W. alternators at the generating station. These can be used singly or in parallel, and the current is transmitted through an underground concentric cable over a distance of about four miles to the sub-stations shown on the right of the diagram. The sectional area of each conductor is .093 square inch, and the total resistance about 3.5 ohms. The alternators are designed for a terminal pressure of from 2,000 to 2,200 volts, so that the loss in transmission, when both are working full power, is under 10 per cent.

Each sub-station contains an alternating continuous current transformer, consisting of a 60 K. W. alternator, A_3, A_4, coupled with two continuous current dynamos, one on either side, D_1, D_2, and D_3, D_4 respectively. The latter machines are connected with each other and with the mains in the usual way adopted in three-wire distribution. At one of the sub-stations there is a battery, B_1, B_2, also arranged on the three-wire system. The mains throughout the district are coupled so that the battery sub-station can supply current to the other sub-station through the town mains. To start any one of the two transformers it is only necessary to switch on the two dynamos which begin to work as motors, and after observing by a synchronizer that the speed of the alternator has reached the required amount to close the high pressure alternating current switch when the alternator works as a motor supplying power to the two dynamos which are directly coupled to it. It will thus be seen that not only are the two alternators at the generating station worked in parallel, but also the two sub-station alternators erected in different parts of the town are worked in parallel. The dynamos are Brown's design and the alternators are my design, both made by the Oerlikon Engineering Works, but I must distinctly state that I can claim no credit whatever for the Cassel installation; and that the whole credit for this (probably the earliest) example of power transmission by alternating currents is due to von Miller who, at a time when most electricians were still in doubt as to the possibility of parallel running, boldly laid down a plant, the success of which was not only dependent on parallel running, but also on the economical and safe transmission of power by single phase alternating current, using for this purpose the ordinary type of alternator as made for lighting. The plant was started on May 15 last year and has been working since then without a hitch.

By the courtesy of Herr von Miller I am able to give the following readings of the working of the battery sub-station taken at my request about a month ago. Although at that time of the year the load is necessarily light the total efficiency of the transformer, even if we neglect the correction due to lag, is satisfactory.

THE CONOVER MANUFACTURING CO.

THE CONOVER MANUFACTURING CO., of 95 Liberty street, builders of independent belt and steam-driven air and circulating pumps and condensers, have published an extremely attractive catalogue descriptive of their specialties. The pamphlet has a tasteful cover of blue and gold, with the name of the company in relief, and, together with the excellent wood cuts it contains, is from the hands of Messrs. Bartlett & Co. An illustrated description of the Conover independent condenser appeared in THE ELECTRICAL ENGINEER of June 29.

[1] Abstract of a paper read at the British Association meeting, Edinburgh.

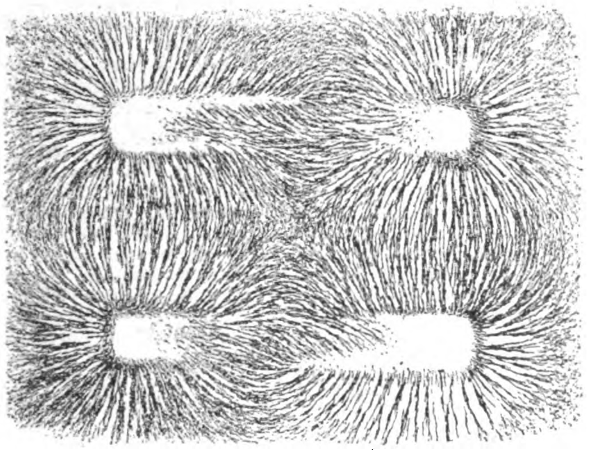
SOME ADDITIONAL NOTES ON THE GRAPHIC REPRESENTATION OF MAGNETIC FIELDS.[1]

BY PROF. EDWIN J. HOUSTON.

In a paper read at the last meeting of the section, entitled "A Graphic Representation of the Magnetic Field,"[2] I described a process for readily fixing and reproducing the peculiarities of different magnetic fields, which consists essentially in forming the fields on wax-covered plates, subsequently fixing the same by gently warming the wax, and employing the plate so prepared as a positive from which photographic prints can be readily obtained. I also briefly described in the same paper a different process for the ready reproduction of such fields, in which the collections of filings are formed in the dark photographic room, directly on the sensitized surface of a plate, which is afterwards exposed for a few seconds to actinic light and subsequently developed, and promised a further description of this method at this meeting.

It will be readily seen that this process differs from the other, in that it produces photographic negatives, in place of the positives formed by the former process.

All actinic light being excluded from the dark room, and the red light being turned down as far as will permit the plate to be seen, when the eyes have become accustomed to the dim light, a sensitized gelatine plate is placed with its sensitized surface upwards, on, or a short distance above, the magnet whose field is to be obtained. Iron filings or bits of wire are then carefully dusted over the sensitized surface, and obtained thereon, in characteristic groupings, by gently tapping the plate with a pencil or similar object in the usual manner. The plate is then exposed to the light of a gas jet for a length of time that will of course depend on the nature of the plate, its sensitometer number, and the character of the effect it is desired to obtain. When very rapid plates are used, the time during which a gas burner can be turned on and off is sufficient. I have, however, obtained the best results from the light of an ordinary friction match held above the plate and at a distance from it of about twelve feet. The match is lighted and immediately blown out. Even this short exposure appears to be greater than is required. With fairly slow plates I have found that an exposure of about three seconds, with a two-candle gas jet, at a distance of about four feet from the plate, gives excellent results. The plate is then turned on edge so as to allow the filings to fall off its surface, and any dust that remains is carefully removed by a camel's-hair brush, and the plate is developed in the ordinary manner.



Magnetic Field Direct from Photographic Plate.

Since it is desired to obtain sharp contrasts of black and white, the best results are obtained by the use of bromides in the developer for the purpose of retarding the rapidity of development. After developing, the plate is treated for a few moments to an alum bath, and is then fixed in the hypo bath as usual.

A number of plates of fields analogous to those shown in connection with his previous communication were exhibited by the author, one of which is shown in the accompanying engraving.

NEW YORK ELECTRIC CLUB.

Resuming promptly with the close of the summer vacation period, the New York Electric Club has thrown its doors wide to returning members, and on Thursday evening last opened its restaurant again under the care of a caterer, who will be on the premises and will make it his special duty to meet the demands in that department. A number of members visited the club house on Thursday, and expressed their great pleasure at finding things on their old footing. The club is to-day as cosy and comfortable as it ever was, and it is believed that electrical men in the city and from out of town will delight, as heretofore in making it their rendezvous and headquarters.

BUYING SUBMARINE CABLE ABROAD FOR THE GOVERNMENT.

In addition to the interesting letters in regard to the Lake Huron Signal Service cables published last week, from the manufacturers of Day's Kerite, Bishop and Habirshaw cables, we are glad to print the following from Prof. M. W. Harrington, the Chief of the Weather Bureau, on the same subject:

U. S. Dept. of Agriculture,
Weather Bureau,
Washington, D. C., August 27, 1892.

Editor Electrical Engineer,
203 Broadway, New York City.

Dear Sir.—In reply to your favor of the 24th instant, and the suggestions in the editorial from The Electrical Engineer, I would say that the estimate for the cost of the cables in question was made by my predecessor some two years ago, and the matter came up again during the last session of Congress. I found on investigation that the cost of the cable had about doubled, and so stated. This, I presume, is due in part to the duty; it may also be due to the increase in the price of the cables; but that matter I have not specially investigated. It was not my intention to have this cable necessarily foreign; when we are ready to purchase it we will submit specifications for bids from both native and foreign manufacturers, and select that which seems on the whole cheapest and best, as allowed to do by law.

The specifications have not yet been made out, as there is some delay in the matter of laying the cables.

Very respectfully,
Mark W. Harrington,
Chief of Weather Bureau.

We are also in receipt of the following:

STANDARD UNDERGROUND CABLE CO.

Pittsburgh, Pa., August 29, 1892.

Referring to your valued favor of August 23d, enclosing copy of an editorial from the pages of the August 24th issue of your publication, I beg to say that I do not believe there is at present any manufacturer of cables in this country equipped with the plant necessary for making submarine cables of great length, say fifty to three thousand miles, but there are no doubt several who are equipped for the manufacture of cables from one to ten miles long) and, perhaps, even forty to fifty miles long, so that there should be no necessity of going abroad for a seven-mile submarine cable.

As you are doubtless aware, there has been little or no demand in this country for submarine cables over ten miles in length, all submarine cables of great length being laid by foreign companies generally under subsidies from foreign governments, and, naturally, this has stimulated English manufacture of this class of cables.

It would be disloyal to our own country, as well as shutting one's eyes to the past history of manufactures in this country, to say that if a sufficient demand existed in the United States to justify it, there would not be plenty of manufacturers enterprising enough to put in the plant requisite to meet such demand; of course, no such plant will be put in unless the differences in prices of raw materials are secured to American manufacturers by an import tariff on the finished article.

Standard Underground Cable Co.,
Per J. W. Marsh,
Vice-President and General Manager.

BLOCK SIGNALS ON THE NEW JERSEY CENTRAL.

The Central Railroad of New Jersey has begun running its trains by the pneumatic signal system, which was recently completed by the Union Switch and Signal Company of Pittsburgh. The semaphore blades work automatically, by means of electricity and compressed air. The power stations are at Communipaw, Roselle and Greenbrook, and the new system is operated as far west as Bound Brook. When a train enters a block, both the red and green semaphores are set so that another train coming behind will be signaled to stop. As the train leaves the block, the red arm drops, leaving the green arm extended, showing that the train is in the second block. When both blocks are clear, both semaphores are down. The signal posts are about half a mile apart. No train is permitted to enter a block till the signal shows that the track is clear. The company decided to put in the new system as a safeguard because of the frequency with which fast suburban trains are run over its tracks between New York and Bound Brook.

Literature.

The Practical Management of Dynamos and Motors. By Prof. Francis B. Crocker and Dr. Schuyler S. Wheeler. New York: *D. Van Nostrand Co.*, 1892. Cloth, 5 x 7½, 98 pages. Price $1.00.

THAT large and ever-increasing body of those placed in charge of dynamo-electric machinery must, of necessity, for the most part be recruited from the ranks of the mechanical trades, while not a few among them have had no previous mechanical training whatever. To enable such to maintain the machinery placed in their charge at its highest efficiency is an object worthy of the best efforts of all whom experience has taught that it is in little things that the successful operation of such machinery must be looked for. The publication in our columns of a series of articles under the title given above has been followed by such a demand for the issues containing them that the authors have very wisely determined to reprint them; and collected as they are now in a handy form their value will, if anything, be enhanced.

The authors divide their subject into two parts. The first treats of the general principles of dynamos and motors and relates to those important details which should govern the selection of such machines and their installation. We here find the purchaser's attention drawn to the construction and finish, the method of regulation, form, weight, cost, etc., of the various machines. The installation of the dynamo with its pulleys, belting, electric connections, etc., is thoroughly explained and elucidated by numerous diagrams and engravings, and the book includes various types of shunt, series and alternating current machines. The method of *starting* machines of these various types—a matter of no small importance—is fully gone into; while the subject of *stopping*, a probably not less important detail, receives its due share of attention. The authors also include general instructions for the use of dynamos and motors and rules for personal safety. For those who desire to enter more deeply into the determination of the quality of the machines they are handling, an excellent chapter of directions for testing dynamos and motors is given, in which the rules and apparatus employed are of the simplest kind.

Aware of the fact, however, that even the best designed and constructed motor or dynamo is apt to get into trouble, the authors have devoted Part II to a systematic treatment of the localization and remedy of the troubles met with in such machines, such, for example, as sparking at the commutator, that most prolific source of annoyance. The various rules for determining and localizing heating in fields or armature or bearings, noise, irregularity in speed, failure of motor to stop or start, etc., are all gone into with considerable fullness.

With the contents of this little volume thoroughly mastered, an intelligent person ought to be able to maintain a dynamo or motor in the best possible condition for work; and as such it ought to be in the hands of every one operating such machinery. Even those abundantly experienced in the maintaining of dynamo-electic machinery will find it of value as including within a narrow compass the many points which at the time are most vital and are apt to be overlooked in the search for trouble. The intensely practical nature of the book throughout is not the least important of its many valuable features, and the little work will not fail to increase the reputation, as well as the popularity, of the authors.

Electricity: Its Theory, Sources and Applications. By John T. Sprague. Third edition, thoroughly revised and extended. *E. & F. N. Spon:* New York and London, 1892. 647 pp.; 5x7½ in. Price $6.

ELECTRICIANS have now become so accustomed to incessant changes and modifications in existing practice and theory that they are apt to lose sight of the really remarkable changes in both, which have been brought about during the last ten years. It is only when the progress so made is systematically recorded and placed, as it were, in "parallel columns" to that of a decade ago that we begin to realize the pace at which we are going. The author whose work is before us has already fully demonstrated that in addition to being an accurate and painstaking recorder of facts and an able analyzer of subtle distinctions, he is possessed of an independence of thought which, though it may lead him to differ from well-recognized authorities, gives his work that freshness and vitality of expression which interests the reader and acts as a mental stimulus to the student.

The general treatment and the divisions of the subject-matter of the present volume are in the main similar to those of the previous editions, but the author has evidently gone over his previous work critically in the light of modern theory and practice, and with the result that we have a most excellent exposé of the subject brought down to within a few months. Thus we find most excellent chapters on static electricity, magnetism, galvanic batteries, measurement, current electromagnetism. electric lighting, electro-metallurgy, terrestrial electricity, etc., in which we believe we are safe in saying that the data to be found is that of the best practice of to-day; and with the clear enunciations of the principles as stated by the author it will give the reader a thorough insight into the various subjects treated.

We have intimated above that the author takes nothing for granted, and as a result he is by no means in sympathy with most modern theories, many of which are based upon assumptions for which he conceives there is no warrant in fact. The views recently put forth by Dr. Lodge seem especially to irritate Mr. Sprague. According to the theory adopted by him, "electricity is not a material or a quasi-material fluid, nor is it a special force or energy; much argument has been used by partisans of each of these views, to prove the other erroneous, and both sides are quite successful in the effort. But unite the two and we have a clear truth. It is energy charged in a special manner upon ordinary matter, and developing special relations among its molecules." As a result the author deprecates the present general tendency to fall back upon the ether alone as a universal agent for the explanation of all electric phenomena. This idea, to his thinking, "is naturally most favored by mathematicians and to all but trained mathematical minds it is nearly incomprehensible and appears only a modification of the one-fluid theory."

On the subject of light as an electrical vibration the author again falls foul of Dr. Lodge, who, he claims, has no evidence to substantiate the idea that "light is an electrical vibration," while on the other hand he holds that there is much to support the view that "light is a vibration of matter which may be produced by many processes which release or set in action the inherent functions of the atoms." We have given the above quotations merely to illustrate the author's independence of thought, and while we are not prepared in every instance to lend support to his own ideas on the subject, they certainly deserve, and will receive, respectful consideration, and are withal interesting.

It would take us too long to follow out in detail the many views to be found in this practically new work. We note, among many other things, that the author believes that the henry is pretty sure to be the name of the unit of inductance, notwithstanding the adoption by the Paris Congress of 1889 of the term "quadrant." We are glad to see the book brought down to so recent a date as to include the work of Mr. Tesla, which the author describes in a brief but exceedingly clear manner. The general extreme accuracy is notable throughout, but it would have been strange, indeed, if a few errors had not crept in, and among others we note a slip in the statement and the formula of Mr. Steinmetz's law on hysteresis. The exponent of *B*, representing the lines of magnetic force per square centimetre, is given as ⅙, whereas it should be 1.6. In the definition of the term choking coil the author appears to limit its employment to circuits carrying "intermittent" currents. If the author conceives the alternating current to be a species of intermittent current we have no fault to find with the definition, but we think the term employed is somewhat ambiguous and is apt to lead to error in the minds of the readers.

The work, as a whole, brought up to date as it is, constitutes a complete compendium of the subject, and, we are safe in saying, constititutes one of the few standard works on electricity in the English language.

DATA CONCERNING PLATINUM.

A VERY interesting pamphlet on platinum has been issued under the above title by Baker & Co., of 408 to 414 New Jersey Railroad avenue, Newark, N. J. This old and well-known firm have had a long experience as gold, silver and platinum refiners, assayers and sweep smelters, and of late years a portion of their large trade has been done in the electrical field, where platinum has been found to be indispensable for a great variety of purposes, both in the industrial arts and for laboratory use. Without platinum, it might be said, the modern incandescent lamp could not have existed, and Baker & Co. for many years have been active in supplying the demands of the lamp factories. But there are many other uses, such as in electric gas lighting, electro-medical apparatus, electrodes, contact points, etc., and platinum is needed for them in various shapes beyond the wire or sheet that are generally familiar. The pamphlet before us enumerates several of these employments of the metal, as well as of iridium, palladium osmium and other of the rarer metals of which in the advances that electricity is making, more and more use will be seen. A number of valuable tables, which we do not remember to have seen before, are also given as to the weight and capacity of platinum articles: the Troy and French weights per foot of platinum wire; the weight per square inch of platinum sheet or foil; a comparison of Troy, avoirdupois and French weights, etc. Several of these tables are copyrighted by the firm, and should prove extremely helpful to all who are interested. The back of the pamphlet gives a good picture of the Baker works at Newark, where this industry has been built up and has become a standard concern, enjoying a remarkably wide range of trade and custom, and growing yearly in magnitude and importance.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED AUG. 23, 1892.

Alarms and Signals :—

Train Indicator, H. L. Manton, 481,364. Filed Dec. 1, 1891.

Employs a dial having a series of holes at different distances from its axis and a series of spring retracted plugs adapted to enter into said holes.

Pneumatic Electric Circuit Controlling and Interlocking Apparatus, W. W. Slater and H. C. Barnes, 481,430. Filed Oct. 24, 1891.

Employs pneumatic devices to take the place of the underground wiring in railway signal service.

Conductors, Conduits and Insulators :—

Insulator, A. J. Wylie, 481,457. Filed Jan. 18, 1892.

Employs a non-conducting bracket having a rounded out-standing portion with a longitudinal wire chamber extending entirely through it, and longitudinally disposed slots extending in a straight line through the face and opening into the wire chamber.

Dynamos and Motors:—

Electric Motor and Generator, C. S. Bradley and James J. Wood, 481,220. Filed Aug. 22, 1891.

Comprises a laminated core, the side plates having their polar projections bent over the end of the magnetizing coils to hold them in position.

Heating:—

Electric Water Heater, T. Ahearn, 481,291. Filed April 9, 1892.

Lamps and Appurtenances :

Shade for Incandescent Electric Lamps, C. J. Salick and E. Sipp. Filed April 10, 1891.

Reflecting Shade for Incandescent Electric Lamps, L. T. Stanley, 481,288. Filed Oct. 22, 1891.

Reflecting Shade for Incandescent Electric Lamps, L. T. Stanley, 481,378. Filed Feb. 29, 1892.

Miscellaneous :—

Circuit Changing Apparatus, A. D. Page, 481,281. Filed May 14, 1892.

Employs a rotatable body having a conducting section, and contact devices adapted to bear thereon, and adjustable with respect to one another.

Mast Arm, A. Wright, 491,381. Filed Oct. 14, 1891.

Electric Elevator, W. Baxter, J., 481,386. Filed Oct. 31, 1890.

An arrangement of circuits connected with a switch upon the elevator through the medium of a flexible cable, the construction being adapted to currents of constant strength.

Life Saving and Pleasure Craft, A. B. Shearer, 481,427. Filed March 29, 1892.

An electrically propelled life raft.

Magnetic Separator, G. Conkling, 481,474. Filed July 23, 1891.

Railways and Appliances :—

Trolley for Electric Railways, W. F. Jenkins, 481,401. Filed Sept. 5, 1891.

Provides means for separating and insulating from each other the wheels making contact with the two conductor wires in a conduit railway system.

Trolley for Electric Railway Conduits, W. F. Jenkins, 481,402. Filed Sept. 5, 1891.

Provides means for so adjusting the trolley to the car that the connection may be readily made, and the vertical and lateral vibration between car and trolley automatically taken care of.

Conduits for Electric Railways, W. F. Jenkins, 481,403. Filed Sept. 5, 1891.

Employs a conductor support having a collar and a screw nut and insulated clamping jaws arranged between them to hold the conductor.

Trolley Switch, J. S. Merkins, 481,503. Filed Oct. 17, 1891.

An automatic device whereby the trolley may be guided to the branch conductor while moving in one direction, and keep the main line conductor while moving in the opposite direction.

Trolley Protector, J. Walsh, 481,517. Filed Dec. 23, 1891.

Employs a mechanism by means of which the trolley pole is automatically drawn down the moment it becomes accidentally disengaged from the trolley wire.

Switches and Cut-Outs :—

Thermal Cut-Out, A. P. Seymour, 481,246. Filed Mar. 21, 1892.

Has for its object a cut out or similar device made of porcelain and moulded in a single piece.

Electric Switch, J. H. Clark, 481,297. Filed Sept. 29, 1891.

Employs a freely suspended weight, a connection between it and the movable member of the switch and a movable pulling point between them through which the connection acts.

Telegraphs:—

Ship's Telegraph, A. B. W. H. Cords, 481,223. Filed Jan. 14, 1892.

Employs a transmitting lever operating a pointer of the receiving instrument and a set of supplementary recording levers.

Telegraphy, J. G. Smith, 481,247. Filed Nov. 2, 1889.

A system by which any one of a number of persons may establish communication with any one other person at a distance with the same privacy that can be secured by means of a private line; the device requiring no hand manipulation except on the part of the persons using the wire.

Telephones and Apparatus :—

Plug Spring-Jack, C. A. Shea, 481,204. Filed April 23, 1892.

Consists of two engaging circuit breaking devices each comprising a plug, a circuit breaker and a holder for an additional circuit breaker and a flexible conductor connecting the insulating contact points of the two devices.

Telephone, A. Rettig, 481,284. Filed Feb. 17, 1892.

Employs several diaphragms varying in size and lever and spring devices connecting the diaphragms.

Arm Rest for Telephones, J. R. Bailey & L. C. Lincoln, 481,293. Filed Jan. 25, 1892.

Telephone System, R. N. Dyer, 481,483. Filed Oct. 30, 1890.

Has for its object to prevent disturbances and dangers arising from grounding the current supplying circuit through the telephone apparatus or line.

Telephony, J. W. Gibboney, 481,539. Filed Feb. 8, 1892.

Claim 10 follows:

The method of telephoning, consisting in passing over a circuit an alternating current or a current of changing value, passing said current through a coil of an inductorium and varying the counter-induction of said inductorium by the agency of sound vibrations.

Obituary.

F. N. GISBORNE.

The death is recorded at Ottawa, Can., on Aug. 30, of Mr. F. N. Gisborne, who was largely instrumental in the construction of the first Atlantic cable. He it was who first directed the attention of Mr. Cyrus Field to the project, and he first carried the land line across Newfoundland.

Mr. Gisborne was born in Broughton, Lancashire, England, March 8, 1824. In 1842 he started on a tour around the world which lasted nearly three years. He finally settled, in July, 1845, in Canada. But he was not long content with the life of a farmer. He had a keen interest in telegraphy, and in 1847 he deserted his farm for a place in the office of the Montreal Telegraph Company. Not long afterwards he opened the first office of the company in Quebec. He advanced rapidly, and in 1850 he was the chief officer of the Nova Scotia Telegraph Company.

It was at this time that he conceived the idea of a telegraph line to connect St. Johns, N. F., with the main continent. He figured that if St. Johns, the most easterly point in America, could be brought into electric connection with the mainland, news could be received forty-eight hours in advance from Europe over the system then in vogue. At this time Newfoundland was an unexplored wilderness. The project of erecting a telegraph line through this wild stretch of country, some 400 miles in length, was hazardous enough, but Gisborne carried his plans even further, it being his intention to ultimately run a submarine cable across the Gulf of St. Lawrence, as was subsequently done. As soon as his plan took definite shape he appeared before the Newfoundland Legislature and succeeded in obtaining a grant of £500 for a preliminary survey. Resigning his office with the Nova Scotia Telegraph Company, he obtained land grants and organized the Newfoundland Electric Telegraph Company. Then he set out upon the survey, which lasted three months.

He finished the survey in spite of tremendous difficulties, and after making a favorable report on the project he came to New York to obtain financial aid. He succeeded in interesting capital in this city. In 1852 he laid the first submarine cable of any length put down in America, from Cape Ray to Prince Edward Island.

In 1853 his backers in New York deserted him, and he found himself hopelessly involved in a project which he had not the means to carry out. He was even arrested and imprisoned for the debts contracted by the company, and only succeeded in regaining his liberty when he had sacrificed every dollar he had in the world. But he still clung to his project, and in 1854 he returned to New York to renew his efforts.

It was at this time that he met Matthew D. Field, a brother of Cyrus W., who was a civil engineer and a railroad builder. Through him he was introduced to Cyrus W. Field. From this grew the work which finally ended in the Atlantic cable being laid. Mr. Gisborne took an active part in the undertaking, and it was under his charter that the Transatlantic Telegraph Company first began operations.

After the cable was finally laid, Mr. Gisborne was appointed superintendent of the Dominion Government Telegraph and Signal Service, an office that he held until his death. He was the inventor of a number of valuable electric appliances, and also produced inventions in other lines. He was one of the original members of the Royal Society of Canada.

JOHN K. DUNBAR.

The death is announced of Mr. John K. Dunbar, at Buffalo Lithia Springs, Va., on August 16. He had been connected with the Southwestern Telephone and Telegraph Co. since its formation in 1881, and at the time of his death was its general superintendent. His illness was primarily due to the grip, and had lasted several months. Mr. Dunbar was popular among his associates and the employees of the company, being kindly and generous of nature. He leaves a widow and two daughters.

ENDOLITHIC PRINTING ON IVORY.

We have received from the Endolithic Ivory Co., Limited, 61½ Fore street, London, England, a sample of their endolithic printing on ivory. The process is one which, it is said, renders the printing indelible in any climate, and is available for switchboards, keyboards, speaking tubes, apparatus, name plates, etc. In England it is used by the Brush Co., Laing, Wharton & Down; B. Verity & Sons; Siemens & Halske; Spagnoletti & Crookes; the National and Consolidated Telephone Companies and others. The switchboard tablets are made in sets as required. The sample before us is a very neat and pretty piece of work that looks as though it would stand wear.

TRADE NOTES AND NOVELTIES

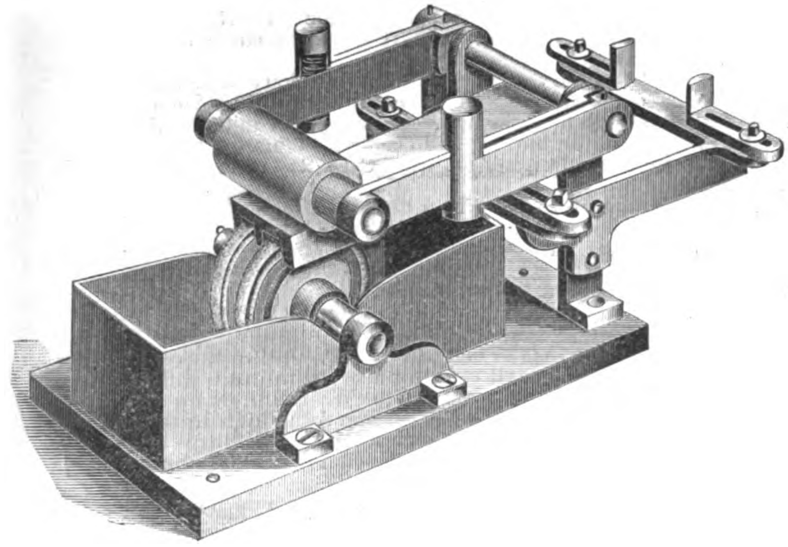
AND MECHANICAL DEPARTMENT.

Let your advertisement be readable without the aid of a magnifying glass, but don't expect large type to take the place of merit in your goods.

THE STANDARD PAINT CO.'S MACHINE FOR PAINTING ELECTRIC MOLDINGS.

The Standard Paint Co., of 2 Liberty street, the sole manufacturers of the P. & B. compounds, etc., have recently put in the market a small machine for painting molding. As almost all molding for inside wiring is now required to be painted with a waterproof compound, they have concluded that it would be to the advantage of those who have this work to do, to use such a machine. It affords a great saving in labor, and a considerable economy in the use of the paint or compound. This painting machine is very simple, as shown by the cut. It can be so arranged that any size molding can be painted by it. Any one can handle it, and two boys can easily paint 1,000 feet of ordinary size molding, inside, outside, and back of capping within an hour.

The machine does its work thoroughly. It does not take up any room to speak of, and is strongly built as well as cheap. The machines are already much used in connection with the P. & B. water and acid proof compound, and are giving very great satisfaction.



Machine for Painting Moldings.

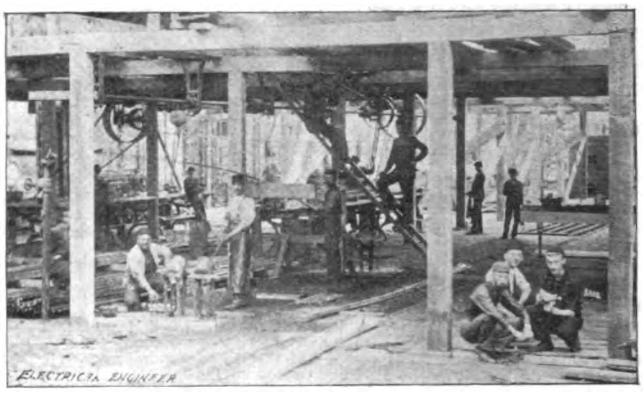
It will be remembered that in most of the large cities the boards of fire underwriters require all moldings through which electric wires run to be coated inside and out with insulating compound. Without such a machine as this, the painting of moldings, necessarily by hand, is slow, tedious and expensive work.

LOW TENSION LIGHTS FOR FIFTH AVENUE, NEW YORK.

Fifth avenue, which, for the past year, has been but feebly illuminated at night by the old-fashioned gas lamps, will soon be lighted by a new and improved system of electric lighting, the contract for which has been made with the Edison Company by the Gas Commission. A new style of electric arc lamp, designed for use on low tension incandescent circuits, will be used. The lamp is the invention of Mr. Sigmund Bergmann, president of the New York Electric Equipment Company. Fifty poles will be erected at intersecting streets from Washington Park to Fifty-ninth street, and on each of the poles will be two of the new lamps. Contracts for the manufacture of the poles, which are to be of cast iron, about twenty feet high, have been made. They will be ornamental, as will also the lamps with which they will be surmounted. These will have artistic brass finishings and ground glass globes of special design. There will be no overhead wires, the cable being introduced from the Edison Company's subway. The hollow of the pole contains a counterpoise, by which the lamps may be lowered for trimming or repairs. The lamps on each pole are independent of those on every other pole, being in multiple to the mains. The lamps can be controlled either from the central station or at the base of the pole, which is fitted with a locked door, the key to which is kept by the illuminating company's officials. These lamps are to be paid for at the rate of 50 cents a night for the pair.

ELECTRIC MOTORS AND THE SCHENECTADY FIRE.

A bad fire occurred in the underground tube department of the General Electric Co., at Schenectady on July 25, razing the building to the ground, with a loss of about $52,000, covered by insurance. The fire appears to have been due to spontaneous combustion, as it flashed up suddenly about 7.30 a. m. while a barrel of kerosene was being rolled through the shop. The weather had been extremely hot, greatly favoring an explosion such as occurred. Some idea of the promptness with which the works and its fire department grappled with the fire may be formed from the fact that it has at work within a few minutes, while a number of photographs were secured within 15 minutes after the flames were seen. One of the accompanying illustrations is from a photograph taken after the fire.



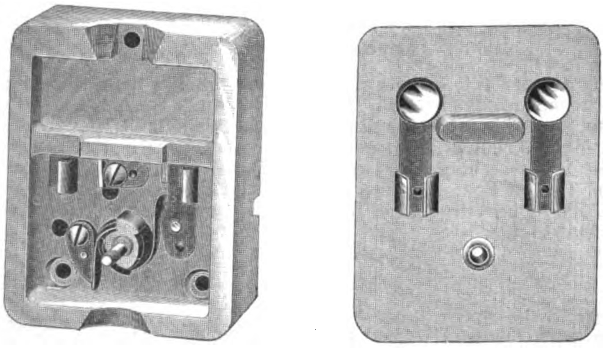
Edison Tube Works Before the Fire.

But the special interest attaching to the fire is due to the prompitude with which work was resumed with the aid of electric motors. Large supplies of the Edison tube were needed for New York, San Francisco and other cities, but the tube shop would have stood idle for a long time, had it waited for steam power. As it was, everything was in full swing the following week, in a practically new factory, the power being supplied by electric motors, to which, of course, the wires were easily run from the big power station. The extensive use of electric motors at Schenectady was described in The Electrical Engineer, and this experience is but another demonstration of the great ability of the electric motor.

Edison Tube Works After the Fire.

THE GENERAL ELECTRIC CO.'S COMBINED SWITCH AND FUSE BOX FOR RAILWAY LIGHTING CIRCUITS.

THE accompanying illustrations show a very neat combination switch and fuse box for use on the lamp circuits of electric street railways cars, recently introduced by the General Electric Co.



FIGS. 1 AND 2.—GENERAL ELECTRIC CO.'S SWITCH AND FUSE BOX.

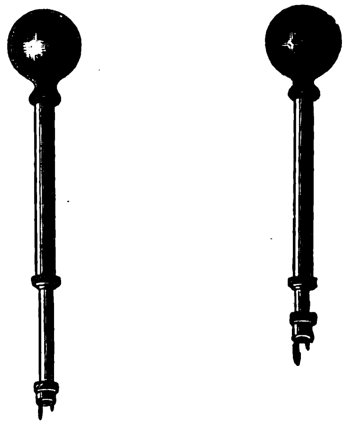
Fig. 1 shows the body of the box with the rotating ratchet switch in the lower compartment, and Fig. 2 the reverse side of the cover with the terminals and thumb screws for the metal fuse.

This box is claimed to possess many advantages over anything heretofore in use for railway lighting service. It is very compact, neat, and, as it is made entirely of porcelain, perfectly incombustible. The switch is of the latest improved type of rotating ratchet switch manufactured by the General Electric Co. and possesses the essential points of good contact and sudden break. The fuse is placed on the inside of the cover, so that in replacing a blown-out fuse the terminals are taken completely out of the circuit, and it is utterly impossible to receive a shock in any way. The brass clips on the cover fit over the two contact posts in the box, and serve the double purpose of holding the cover in place and forming part of the circuit.

As will be seen in Fig. 1, the box is divided into two parts, the lower holding the switch and the terminals for the wire, and the upper part consisting of a shallow recess into which the thumb screws on the inside of the cover project. In the back of the box behind this upper recess is a magnetic blow-out, which breaks the arc formed when the fuse is blown. In general appearance the box is quite ornamental, and with its great superiority over other and older devices for the same purpose it should commend itself strongly to all street railway men.

THE DANDY DOUBLE-POINT TACK DRIVER.

THE "Dandy Double-Point Tack Driver" is illustrated herewith. Fig. 1. shows the tool at rest with a double-pointed tack protruding from the end.



FIGS. 1 AND 2.—DANDY DOUBLE-POINT TACK DRIVER.

Fig. 2 shows the action of the tool in the position of having driven the tack in place. This little tool is useful in driving double-pointed tacks into corners and places where an ordinary hammer cannot be employed. It effects a great saving of labor, the use of the tool permitting the wireman to facilitate his work very materially. Telephone companies and other large wiring companies who use double pointed tacks, should find it very convenient.

Applications have been made for a patent, and the Central Electric Company, Chicago, are putting it on the market.

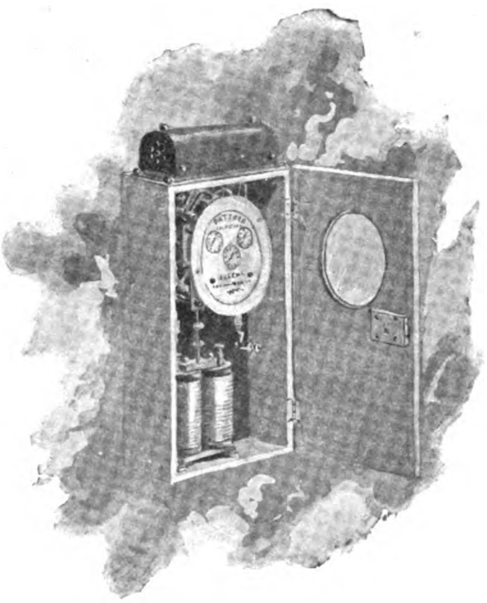
THE PURITY OIL FILTER MANUFACTURING CO.

THE above company of Pittsburgh, Pa., report the following shipments in July to the 15th ult.: Vacuum Oil Co., New York City; San Francisco and San Mateo Electric Railway, San Francisco, Cal.; Marshall Kennedy & Co. Flour Mills, Allegheny Pa.; Homestake Mining Co. Lead City, South Dakota; Black Hills Mining Co., Rapid City, South Dakota; Tennessee Manufacturing Co. and Union Mill Co. one No. 2 Ideal each, Nashville, Tenn.; Thomson-Houston International Co., for export to England; House of Refuge, Glen Mills, Pa.; E. H. Kellogg & Co. two No. 2 Purity Oil Filters, New York. The company cannot get any stock ahead with their present force, but intend to double their capacity.

PATTEE'S LAMP-HOUR RECORDER.

GEORGE CUTTER is putting out a new form of the Pattee lamp-hour recorder which is already used by a number of Western stations. It is well adapted for use with arc lamps or series incandescents, and thus fills a long-felt want. The illustration shows one designed for use with a motor working on a steady load, the charges for current being in direct proportion to the running hours.

For arc lamps, the use of this device leaves the consumer free to burn his lamps early and late, and still gives the central station an exact record of the current used. The new form has recently been patented and is supplied to the trade by George Cutter of Chicago.



PATTEE'S LAMP-HOUR RECORDER.

ELECTRIC LIGHT EXHAUST STEAM FOR HEATING PURPOSES.

THE ELECTRIC LIGHT AND POWER COMPANY, of Grinnell, Iowa, is laying a line of protected underground steam pipe through which to circulate its exhaust steam for heating purposes. The work and material is being furnished by the American District Steam Company, of Lockport, N. Y. At St. Joseph, Mo., Canton, Ohio, and several other places, electric companies are preparing to build exhaust steam plants the present season.

OCEAN LIGHT SHIPS.

THE London *Telegraph's* Paris correspondent says: "The French Transatlantic Company takes up again the project relative to ocean lights which was dropped a few years ago. The proposal is that light ships connected by telegraph cables be stationed at intervals of 200 miles across the Atlantic."

ENTERPRISE ELECTRIC CO.

THE branch house of this company has now been opened at 15 North 9th street, St. Louis, and Mr. W. H. Ferris, the manager, reports that the business is already brisk. The Chicago end of the line states that it feels elated, not having been affected by the hot weather lethargy that handicapped Western trade generally for a while.

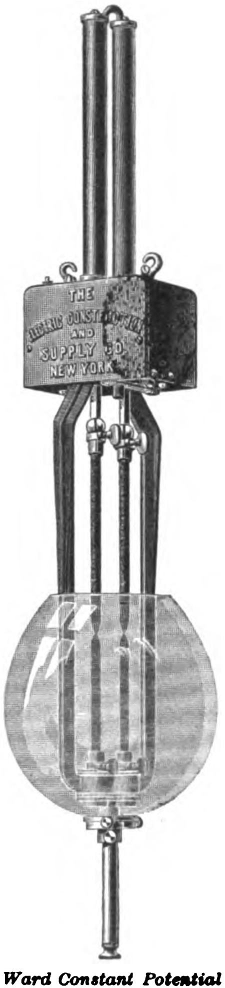
MR. C. D. SHAIN.

HAVING lately severed his connection with the Edison General Electric Co., for which he was the manager in the Eastern District, Mr. C. D. Shain has established himself as an electrical engineer and manufacturer's agent, with headquarters at 303 Electrical Exchange Building, 136 Liberty street, this city. While he is not yet prepared to make all his announcements, Mr. Shain has, it may be stated, become selling agent for the Western Electrical Instrument Co., in which capacity he will attend to the large trade already built up in the well-known Weston voltmeters, ammeters, etc.

THE WARD CONSTANT POTENTIAL ARC LAMP FOR STREET LIGHTING.

IT is the opinion of many observers that the day has come for the extensive use of low tension arc lamps for street lighting, enabling companies to combat the strong prejudice that exists against high tension series lamps, and also to avoid the stringing of wires, as the low tension lamps are run in multiple on the regular incandescent circuits. These circuits are generally underground in large cities; and even when overhead, the fact that they carry only a low, safe potential disarms criticism. Constant potential arc lamps, run in multiple and multiple series across the incandescent mains of isolated plants and local companies, are now counted by their thousands, and it has come to be only a question of time when they would be used for a whole street, under contract, like the familiar series arcs.

The Electric Construction & Supply Co., of 16 and 18 Cortlandt street, the makers of the celebrated "Ward" constant potential arc lamps, have been keen students of the situation, which, in fact, they have done much to create; and they are now putting on the market a "twin lamp," intended for regular municipal street work, and with which very successful results have been obtained during the past eighteen months. This "twin lamp" is of the appearance shown by the cut, being practically indistinguishable from a double lamp. It has two independent regulating mechanisms and two corresponding magnet systems in continuous operative connection with the supply circuit. The lamp thus constructed and run on a 110-volt circuit will pass 4 or 5 amperes through each of its two sets of carbons constantly burning in series to each other, in the one frame. This gives at least as much light as, and probably much more than, a single 8 or 10 ampere lamp, and hence can be used as an economical and unusually satisfactory substitute for a single lamp giving the standard illumination, since the two arcs use up substantially the whole voltage and wasteful resistance is unnecessary. It is obvious also that, for the current consumed, the distribution of the light is much better and much more effective. Evidently there is a very large field for such a lamp as this.



Ward Constant Potential Arc Lamp for Street Lighting.

FINANCIAL.

NEW THOMSON-HOUSTON BONDS.—The Thomson-Houston Electric Company has issued $500,000 collateral trust thirty-year 5 per cent. gold bonds due July, 1919, and secured by $600,000 Manhattan Electric Light Company of New York first mortgage thirty-year 5 per cent. gold bonds. The bonds are redeemable after 1899 at 105 and interest.

ABNORMAL LAMP BREAKAGE.

WHO broke that electric light on the west side? It is rumored that certain young people who are ashamed to do courting in a hammock under the glare of electricity are responsible for the deed. They had better look out.—*Manson, Ia., Democrat.*

THE NEW ORLEANS ELECTRIC ROAD.

THE BERLIN IRON BRIDGE CO., of East Berlin, Conn., will design and construct the new buildings for the New Orleans and Carrollton Railroad Co. The power house is 83 x 130 feet, with brick walls and an iron roof. The car shed will be built entirely of iron 130 x 140 feet. It is the intention of the New Orleans and Carrollton Railway Co. to have the finest electric railroad plant in the Southern States.

PEPPER & REGISTER.

THE above Philadelphia electrical engineering firm, who have the contract for the Easton, Pa., Rapid Transit Co., write us that it is to be a Westinghouse plant, with 20 cars of 40 h. p. each, and with Westinghouse multipolar generators, with steam power furnished from the present plant of the Edison Electric Illuminating Co., of Boston. Iron poles will be used, made by Milliken Bros.; Simplex wire and either the Johns or the Anderson overhead material.

OKONITE.

AMONG the many large buildings which have recently been wired with Okonite wire, the Central Electric Company report having secured the St. Charles Hotel, Chicago, which will be furnished with 1,100 lights, Okonite being used throughout. This insulation was decided upon, it is said, in the face of the fact that the prices were considerably higher than those of other grades of rubber wire.

ENTERPRISE ELECTRIC CO.

THE above company, of 313 to 315 Dearborn street, Chicago, has elected Mr. Geo. Dickinson as its secretary. He has had extensive experience and will prove a valuable acquisition. Mr. W. C. McKinlock, the president, has been in St. Louis, studying the development of the business there.

NEW ENGLAND NOTES.

THE BERLIN IRON BRIDGE CO., of East Berlin, Conn., are putting up two iron buildings for the Randolph & Clowes Co., at Waterbury, Conn. One is a casting shop 42 feet wide by 82 feet long, and the other a pickle-room 25 feet wide by 100 feet long. The Berlin Company are also building a new gas house for the Philadelphia & Reading R. R., at Philadelphia, Pa., a new retort house for the Geo. H. Morrill Co., of Boston, Mass., and a new boiler house for the Pope Manufacturing Co., of Hartford, Conn. All of these buildings are to be of iron, after the well known plans of the Berlin Company.

NEW ORLEANS NOTES.

MR. WILLIAM OSWALD, the manager of the Southern Electrical Manufacturing and Supply Company, Limited, of New Orleans, Louisiana, has closed the following contracts: Elm Hall Plantation, 450 incandescent and 4 arc lights, with New York Safety Steam Power Company's engine; Cora Plantation, 360 incandescent and 4 arc lights, with engine; Morbihan Plantation, 250 incandescent lights, with engine; Albania Plantation, 150 incandescent and 2 arc lights, with engine.

PHILADELPHIA NOTES.

FRANCIS & NARDI announce that they have associated with them Mr. Elmer P. Strang, late with the Novelty Electric Co., and Mr. Myer S. Levy; and that they will continue their business of electrical engineering and construction at their new offices in the Haseltine Building, 1418 Chestnut street. The new firm name will be Francis, Nardi, Strang & Co.

WESTERN NOTES.

THE SCHUTTLER RATCHET DRILL.—The Electric Appliance Company are placing upon the market a device which promises to become very popular among electrical and street railways generally. It is known as the Schuttler ratchet drill. It is a new track drill, its special feature being that a continuous rotary motion is produced by a powerful ratchet action, making it, the claim is, the most powerful and rapid track drill on the market. It is sold at a price which is also an attraction.

☞ ***Departmental items of Electric Light, Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

THE
Electrical Engineer.

VOL. XIV. SEPTEMBER 14, 1892. No. 228.

A BIOGRAPHICAL REVIEW OF THE KHOTINSKY ACCUMULATOR.—I.

BY

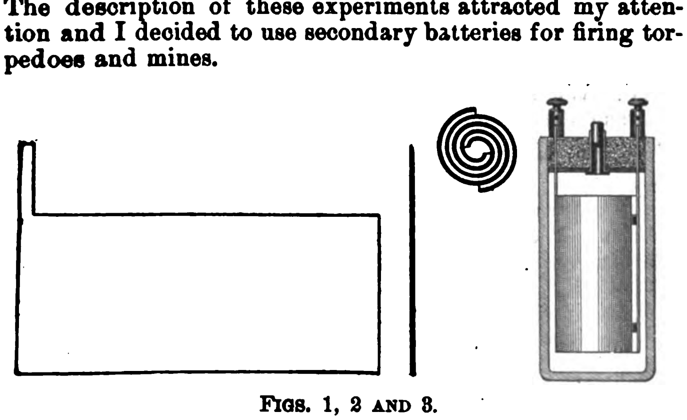
Capt. A. de Khotinsky

DURING the year 1871, when I was flag officer of Commander Admiral Butakoff, I was appointed to take charge of the electric lighting, also experimenting with torpedoes in the iron-clad squadron of the Russian-Baltic fleet.

In the summer of 1871 platinum primers were used to explode mines, this being accomplished by electrically heating the platinum breech by means of a large surfaced Grénet battery cell of small internal resistance. The cells were composed of three fixed carbon plates and two movable zinc plates. These cells fulfilled their purpose fairly well during a calm sea, but in rough weather they soon got out of order. It was unsafe to let the zinc plates of these cells remain in the fluid because the local action of the chromic acid on zinc polarized the cell, and, therefore, at the decisive moment, when most wanted, the battery failed to do its work.

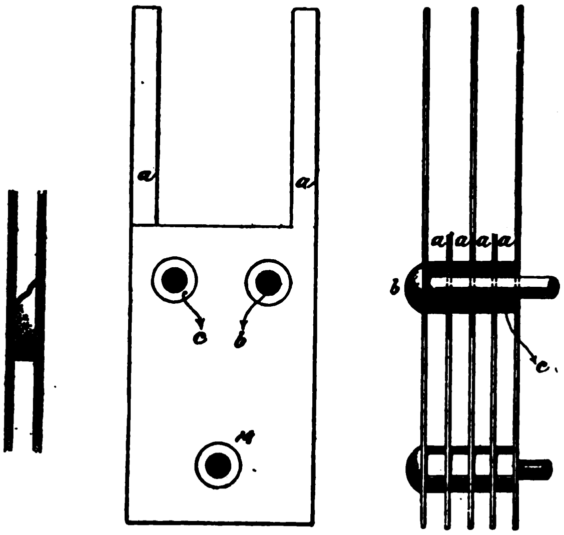
To prevent this, particular care was taken to have the zinc plates first touch the fluid just before the decisive moment. The result was, however, that very frequently in this way the explosion entirely failed or followed too late, while under the prevailing excitement either the sinking of the zinc plates in the fluid was overlooked or the movable contact failed because the connecting rods, by contact with the swaying acid, had oxidized. By this occurrence it was proved that with Grénet cells of the construction used in 1871, it was impossible to be sure of effecting an explosion at a desired moment.

About this time I read in the scientific papers of the experiments of M. Gaston Planté with secondary batteries. The description of these experiments attracted my attention and I decided to use secondary batteries for firing torpedoes and mines.



FIGS. 1, 2 AND 3.

For this purpose I constructed, in the winter of 1872, cells exactly in accordance with the idea of M. Planté, as shown in Figs. 1 and 2. I rolled together in a spiral shape lead plates 1 mm. thick, 80 mm. broad, 180 mm. long with intervening layers of two rubber strips $2\frac{1}{2}$ mm. in thickness and the same in breadth and put these rolls in a glass vessel filled with 10 per cent. sulphuric acid, Fig. 3. I formed these secondary cells with a battery of four Daniell cells by frequently changing polarity as Planté prescribed.



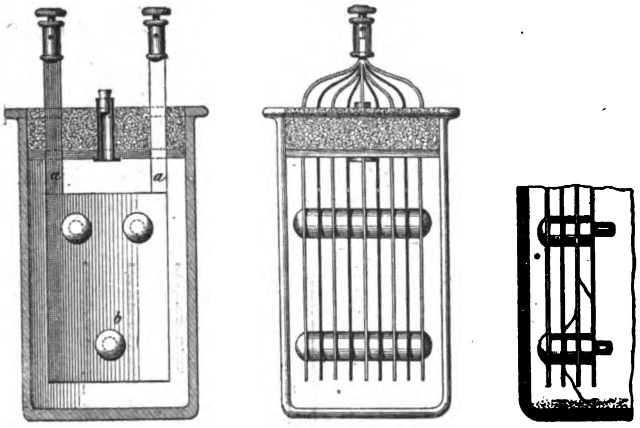
FIGS. 4, 5 AND 6.

After taking a month to form these cells, I began to experiment with them in order to fire a common platinum primer. This experiment gave much better results as compared with the Grénet elements. I carefully charged two of them and traveled from St. Petersburg to Kronstadt (35 kilometres) to show that an explosion could be produced by one pocket secondary cell. But, unfortunately, the experiment did not succeed, because in neither of the cells was there any charge remaining. This misfortune compelled me to carefully study the peculiarities and existing deficiencies of secondary batteries.

Returning to St. Petersburg, I began to examine the surface of the elements and then discovered that the positive plate in several places had become corroded and the whole surface was of a brownish yellow color which proved to me that the battery was entirely discharged. The further proof of the discharge was that the negative plate had assumed a bluish gray instead of a light gray color.

On removing the plates I found on the bottom of the vessel a sediment of light yellow powder mixed with dark brown scales, and after unrolling the plates I found that the same yellow powder had settled on the insulating strips and covered them with yellow scales. Some of these were larger than the distance between the positive and negative plates, as shown in Fig. 4. By measuring the resistance of the scales and the powder, it appeared that both materials were conductors, but the scales better conductors than the powder.

These experiments proved that my secondary battery by discharging itself during the journey from St. Petersburg to Kronstadt had lost its charge and that this discharging must have resulted from short-circuiting brought about by parts of the positive plates that had fallen off in the journey. This showed to me that it was impossible to make a rational element in accordance with the specifications of M. Planté and I discontinued further investigation of secondary batteries till I should have more time at my disposal. I then spent all the time I had on further experiments with incandescent lamps, which I had already begun in August, 1871, when I was interrupted by the before-mentioned experiments with secondary batteries.



FIGS. 7, 8 AND 9.

In the spring of 1874 I received a commission from Admiral Possiet, Minister of Commerce in St. Petersburg, to take part in a commission for lighting the harbor at Odessa, under the presidency of General Agustinovitch. One of the problems for the commission was to find the best way to light and extinguish the signal lights at the entrance of the harbor from a distance of about half a mile; these were gas lights. The solution of this problem was given to me.

Here again was a chance for me to deal with secondary batteries, for I thought I should find the most direct and best solution of the problem if I could light the gas in the signal lights by glowing platinum and bringing it to a glow by means of the electric current. This is not the place to describe the whole apparatus, which I used to turn on and off and light the gas, but I turn directly to the description of the secondary batteries, which I made and used to fulfil my purpose.

I knew from previous experience that the use of rubber strips over the whole length of the plate was the reason for the short-circuit of the plates. After trying many devices to avoid this drawback I decided upon the following construction: I cut the lead plates 1 mm. thick, 45 mm. broad, 56 mm. in height, with a contact prolongation on one side, as shown in Fig. 5. Every plate had three holes for the purpose of connecting nine plates to make one element, shown in Fig. 6. Hard rubber pins *b* were put through the plates *a* to hold them in rows, and at the holes each plate was insulated from the next by soft rubber washers, *c*. By this arrangement I thought that the peroxide would be free to fall on the bottom of the vessel without lodging on the insulation. I left, therefore, a space of 1½ cm. at the bottoms. Figs. 7 and 8.

This element, produced in the summer of 1874, as described, worked well at first to light gas, and also when used for the explosion of torpedoes. After working all summer they showed in the fall that if they were charged and left for one day on open circuit then they gave no current on the following day. On closer examination of this element I found no longer, as before, only small scales, but whole layers of peroxide loosened from the surface of the positive plates, see Fig. 9. I cleaned the element entirely of these scales and commenced again to charge, but the result reached was poor.

Instead of being able to light 60 to 80 times with the fully charged elements, the capacity now was only from 8 to 10 times. I thereupon again took a very long time in charging it, but the whole surface of the positive plate loosened and fell off, while the plate itself commenced to warp in all directions. The whole element looked as if it had been made of lead and was going to be formed anew.

My service duties did not allow me after these disappointments to further occupy myself with secondary batteries. In the beginning of 1878, during the Russo-Turkish war, I was commanded by the Russian Marine Ministry to build cruising ships in America for the Government. Returning from America in 1879 I was employed by my chief, General Admiral Grand Duke Constantine, as chief engineer in the Jablochkoff Company, and was again prevented from occupying myself with secondary batteries. At that time I continued my experiments with good results in oxy-hydrogen illumination, which was based on the cheap production of oxygen. I found capital for working up this patent, which is still in force, and resigned from service in the Russian navy.

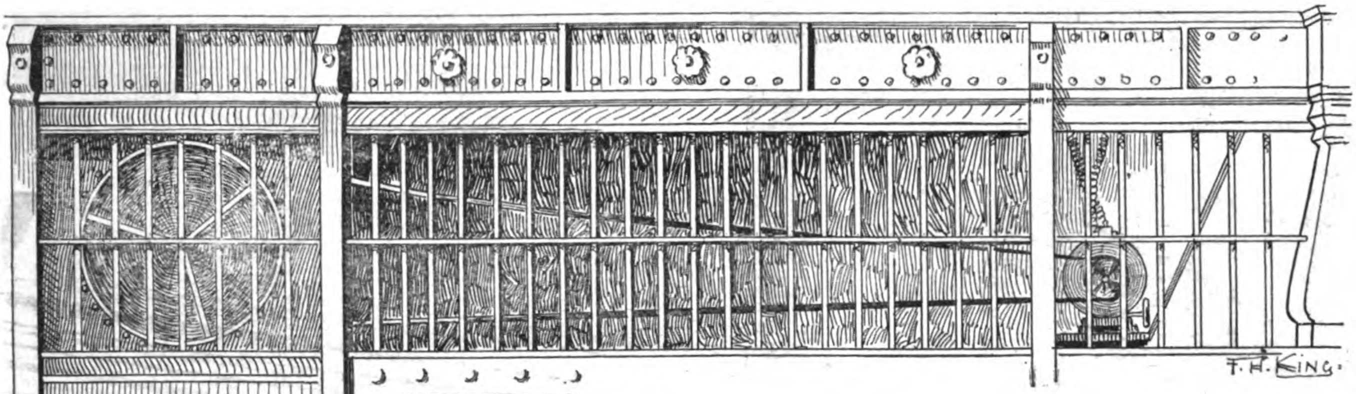
Mr. N. de Kabath, founder and owner of the journal *l' Electricien* in Paris, had in St. Petersburg seen my oxy-hydrogen light and saw the prospect for making money out of my patent in Paris. I therefore went to Paris early in the year 1880 supplied with all necessary apparatus and established there an experimental station in the bureau of the Compagnie des Horloges Pneumatiques, Système Popp. There was plenty of time left at my disposal, and I called on Mr. Kabath to get permission to make further experiments with accumulators in the laboratory of the journal *l' Electricien.* This permission was given to me, and the work in this laboratory was the more interesting as I there made the acquaintance with M. Hospitalier, editor-in-chief of *l' Electricien* and a man of considerable learning. I had, besides this, opportunity for almost daily intercourse with Messrs. Gaston Planté, Niaudet and Tissandier.

ROTARY STATIC DISCHARGES.

THE interesting article by Dr. William James Morton, on "The Nature of Electric Currents," published in THE ELECTRICAL ENGINEER of July 20, ult., has led to considerable discussion in regard to the twisting, or helical, motion of a spark shown by its passage through a number of sheets of paper. A photograph of an actual discharge, which in this case was a lightning flash, has been sent us by Mr. T. H. Bailey, of Haverhill, Mass., which seems to show this twist very clearly. The accompanying illustration is reproduced directly from Mr. Bailey's photograph, taken about the time that Dr. Morton's article appeared. We regret that the engraving of this photograph is not as clear as could be desired, but the twist is discernible in the original.

ELECTRIC BOATS ON THE SEINE.

MESSRS. WOODHOUSE & RAWSON have just launched upon the Seine, at Asnières, an electric boat, *L'Eclair*. Its first trip was made on August 9th, in the presence of the Parisian electrical press. This boat is 37 feet long, 5 feet 10 inches wide, and has a draught of 16 inches. It contains two batteries of 20 accumulators of 160 ampere-hours, and a 3 h. p. motor. The accumulators are all connected in series (80 volts, 30 amperes), for the express speed of 8 miles an hour. They are connected in quantity for lower speeds. The boat is constructed to hold 20 persons. The charging is effected at the accumulator station at St. Ouen.



A DAY WITH EXCELSIOR MOTORS IN NEW YORK CITY.

BY

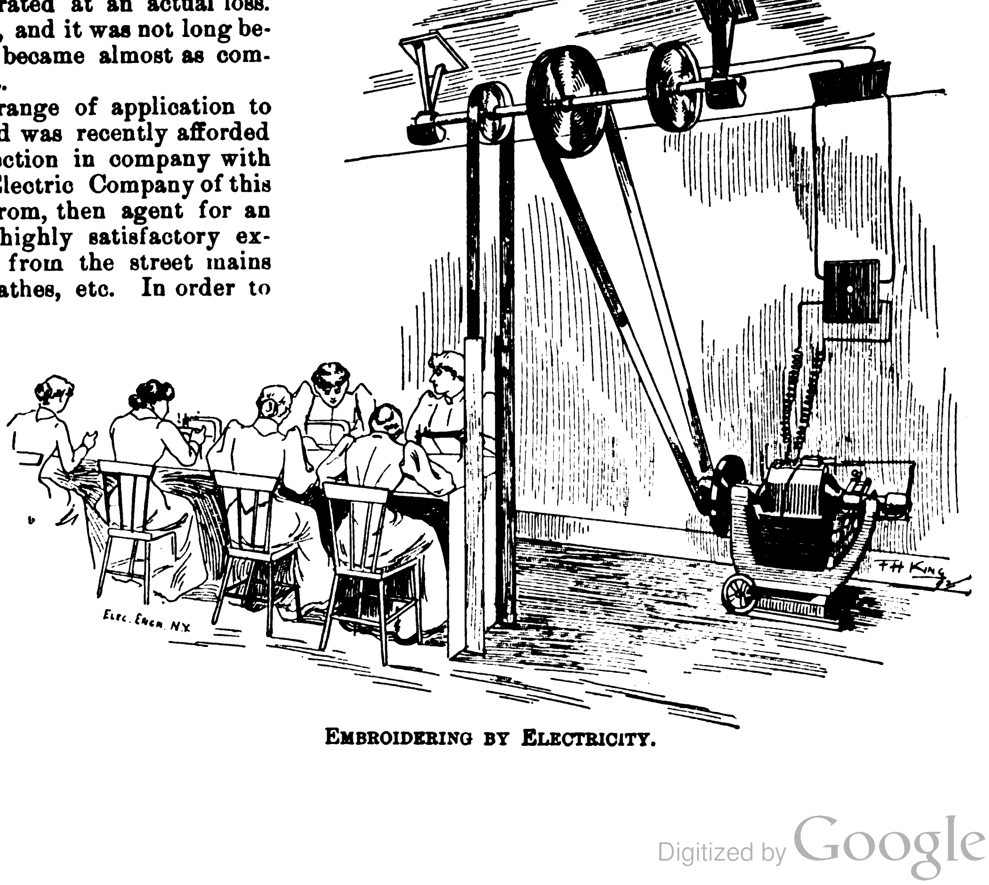
George Barton Muldaur

ALTHOUGH the use of electricity for the transmission of power is of such recent date, the fact has already become permanently established, even in the public mind—and the public is not over quick in such matters—that in regard to cheapness, cleanliness, compactness, and freedom from noise the electric motor of to-day stands without a rival in very many departments of labor. Especially is this true where power is to be applied at a distance from its source of generation, or subdivided into a number of independent units; and also where used only at such short intervals that the expense of maintaining a steam plant would amount to foolish extravagance.

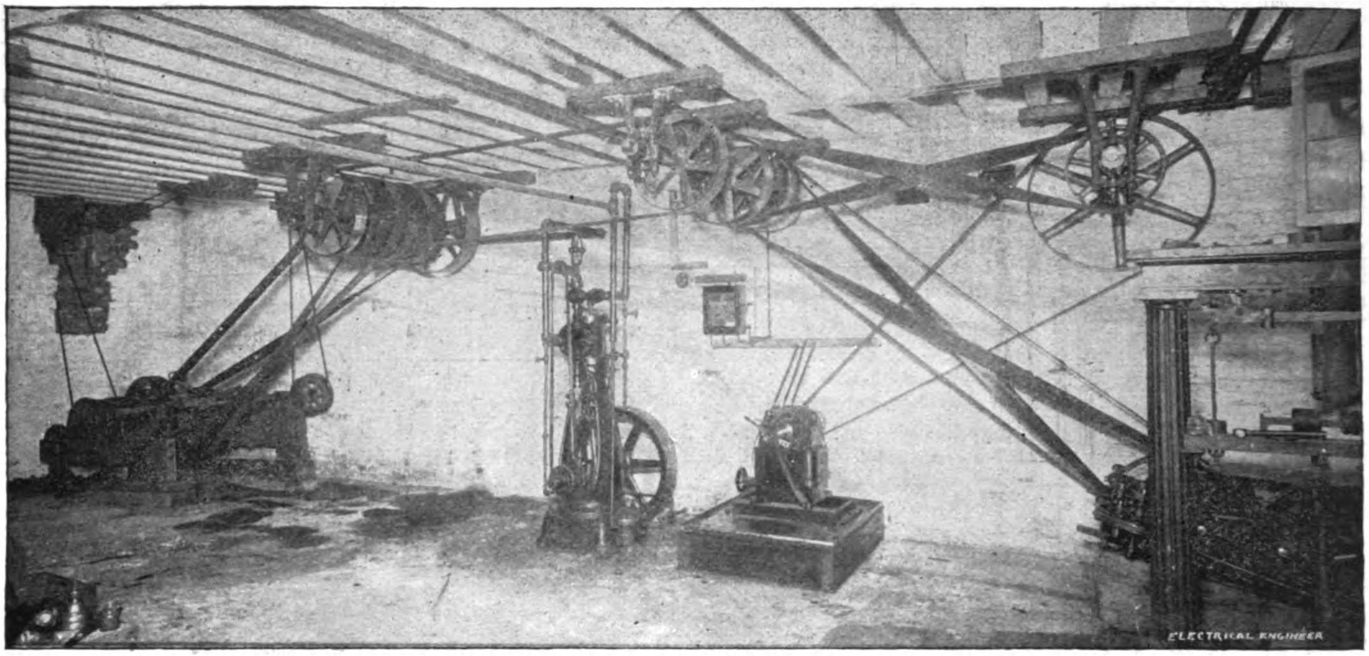
When the electrical illumination of cities and towns became general the question of how to best utilize steadily through the day the machinery at the central station in order to reduce the cost of lights while realizing a fair profit on the capital invested began to assume formidable proportions, as the part of the plant kept running during daylight hours was frequently operated at an actual loss. A demand usually creates a supply, and it was not long before the sale of current for power became almost as common as the sale of current for light.

A striking instance of the wide range of application to which the electric motor is adapted was recently afforded me during a short round of inspection in company with Mr. J. L. Krom of the Excelsior Electric Company of this city. Not many years ago Mr. Krom, then agent for an engine company, installed many highly satisfactory examples of his wares, taking steam from the street mains and operating elevators, pumps, lathes, etc. In order to keep up with the march of progress, he is now busily engaged in replacing engines, with electric motors, which give better results at a considerably less cost.

A model plant of this kind is that in the basement of Messrs. Callahan & Kemp, dealers in groceries and teas at 41 and 43 Vesey street. Here are three elevators, two running to the top of the building and the other to the sidewalk. These have been operated from 1885 until quite recently by a vertical engine, with about seventy feet of shafting extending the entire width of the basement. The present arrangement is as follows: A 10 horse power Excelsior or Hochhausen 220-volt motor is set on a Georgia pine foundation lagged to the concrete floor, and occupies a space about three feet square between the sidewalk elevator and one of those running to the roof. The former is of the "A. B. C.," spur gear type, and carries an actual load of 2,500 pounds, while the latter is a Brigham & Webb lift of 3,000 pounds capacity. The motor is belted with a double leather belt to a main shaft, and thence to a countershaft from which power is transmitted by belts to both elevators. The wiring is done after the most approved methods and is encased in Interior Conduit metal tubing, while the specially arranged cut-out and starting switch are provided with a backing of asbestos. The Excelsior motor runs at 1,350 revolutions per minute, and is cool under the load of both elevators operating simultaneously at



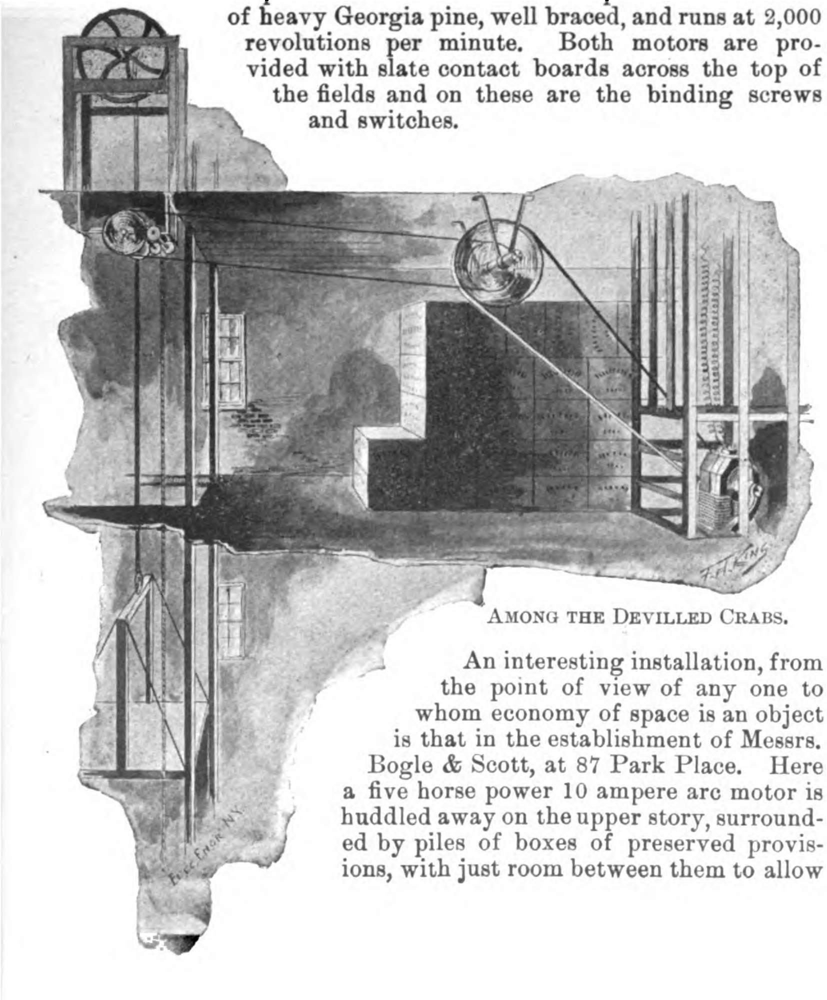
EMBROIDERING BY ELECTRICITY.



TEN HORSE POWER MOTOR RUNNING TWO ELEVATORS.—*From a photograph by flash light.*

their full capacity. It is provided with double brushes, and its sliding base permits the use of an endless belt. The constant hammering of the joint of an ordinary belt against the pulley, aside from the noise it makes, has the effect of jarring the motor and eventually of injuring the bearings, so that this feature of endless belts is one of considerable importance.

At the opposite side of the basement, about seventy feet away, is the other elevator running to the roof and having a capacity of 1,500 pounds, driven by a little two horse power Excelsior motor resembling the other in all respects except that of size. This stands upon a kind of table of heavy Georgia pine, well braced, and runs at 2,000 revolutions per minute. Both motors are provided with slate contact boards across the top of the fields and on these are the binding screws and switches.

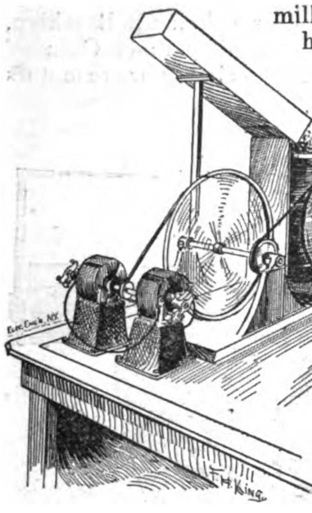


AMONG THE DEVILLED CRABS.

An interesting installation, from the point of view of any one to whom economy of space is an object is that in the establishment of Messrs. Bogle & Scott, at 87 Park Place. Here a five horse power 10 ampere arc motor is huddled away on the upper story, surrounded by piles of boxes of preserved provisions, with just room between them to allow the belt to run to the mechanism of the grip hoist, ten feet away. The whole floor space devoted to the motor is not more than one square yard and the passage way through which an attendant is supposed to pass sometimes, to clean and oil it, is too small to count and exists chiefly in imagination. The motor, on the day I saw it, was doing excellent work raising loads a height of four or five stories without a murmur; and it had probably not been touched, for months, except for the purpose of starting and stopping. The commutator was actually so caked with dirt as to show no metallic lustre whatever, yet the work went on regularly and every one seemed perfectly satisfied. The man in charge said he had not time to clean the motor, yet when its condition was casually explained to the proprietor, there seemed to be a difference of opinion on the subject; and since then the commutator shines like gold. This is one of the disadvantages under which the manufacturers of motors labor, and when bye and bye there is a flash and the machinery stops, the illused motor is anathematized and occasionally thrown out for a while to make room for a second hand gas engine! But it goes in again.

Several other elevators were seen operated by five horse power 220 volts Excelsior motors, all of which called forth the highest praise from the users. Most of these are grip hoists carrying from one to one and a half tons, and can be run either by hand or power as circumstances require. In some instances a starting switch is placed on the ground floor and the current only turned on during the time the load is actually being lifted. The car descends by gravity in any case, so that the expense seems to have been reduced to a minimum. At Messrs. Markt & Co., 87 North Moore street, the elevator is run by a ten horse power arc motor suspended from the ceiling in the upper story and belted from a countershaft through a brick wall to the hoist. The motor is only started by the operation of pulling down the elevator cord, which throws a double pole starting switch with carbon contacts placed at the top of the well. When the car reaches the upper floor, the switch is automatically opened, and gravity alone is made use of in the descent.

In the establishment of Wing Bros. & Hart, 81 North Moore street, a ten horse power, ten ampere motor drives a blower and a coffee cleaner. After the roasting is done and the coffee sold, some of it is perhaps bought by the Hotel Vendome where it is ground by two $\frac{1}{8}$ horse power alternating motors in a manner worthy of notice. The



Twin Motors and Coffee Mill.

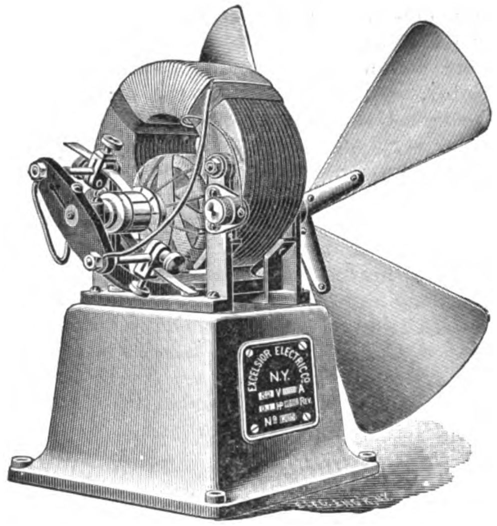
mill at the hotel is fastened upon a heavy deal table and is belted from a twenty inch wheel to a three inch wheel on a countershaft. This countershaft has keyed upon it another twenty inch pulley and this is belted to the Excelsior alternating motors. The latter are operated on the Siamese twin plan. They are bolted on the edge of the table, side by side, and have a common shaft with the pulley midway between them. The current is taken from the nearest chandelier, and the whole arrangement looks more like an ingenious toy than the useful piece of mechanism it is. There can be no question as to the excellent work done by this alternating motor, and one would be glad to see more of them.

The question of ventilation, especially in large and crowded buildings, is one that has burst upon us lately with persistence, refusing to be answered by any but radical measures. Where comfort only was once considered, absolute necessity now demands that the air we breathe shall be comparatively fresh, and even those employers upon whom philanthropic motives have no hold are beginning to understand that the money expended in providing ventilation appliances for their workrooms and factories is more than returned to them by the extra work accomplished in the pure air by their employees. The electric motor has shown itself so eminently adapted to the work of running fans for this purpose that the "fan motor" industry is a business in itself. There are, however, ways and ways of installing ventilating plants, and conditions differ widely according to circumstances. Here again ingenuity has its opportunity.

For instance, the store of Hearn & Co., on West Fourteenth street, is lighted entirely by arc lamps taking current from their own isolated plant in Thirteenth street, directly back of the store. There is no incandescent circuit in the building, and hence none of the various makes of low tension current motors could be used. The Excelsior arc motor, however, rose to the occasion, and through the ingenuity of Mr. Krom, and the careful management of Mr. Ebbert, who has personal supervision of all the electric work on the premises, the system of ventilation is probably unsurpassed by that of any similar building in the city.

The Distributing Ventilator.

The isolated plant occupies the basement of the stable on Thirteenth street. The engine and dynamo room is in the rear, and a narrow passage leads into the boiler and pump room in the front of the basement and extending under the sidewalk. A wide airshaft runs up past the pipes at one side of this room and terminates at a grating on one side of the door of the stable, and about twelve feet from the ground. Behind this grating revolves a 48-inch Blackman exhaust fan, taking the heated air from the boiler-room and keeping up a constantly changing current throughout the whole basement. The fan is driven by a three horse power ten ampere Excelsior arc motor occupying a bracket at the other side of the stable door and belted across the intervening space. The head piece to this article shows the arrangement. On the day when the fan was started for the first time the temperature in the boiler room was 145 degrees. After the motor had run for fifteen minutes the mercury stood at 95 degrees, at which cheerful temperature it remained. The men say that without the fan, they could not possibly have lived in the room during the hot weather of the past summer.



EXCELSIOR ELECTRIC CO. N.Y.

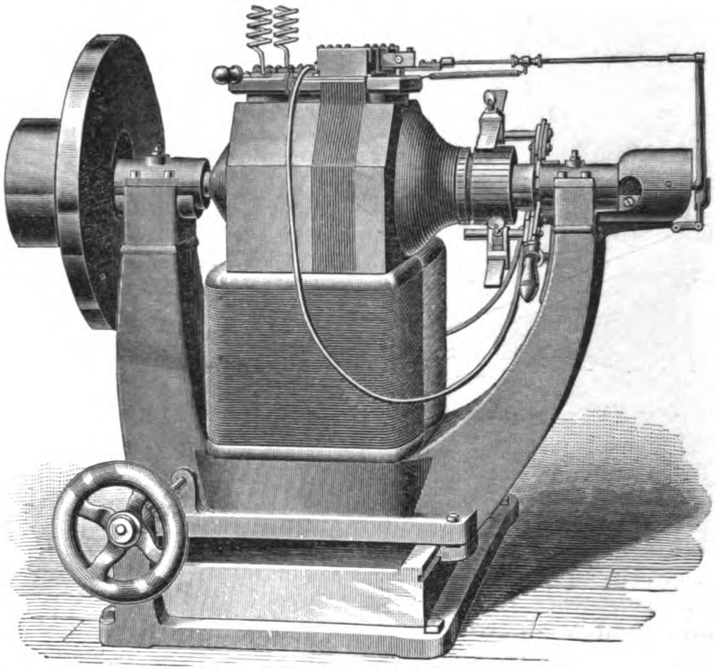
One-Tenth Horse Power Alternating Excelsior Motor.

Across the street in the store, five more Excelsior motors are kept busy bringing air from the roof and distributing it among the counters and aisles where it is most needed. The plan adopted is exceedingly ingenious and merits especial description and illustration.

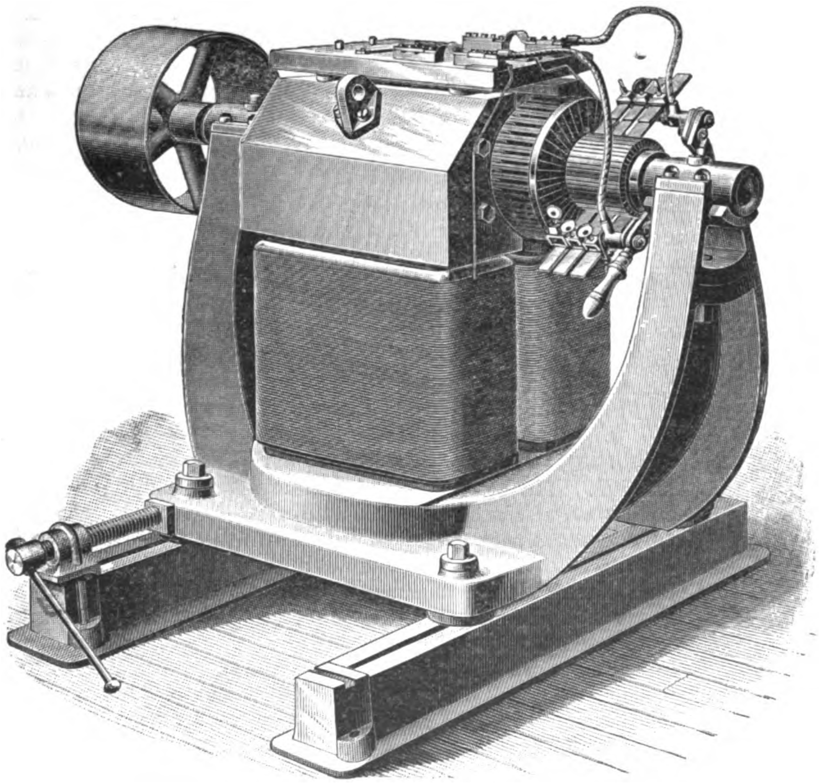
The customary arrangement of shelves and counters in rooms of this character, it will be remembered, is a long row of the former running between two of the latter, the shelves extending some eight or ten feet above the floor. Here, they stop at the height of about six feet and are topped by a long hollow sheet iron flue, or air chamber, having openings at intervals along its sides and a larger one at the end. At the opposite end of the shelf is a little closet with locked glass doors in which runs a motor belted vertically to a fan that forces pure air from the roof into the "distributing box," whence it is furnished to the pleased public and the grateful employees. In other parts of the store where there is no natural ventilation whatever, a horizontal current of air is forced in a solid volume just above the heads of the people, insuring perfect circulation and avoiding direct drafts. There are two motors of three horse power and three of one horse power employed in this work, each running its own fan, and being complete in itself.

On the fourth floor of the building there is plenty of air and no need of artificial breezes, but here again the motor comes to the front, this time as a labor saving device and a patron of the fine arts at one and the same time. Here are rows of girls doing embroidery work in the most intricate patterns, some of which have considerable merit from the designer's point of view. They are sitting at sewing machines, but their feet only move now and then as they start or stop a piece of work, for the machines are all run by electricity, and are geared to a shaft running beneath the floor between them. A friction clutch, operated by the treadle sets them in motion and regulates their speed at will. In this room are fifteen machines in two rows facing each other, and all run by a five horse power Excelsior motor in the corner belted to a countershaft and thence to the line shaft under the machines. A small steam engine formerly attended to this work but was recently invited to send in its resignation.

These are some of the applications of the modern electric motor, as represented by the work of the Excelsior Electric Company in New York City, and they constitute a very good object lesson as to the manner in which the motor can be applied to a variety of work, as a successful Jack-of-all-trades. Here, almost side by side, are three distinct types of motor, made by one company and using three different forms of current, direct high tension, direct low tension and alternating, each doing excellent work and giving the utmost satisfaction in its particular field of usefulness. The Excelsior Company, while they have shown that the use of the arc motor for ordinary business purposes is entirely practicable are untrammeled by exclusive adherence to any one system and can thus range at large through the whole wide field of electric power transmission. It is worthy of mention, too, that these results in New York are duplicated in other cities. I am informed that in Brooklyn, for example, on the circuits of the Municipal and Citizens' Companies, there are no fewer than 50 Excelsior arc motors running very successfully on such work as large wholesale ice cream freezers, saw mills, meat choppers and a toboggan slide. In Chicago a similar experience has been had on an equally large range of work, the motors being placed upon a variety of circuits, and yielding excellent results.



Constant Current Excelsior Motor.



Constant Potential Excelsior Motor.

A POLARIZATION EXPERIMENT.

At a recent meeting of the Physical Society of Berlin, Herr Arons described the following experiment on electrolytic polarization. If we divide an electrolytic vessel with platinum electrodes and acidulated water solution by a partition of some precious metal, such as gold, silver or platinum, a diminution of current is usually observed; and the metallic partition will be hydrogen polarized on one surface and oxygen polarized on the other. Herr Arons experimented with a view to seeing whether he could obtain a thin enough partition for the two polarizations to annul one another. He employed for this purpose an electrolytic vessel 22 cms. long by 5 broad and 8 high, divided in the middle by a sheet of glass pierced by a hole 1.5 cm. in diameter. When the sheet of glass with an unobstructed opening was replaced by one which had the opening covered by a piece of platinum foil 0.1 mm. thick, the deflection of the galvanometer was diminished, and there was a violent ebullition of gas. Gold and silver leaf partitions caused no disturbance. By altering the resistance out of the galvanometer circuit its deflection was in each experiment brought back to its original value. The following figures give the resistance which it was found necessary to take out of circuit in each case: Solid platinum plates, 19 ohms; platinum plate pierced with a hole 3 mm. in diameter, 5 ohms; silver and gold (leaf) 0 ohm; four layers of gold leaf super-posed 0.25 ohm.

APPARENT MAGNETIC RESISTANCE AND CONDUCTIVITY.

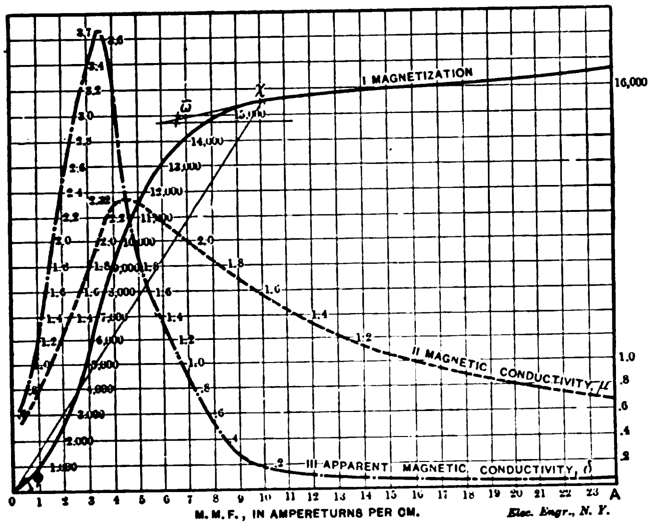
BY

Chas. Steinmetz.

If we subject a magnetic circuit of any kind to a magnetomotive force F, this magnetomotive force F produces a "magnetic current," that is, a certain number of lines of magnetic force M, and as the *magnetic resistance* or *reluctance* of the circuit we define the ratio $P = \frac{F}{M}$; as its magnetic conductivity or permeability, the inverse value, $\mu = \frac{1}{P} = \frac{M}{F}$.

As is well known, in magnetic circuits consisting wholly or partly of iron, etc., the magnetic resistance P and hence the magnetic conductivity μ is a variable quantity and depends largely upon the density of the magnetic current, that is, upon the number of lines of magnetic force passing through the unit of cross-section.

No entirely satisfactory mathematical equation being known for the dependence of the magnetic resistance, and therefore the magnetic current, upon the magnetomotive force, this dependence has for practical use to be plotted in curves; usually in such a way that the abscissæ represent the magnetomotive forces F, preferably in ampere-turns per centimetre or per inch length of the magnetic circuit, while the ordinates represent the magnetic current density in kilolines per square centimetre, or per square inch, as shown in curve I of the accompanying diagram.



Elec. Engr., N. Y.

The magnetic conductivity has a simple geometrical meaning in the characteristic magnetic curve also. Connect any point x of the curve I with the starting point o, then the tangent function of the angle φ between this line x o and axis of abscissæ oA is the magnetic conductivity at the point x:

$$\mu = \frac{M}{F} = \tan \varphi = \tan x \text{ o A}.$$

This allows us to survey the variations of the magnetic conductivity μ by following the radius vector o x, when x travels on the characteristic curve from its starting point to saturation.

We see that the magnetic conductivity is first a minimum, $\mu_0 = \tan \varphi_0 = 500$, and then increases up to a maximum, $\mu^1 = \tan \varphi^1 = 2{,}320$, for the tangent point of the tangent drawn from o upon curve I; and then decreases again, reaching 640 for the magnetomotive force $F = 24$. This value of the tan φ has been plotted in curve II, the susceptibility curve, and shows plainly the rise up to a maximum and then the decrease again.

But we derive still another tangent function from the magnetic characteristic. In drawing at any point x of the curve I a tangent to this curve, this tangent forms an angle ω, with the axis of abscissæ, or with any other horizontal line. The tangent function of this angle ω is what I call the *apparent magnetic conductivity at the point x.* This apparent magnetic conductivity is often of even greater importance than the true magnetic conductivity. It is the magnetic conductivity which a magnetomotive force meets when acting upon a magnetic circuit magnetized already up to the point x by another magnetomotive force.

Let, for instance, a magnetic circuit be magnetized by the magnetomotive force $F = 6$ ampere-turns per centimetre, which produce the magnetism $M = 12.95$ kilolines, per square centimetre. Introducing now in this magnetic circuit a further magnetomotive force of $f = .1$ ampere-turn, this magnetomotive force, superposed upon F, will either increase or decrease, according to its direction, the magnetism M produced by F, to 13.08 or 12.82 kilolines respectively; that is, the magnetomotive force $f = .1$ will produce an additional magnetism, $m = .13$, superposed upon the magnetism $M = 12.95$, caused by $F = 6$, and hence the magnetomotive force f will meet with an apparent magnetic conductivity of $\delta = \frac{m}{f} = 1{,}300$, while the true magnetic conductivity at this point is:

$$\mu = \frac{M}{F} = 2{,}160.$$

This apparent magnetic conductivity will be of importance in all cases where another magnetomotive force is superposed upon a magnetized circuit, as, for instance, in the compound dynamo, in which the magnetomotive force of the series coil is superposed upon the shunt magnetomotive force; or, in the dynamo alternator in which the pulsating armature magnetomotive force is superposed upon the constant field magnetomotive force. This apparent magnetic conductivity is much more variable than the true magnetic conductivity. Twice it has the same value, at the initial point, and at the maximum point of the true magnetic conductivity. Between both points it is larger; beyond the maximum point of true magnetic conductivity it is smaller than the latter, so that it decreases faster than this does.

Following the variations of the tangent of the characteristic curve I we see the apparent magnetic conductivity—plotted in curve III—start at the same point, 500, as curve II, but rise very rapidly up to a maximum value of 3,700, for the magnetization $M = 7.25$ corresponding to a M. M. F., $F = 3.5$, then decrease again just as rapidly, intersect II at 2,320, and rapidly decrease to 100, for $F = 12$, then decreasing very slowly down to 40, for $F = 24$.

It is interesting to note that at about 2.5 ampere-turns the apparent conductivity is more than twice as large as the true conductivity, while at about 14 ampere-turns the apparent conductivity is already less than $\frac{1}{14}$ of the true conductivity.

Of still more importance than for the design of continuous current dynamos is the consideration of the apparent magnetic conductivity in alternating current dynamos. For in the alternator the armature reaction upon the field is well known to be usually much larger than in the continuous current dynamo, because of the very sudden fluctuations of the armature magnetism. At the same time, for the constant potential alternator a small armature reaction is of more importance even than for the continous current dynamo, because the alternator has, besides the drop of potential due to armature resistance and to self-induction, still another cause for a drop of potential with increasing load, which the continuous dynamo current has not.

Now, every time that an armature coil passes in front of a field pole, the current flowing at this moment in the armature coil, throws a magnetomotive force into the magnetic field circuit, which is magnetized by the exciting current. In consequence thereof, the magnetic field circuits are acted upon by two magnetomotive forces, namely, the magnetomotive force of the exciting current, which is supposed to be constant, and the fluctuating magnetomotive force of the armature current. This latter magnetomotive force, if of considerable influence, will not only cause the field magnetism to fluctuate also, and to be a minimum, where it is needed most for inducing electromotive force—thereby changing the shape of the current wave from the true sine shape to a more ragged appearance—but this fluctuation of the field magnetism will induce an alternating electromotive force in the exciting circuit, which, besides causing the exciter dynamo to spark, wastes quite a considerable amount of energy.

From what has been said it is obvious that, to keep the fluctuations of the exciting current of an alternator down as much as possible, the field magnets have to be magnetized up to that point of the magnetic characteristic, at which the apparent magnetic conductivity is very low. For instance, employing iron of the characteristic shown in the diagram, when magnetizing the field with a density of 15,000 lines of magnetic force per sq. cm., in spite of the larger number of exciting turns the fluctuations of the field current will be reduced to about $\frac{1}{12}$ the value they have when the field is magnetized with 8,000 lines per sq. cm. The fluctuation of the field magnetism will even be reduced still more. In practice, indeed, these fluctuations of the exciting current are somewhat decreased in many cases by eddy currents set up in the field iron. But to rely upon eddy currents in the iron is certainly anything but an economical way of dynamo building.

INSULATED ELECTRIC CONDUCTORS.[1]—X.

BY

James Bowstead Williams

Linseed Oil.—This oil is obtained from flax seed either by crushing the seeds and then subjecting them to great pressure, or by dissolving the oil out of the crushed seeds by bisulphide of carbon and then distilling off the solvent for future use. The oil, when pure, is of a clear yellow color; but on account of its high price it is too often adulterated with whale, hemp seed, and other cheaper oils. In fact, there are "linseed oils" in the market which do not contain more than about one-fifth of the genuine oil, the balance being composed of the cheaper oils just mentioned, caustic alkalies dissolved in water, turpentine, etc. The writer has used such oil which had nearly the same specific gravity and color of the pure oil, yet the oil, owing to the alkali present—which virtually caused the oil to become liquid soap—would not only of itself dissolve in cold water but would cause compounds containing the oil, resins, and paraffine to dissolve freely in cold water also. It need hardly be said that such material is worthless for insulation. Moisture is the great foe of insulating material; therefore no material which will combine with, or absorb, moisture should be used for insulation unless such material can be protected from the atmosphere.

Linseed oil is the best oil for use in compounds which are mixed and applied hot, especially those which contain the three hard resins, amber, copal, and shellac, on account of its low freezing point and density. It is also the best oil for paints. When a thin layer of the oil is exposed to the air it gradually changes to an elastic substance resembling rubber, and this in time changes to a brittle resin. This change, or "drying" as it is usually called, takes place much faster in oil which has been boiled, and it is still further hastened by the addition to the oil of "dryers." Dryers are made by boiling with the oil litharge, sulphate of zinc, acetate of lead, etc. Borate of manganese is probably the best dryer now known.

For paints, quickly drying oil is necessary; but for melted compounds, raw oil is preferable as it remains in a liquid state much longer and therefore keeps the compounds flexible for a greater length of time.[2]

Linseed oil dissolves rubber in about five hours at a gentle boiling heat. It also dissolves shellac in about the same time, but it will not dissolve cold copal or amber, even by long-continued boiling. It dissolves the other resins in a few minutes. It does not combine with paraffine wax in all proportions, as the writer has seen published, for, though they mix when heated, most of the wax separates from the oil as soon as the mixture cools. But it will readily unite with suitable compounds formed of the resins and paraffine, in all proportions. In moderate proportions, it combines with rubber compounds containing sulphur if the compounds are subjected to a vulcanizing temperature. If heated with sulphur at 280° F. and upwards it soon changes to a substance resembling rubber. A similar substance can also be obtained by subjecting the oil to the action of chloride of sulphur, and also by mixing the oil with cotton seed oil, coal tar, and sulphur, and then heating the mixture for several hours. But such compounds are not durable if exposed to air and light. If linseed oil, or a mixture of it and other vegetable oils, be distilled with a mixture of nitric and sulphuric acids an artificial rubber is produced which is called elastikon.

Oxidized linseed oil is made by boiling the oil with litharge for several hours and then exposing it, while in thin layers, to the air, or by blowing hot air over thin layers of the oil. It can also be produced by chemicals which are mixed with the oils. These are simply quick processes of changing the oil to the rubber-like substance which all the drying oils undergo, when thin films are exposed. This material is translucent, and has a straw yellow color. It will not stain paper, thus showing that there is no free oil present. It is not a permanent material but is continually changing, by oxidization, to a brittle resin which soon gets full of cracks and admits moisture by capillary attraction. It has been used alone and in combination with resins, etc., but the results were very unsatisfactory. Linseed oil may absorb as much as 50 per cent. of its weight of oxygen.

Cottonseed Oil.—This oil is expressed from the seeds of the cotton plant. It is a drying oil, and can be used to impart flexibility to suitable compounds[3] of the resins, paraffine, etc. It is not as dense as linseed oil, nor has it as low a freezing point; therefore it requires a larger quantity of it in combinations to produce the same results as the linseed. Its specific resistance is about that of linseed but its cost is much less. The effects of chemical agents upon it are practically the same as those on linseed, but linseed is preferable for paints and insulating purposes generally.

Olive Oil.—This oil, when pure, is expressed from the fruit of the olive tree, but, as sold, it is a mixture of clarified cottonseed oil and olive oil, the former often forming as high as three-fourths or more of the whole.[4] This oil is classed among the non-drying oils. Its uses for insulating purposes are very limited, and its place can well be supplied with other and much cheaper oils.

---

[1] *Copyrighted 1892, by J. B. Williams.*

[2] Whenever the word "paint" is used it means, unless otherwise specified, insulating paints. As will be shown hereafter, the requirements of insulating paints are very different from those of ordinary paints.

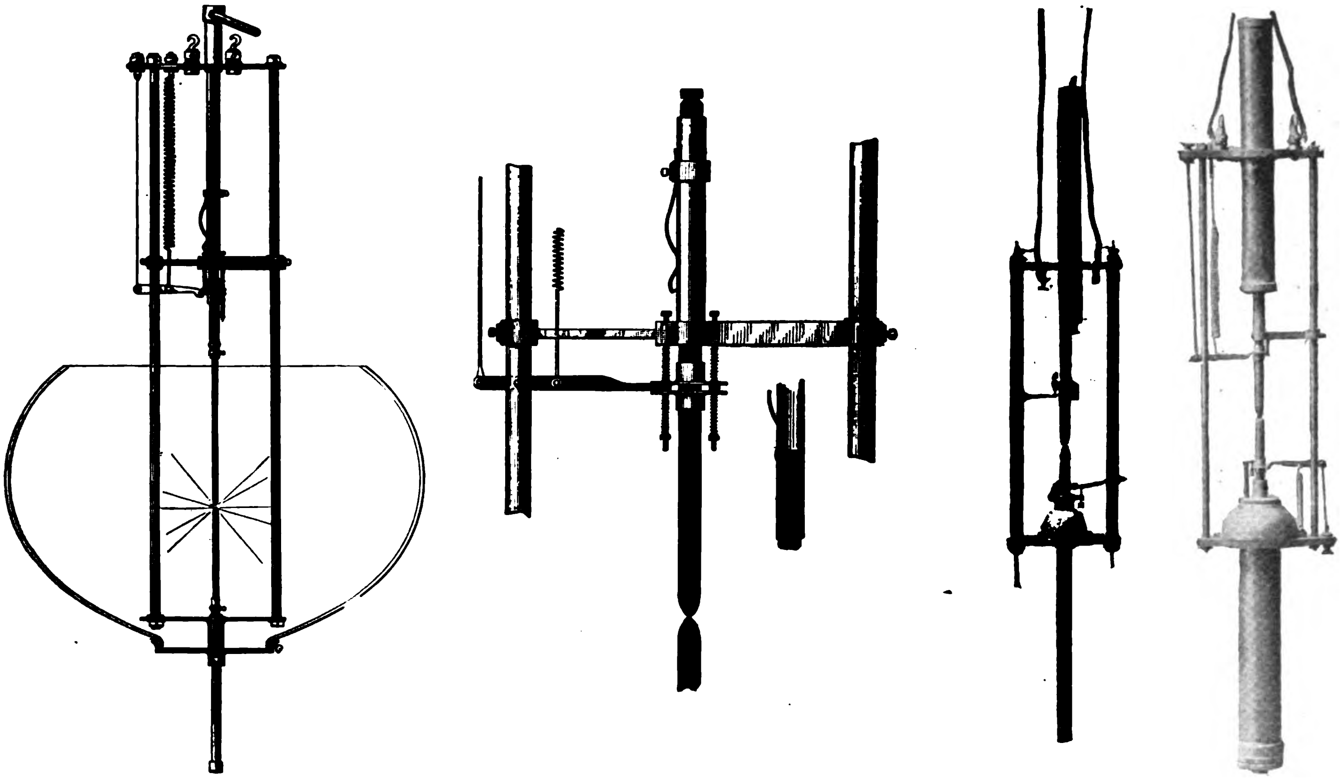
[3] To illustrate what is meant by a "suitable" compound, the following is given as an example: Resin 50, shellac 10, cottonseed oil 30, all by weight. The resins are combined by heat, and the oil then added to the melted resins. Now, if the shellac be 35 parts instead of 10, the combination of resins is not a suitable one, for the shellac will separate when the oil is added.

[4] Probably the only place where the pure oil can be purchased is in Santa Barbara, Cal., from the factory of Mr. Elwood Cooper. But the cost is several dollars per gallon. A written guarantee is given with each purchase of the pure oil.

IRISH'S THERMAL ARC LAMP REGULATOR.

To design an arc lamp equally well adapted to arc, incandescent or alternating circuits, with single, double or magazine carbons, to run singly or in series and to give a light varying from 500 to 3,000 c. p. according to the energy supplied, and to burn from eight up to eighty-four hours or more for each trimming, is a problem which will be admitted to be one of no small magnitude. Yet this has been accomplished in a very simple and ingenious manner by Mr. W. E. Irish, of Cleveland, Ohio.

To obtain this result Mr. Irish has applied a principle employed by him in other inventions of his, among them the thermo-electric telephone, the photo-electrograph, phonautograph, automatic cut-outs, resistance regulators and many other thermo-electric devices, several of which have been described in these columns. In this instance Mr. Irish simply substitutes for the electromagnets usually employed to actuate arc lamps a metallic strip affected to expansion due to the thermal effect of the current passing through it to supply the lamp, of which it forms part. In combination with the thermal expanding strip he employs a lever and counteracting spring.



FIGS. 1, 2, 3 AND 4.—IRISH'S THERMAL ARC LAMP.

The accompanying illustration, Fig. 1, represents a simple form of single carbon lamp to burn from eight to seventeen hours on any circuit; and Fig. 2 is an enlarged view of the mechanism showing the lever, spring, and thermal strip actuating differential clutches which feed the carbon pencil directly without the aid of the usual rod.

The thermal strip, lever, spring and arc form, when the lamp is in circuit, a perfectly automatic balance, operating in the following manner: when the circuit is closed the thermal strip expands by reason of the current, allowing the spring to recoil and raise one end of the lever, which also lifts the upper carbon, thereby establishing the arc; then as the arc varies in length, so in proportion will its resistance vary and so will the length of the thermal strip correspondingly vary. This strip regulates the length of the arc and gradually and imperceptibly feeds the carbon so as to maintain a constant length of arc with an unvarying light.

Lamps may be removed from a circuit of low to a circuit of high tension, or to an alternating circuit and vice versa, and, it is claimed, will work perfectly.

The lamps are easily and quickly adjusted while burning and may be readily regulated to give a maximum length of arc by altering the length of the thermal expansion strip by means of the knurled nut.

On low tension circuits the most satisfactory working limit of arc is reached just before hissing appears, while on high tension circuits the best regulation is effected when the hissing ceases, and on alternating circuits when the lamp burns without noise or with very little noise.

Each lamp is provided with an automatic cut-out as well as a hand switch. The automatic cut-out on a lamp running on an incandescent circuit, as it cuts out the lamp, introduces a resistance equal to that of the lamp when burning. On an arc or alternating circuit the cut-out simply bridges the lamp terminals whenever the lamp circuit opens for any reason. The cut-out will only act when the lamp fails. This arrangement prevents lamps, while burning on a circuit, from being affected by others that may become faulty or have consumed their carbons, and it permits of lamps being trimmed while others on the circuit are in use, although a hand switch is also provided. A shunt of high resistance is employed with the arc lamp.

The engraving, Fig. 3, is made from a photograph of one of the first models of a double-carbon lamp. The upper carbons fall by their own weight and the lower carbon is raised by mercury. This lamp runs about 15 hours without attention. Fig. 4 illustrates a magazine lamp. The carbons in the upper magazine fall in succession, one at a time, with their tapered ends entering a cavity made in the top of the one preceding it. This occurs when the lowermost carbon is about half consumed. As the carbon shortens, the point of junction becomes so heated as to temporarily soften the sealing compound contained in the cavity, and cement the carbons together, so that they feed out as one continuous pencil. The carbons in the lower magazine also dovetail and cement together in succession as they feed up.

The lower magazine contains a quantity of mercury which is employed to force the burning carbon up when the current passing through the lower thermal strip is such as to cause the grip to relax its hold on the carbon.

This lamp will burn twelve hours a day for seven days without attention, or for eighty-six hours. These lamps reach their normal candle power in about thirty seconds and then maintain it.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, SEPTEMBER 14, 1892. No. 228.

To decry steam and electricity—inventions and products—is to deny the price that civilization has to pay for the use of them.—Frederic Harrison.

NEW YORK IGNORANCE VERSUS AMERICAN APPRECIATION.

VERY much in the same way that a number of able New York politicians went to Chicago to make the Democracy of the country believe that Mr. Cleveland was not the candidate that it wanted or could have, a number of able New York editors have been trying to make the country believe that the trolley system is a bad thing and not what it wants or should put up with. In the one case as in the other, the people appealed to have brushed aside as trivial the objection that anything must be bad because New York thinks it doesn't like it. This is hardly complimentary to New York editorial judgment, and would imply, moreover, that after all what is really required is a little more fact and a little less ignorant argument. If these esteemed colleagues of ours of the daily press cannot travel about a bit, they should at least make an effort to keep their opposition within the bounds of prejudice and let it pass for that. If they travel, they will discover how narrow and unfair has been their view of that which nearly every city in the Union regards as one of the greatest blessings of the age—the "deadly trolley" that has never killed anybody.

It is easy enough to write scare headlines, and to rake up fanciful objections, but it should be not less easy for leaders of public opinion to set forth honestly the points and qualities that tell in favor of a new idea or invention. If they do not take such an attitude of helping toward fuller knowledge, what are they good for? And yet if anybody has been able to find in the New York papers lately anything but abuse, fake "accidents," misrepresentation, prejudice, and the worst kind of medieval conservatism, he must have limited his reading to two journals—the *Sun* and the *Press.* We are glad to be able to mention two that have sensible words, and not a parcel of nonsense, about the trolley; and as other innovations have universally triumphed in the long run of intelligent discussion, we live in hopes of seeing additions to the number of metropolitan papers that can print both sides of the question.

According to the Mohammedan faith, the day of judgment has three periods, each of which is heralded with a blast. The first of the blasts is Consternation, to which succeeds Examination, the final one being that of Resurrection. Our New York papers have fired off their blast of Consternation about the trolley, in magnificent style. The skill shown by some of them in blowing their own trumpet has come in very handily. Just now we are being treated to the blast of Examination, from which good results may be expected, and then later on we shall see a change of heart when our contemporaries will rise on the stepping stones of their old ignorance to higher things, and come to acknowledge in the hour of intellectual Resurrection that the Trolley, equally with the Newspaper, makes for public welfare.

We have referred to the *New York Press.* That journal has not been satisfied with telling how a drunken man sat down on a street railway track on a dark night and naturally got run over by a trolley car, but has started an independent investigation of its own, and has asked the mayors of a large number of towns and cities all over these broad United States what they think of the trolley, from experience of it. That is modern journalism. It is better journalism than giving a good thing a bad name and then repeating it several times like an exorcism. The *Press* printed the replies in its issue of September 4, whether for or against. That, too, is good journalism. News is not partisanship but truth. It happens, however, that there is mighty little evidence sent in against the trolley, and an overwhelming mass of testimony in its favor as safe and popular. Which is just what might have been expected.

This futile struggle against the trolley in New York marks only one stage of advance in electric traction. It is cause for congratulation for every electrical engineer that everywhere outside of New York the trolley has made its fight and won it like a young Corbett. Such victories simply help us to look forward to the time when the public will also have conduit roads, and storage battery cars, too. We are personally as much prejudiced in favor of both these as we are in behalf of the trolley, and we do not let our hopes be dashed by the grim fact that New York's only storage cars were sold as junk last week and that at this very minute the pickaxe is ripping out of Fulton street the last traces of New York's first conduit road. It was our luck to help the first trolley roads go into operation, years ago, when it was predicted that they must fail and that even if they succeeded it would be impossible to run more than two or three cars on any line. Those early systems are superseded and their very methods are forgotten, but the art lives on in higher and higher perfection; and we refuse to believe that either the conduit car or the battery car will not in due time follow in the wake of the trolley car as a living success. Every indication promises their permanence as elements in the domain of electric traction, and unless we mistake the signs, they are coming soon. God speed the day! When they come they will reap some of the richest harvests ever garnered in the boundless fields of electricity. Till they come, the trolley is king, and no amount of abuse or lying will unseat him from the throne. And even when they come, they will but share his kingdom with him. There is room for them all.

GOVERNING DYNAMOS DRIVEN BY WATER WHEELS.

We print in this issue a communication on a subject in which electrical engineers are largely interested, not only on account of the considerable number of dynamo plants now operated by water wheels, but also on account of the many that will be so operated in the future. Where the load on a dynamo is tolerably steady, or its variations are gradual, no difficulty has been experienced in regulating the speed of the turbine within a few per cent. of the normal and for this purpose more than one electrical device has been devised. But when cases arise involving the fluctuation of power such as is experienced in electric railway work, and one of which is cited by our contributor, we believe that experience has shown the inadequacy of the methods now in use for obtaining regulation of speed. Our contributor points out that while a device could be designed to open and close the gates sufficiently quickly to correspond with the change in load, it is doubtful whether it would be feasible considering the shocks which the apparatus would be subjected to in overcoming the accumulated momentum of a large mass of moving water. As a solution of the problem there is suggested a plan which would involve what the writer terms an "automatic load brake," in which dynamos under certain conditions would be employed to act as brakes and by means of which the power given out by the turbine could, if necessary, be constantly maintained at its maximum with the gate full open. As to the efficiency of this method there can be little doubt but that it would be comparatively low, but where the quantity of water available would permit of it that question would hardly enter. It would appear, however, that other methods of an electrical nature are available, and that simple means could be adopted for maintaining constancy of potential at the machine at variable speeds. This could be accomplished in several ways and we leave it to our readers to work out the problem.

THE POPP STORAGE BATTERY DISTRIBUTION SYSTEM.

A storage battery system of distribution, unique in its way, is the Popp system now in operation in Paris, which is described elsewhere in this issue by Mr. Ernst Egger. The plan here put in operation is one which was early proposed and, indeed, put into operation on a small scale in this country some years ago; but we believe that its lack of success, or rather its abandonment, was due to the fact that it was not operated on a sufficiently large scale. The Popp system, as described by Mr. Egger, is evidently one of great simplicity, and so far as its practical operation is concerned has, we believe, met with entire success. It is to be regretted, therefore, that no reliable figures as to the working expenses of the plant are available so that comparison may be drawn between this system and that of direct supply as ordinarily practiced.

ELECTRIC POWER IN THE CITY.

New York City is at present undergoing a silent but none the less remarkable and thorough change in the motive power by which its industries are driven. Right and left, wherever one goes, electric motors are being installed, and the demand for power current is becoming enormous. In this issue, Mr. George B. Muldaur, of the Engineer staff, has an interesting article on a recent tour of observation made by him with the agent of one of the motor companies, who has placed motors on all classes of circuit. That the constant potential motor is a success goes without saying, but it will be a surprise to many people to hear that the arc motors give such satisfactory service. It has been a general opinion that arc motor work was something of a failure, but in this instance the contrary is true. Mr. Muldaur's article touches on various other points of unusual interest.

A STORAGE BATTERY HISTORY.

It has often been remarked that if we could but have access to the records of the trials and failures encountered in men's work it would be of value equal to, if not greater than, that of their successes. Such a record would enable a beginner to avoid many mistakes which consume much time and frequently involve much useless expenditure of money. Probably no more conspicuous example of the value of such a record could be selected than the storage battery. The skeletons that mark the advances of pioneers in this alluring field form a ghastly spectacle, but nevertheless they have their use as finger-posts on the road to success. It is in this light that we begin in this issue the publication of an autobiographical sketch of the storage battery work of Captain A. de Khotinsky. One of the earliest in the field, he has had exceptional opportunities for study as well as for practical experimentation, and the record of his work, we are sure, will prove of benefit to all those who may undertake the building of storage batteries, whether as amateurs or as manufacturers.

THE VIBRATING HELMET IN NERVOUS DISEASES.

We publish on another page a very interesting article on a curious device, known as the vibrating helmet, used effectually as a cure for neurasthenia and complaints in the same category. Dr. William J. Morton, the eminent specialist who recently contributed to our columns an article on the spiral character of electric discharges, has already advanced the theory that in many cases the effect due to the application of the electric current is to put the nerve into mechanical vibration and that the electric action is not the direct salutary agent. Even with this limitation, the electric current seems to be about the only way of reaching the nerve.

TWISTING MAGNETISM.

BY

S. W. Balch

THERE are many traps by which the venturesome inventor is ensnared in Dame Nature's unexplored domain. They are so numerous and crop up in such unexpected places, and they are baited with such inviting prospects that the inventors are indeed few who have not fallen into many of them. Unfortunately, however, they have all been so chargined at their mishaps, and forgetful that similar pitfalls have been the experience of their fellows, that they have rarely made them known to those who follow. Could we but know all the results of past experimental research, and where it has led to failure as well as where it has brought honor to the investigators, we would be appalled at the time that experimenters have wasted in unproductive directions because they have not been warned by those who have pursued the same course before them.

One of the fields which has been especially productive of theories that have not proved true, and experiments that have failed to yield results, is to be found in the investigations that have been conducted with a view to the production of an efficient high voltage dynamo of the so-called unipolar type.

In the unipolar machine the conductor remains constantly in the same magnetic field and the brushes revolve in contact with rings. For these reasons, it affords the two features of a perfectly uniform current in one direction, and there is no point where the circuit is opened and closed as in all other continuous current machines. Part of the electrical circuit has to be through the moving member of the machine, and two commutator brushes or other sliding contacts have to be employed. The main difficulty with this type of machine, however, lies in the fact that the conductor cannot be coiled, and thus repassed through the lines of force so as to multiply the voltage to a useful value.

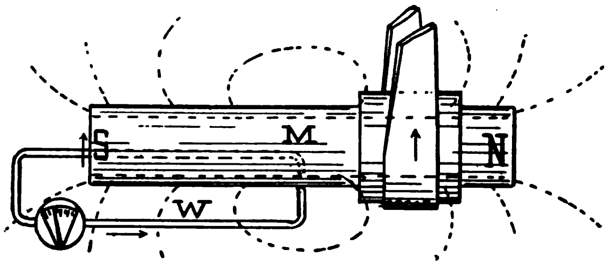

FIG. 1.

Fig. 1 illustrates a simple type of the unipolar machine. A magnet M is mounted in suitable bearings, not shown, and revolved in the direction of the arrow. It is shown as a tubular magnet in order to adapt it to the experiment which will be described later. A stationary loop of wire W has one of its ends in contact with the periphery of the magnet midway between its two poles, and its other end in contact with the interior surface. As the magnet revolves, the lines of force radiating from its poles revolve with it, and these, cutting across the wire loop, according to the accepted explanation, will induce a current through it in the direction indicated. If the experiment is performed with the other end of the magnet the current will be found to be in the opposite direction; but, by reversing the direction in which the magnet is revolved, as in Fig. 2, the current through the conductor will have the same direction as in the former figure. If a soft iron tube is employed, a coil of wire, not shown, will have to be slipped over it to excite the magnetism. It will be immaterial whether the coil of wire revolves with the tube or is stationary while the tube revolves within, as the magnetism resides in the tube and is carried around with it. Thus far theory and experiment are in perfect accord.

The suggestion of revolving the two ends of the magnet in opposite directions at the same time, leads to the joining of the loop shown in Fig. 1 with the loop shown in Fig. 2, and omitting the circuit through the wall of the magnet. Fig. 3 illustrates this experiment. The magnet M is divided at the centre so that there are two independent tubes of iron that can be independently revolved, but, since their unlike poles closely adjoin, they act together as one magnet. The conductor passes through the centre of the two magnets and returns outside, thus completing the circuit without being in contact through the magnet. The conductor may be coiled, if desired, so as to multiply the expected effect. If it will work as the two preceding experiments seems to indicate, then the lines of force radiating from the outer ends as they are revolved, will cut the conductor and generate current. Furthermore, this construction will eliminate all sliding contacts and since the conductor can be coiled, and so repassed indefinitely through the magnetic field, the voltage can be multiplied to a useful figure. Obviously if these advantages were attainable, they would prove a very valuable contribution to dynamo-electric machinery; unfortunately, however, experiment has developed a defect that completely offsets the attainment of these merits on the lines above laid down. Such a machine will not yield even the slightest current.

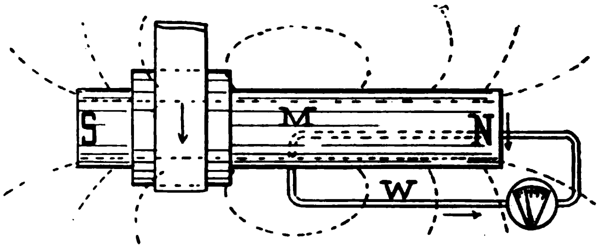

FIG. 2.

Why it should fail to yield a current, it does not seem possible to explain as satisfactorily as might be desired from the electromagnetic laws as they are ordinarily enunciated. The larger part of the magnetic circuit in this experiment is through the air, and an efficient machine would therefore not be expected, but this will not account for an absolutely negative result.

From the fundamental principle of the dynamo, as illustrated in Fig. 4, a similar train of reasoning leads up to a machine for twisting magnetism, as indicated in Fig. 5. In the dynamo, as above shown, the loop of wire wound around the drum twists in the field of the magnet so that a current downward is induced in one side and an upward current is induced in the other side. These currents are in such a direction that they will flow into, and mutually strengthen each other.

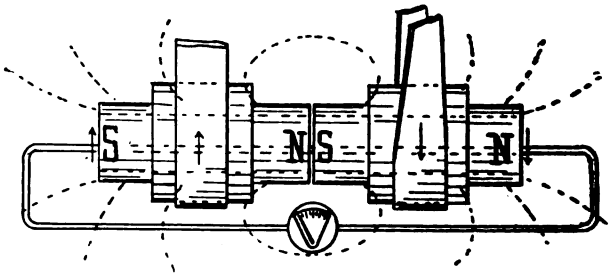

FIG. 3.

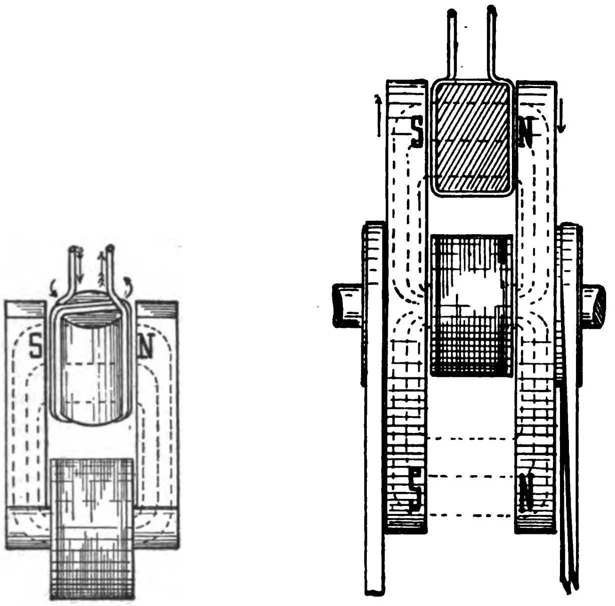
In Fig. 5, instead of twisting the loop of wire through the lines of force, an attempt is made to twist these through a stationary loop of wire. The pole-pieces of the field magnets in this experiment are expanded into discs, and these are revolved in contrary direction to that in which the wire was moved in Fig. 4. As the generation of a current in a wire is certainly due to the relative and not to the absolute movement of a conductor with respect to a magnetic field, the conclusion seems irresistible, that if the field is moved with respect to the conductor in the opposite direction to that in which the conductor was moved in Fig. 4, thus producing the same relative movement, then a like current would be generated.

A continuous magnetic circuit, part of which of course is through the air, is a fundamental fact in all dynamo-electric machines. With this circuit, the electrical circuit interlocks, like two links of a chain. In all dynamos the current results from the separation and relinking of these circuits. In the ordinary type of dynamo the electrical circuit is alternately passed in and out of magnetic circuits with opposite directions of polarity. In the unipolar machine, the electrical circuit is continually passing in and out of magnetic circuits with their polarities in the same direction. In the above described experiments, there is introduced as an essential feature of the constructions, the novel idea of continuously twisting the magnetic circuit in one direction, as the candy man does his loop of molasses candy. Although the behavior of copper discs moved in front of the poles of a powerful magnet is suggestive of the presence of a resisting medium similar to molasses, yet when an effort is made to twist the magnetiem in the manner above described the negative results obtained show conclusively that magnetism here ceases to resemble that sticky article.



FIGS. 4 AND 5.

If it should be necessary for the present to explain this anomaly by enunciating a new law that magnetism refuses to twist, it will be well to remember that it is an explanation about on a par with that which contented the ancient philosophers and kept them from discovering the pressure of the atmosphere, when they explained the rise of water to a pump by saying that nature abhors a vacuum.

When the idea of twisting magnetism was advanced by the writer, there was no difficulty in finding electricians who were ready to assert that it would not twist and that it was useless to attempt to fool Nature; but on the other hand, it seems that the idea of exciting the field magnets with the current which they generated—an idea that was likened, before it was tried, to that of a man attempting to lift himself up by his boot-straps—was also an attempt to fool Nature, and one that was so highly successful that it was quite justifiable to attempt to fool her again.

THE ELECTRIC ILLUMINATION OF THE SECTEUR POPP IN PARIS.

BY

Ernst Egger

The employment of storage batteries in central stations is not of long standing, but has, nevertheless, made considerable progress in a short time. In Germany and Austria the following systems have been chiefly carried out:

1. The central station has a small battery for the illumination necessary during daylight.
2. The central station has a large battery for combined operation with the engine plant.
3. Storage batteries are used as compensators in the five-wire system.

Plan No. 1 is probably the oldest and originates from the practice of the smaller plants. There are many plants, in which the consumption of current in the daytime is not more than from 5 to 15 per cent. of the consumption at night. It would not be economical, to run in such cases with the engines; therefore the illumination during the daytime is effected with accumulators. The charging is done during the operation of the machines, which can thus be done at full load. This is an advantage of this method of employing storage batteries. The second plan is different from the first, because for the night lighting; that is, for the heavy consumption of current, the storage batteries are also used. This plan has been carried out in some of the important new large central stations; there the batteries are able to furnish a third of the whole current. The charging is done during the daytime, with steam engines at full load and therefore working economically. This arrangement effects a considerable diminution in the motive power plant of the central station, which is important in stations which are situated in the centre of towns.

The third method is not often used in practice. Storage batteries are coupled on the individual circuits of a five-wire system in parallel with the dynamos, so that they can receive or deliver current, if there are differences of load on the branches.

Besides these cases another sometimes comes into consideration, and that is, to remove the central station out of the territory of consumption, and to place in the latter accumulator substations, which are charged from outside and furnish the desired current. If all these batteries are charged in the daytime, it is possible to save copper and to feed more lamps than the machine plant would otherwise admit of.

The installation of the Secteur Popp in Paris is based on such a plan, but there has been no intention, up to the present, to get a higher discharge current than the charging current; the intention was to overcome the very long distances due to local circumstances. The following will explain this: When the municipality of Paris decided to introduce the electric light, they would not give the concession to one contractor alone, so as to avoid a monopoly. Hence parts of the city, called, "secteurs" were divided among the various contractors. Mr. Popp's secteur is the largest of all, because its centre is near the Bastille and extends on each side to a radius of about 3½ miles. Owing to this great distance a choice of this system of conducting the current was made after the designs of Mr. Solignac. The plan is, to produce in the central station continuous current of high tension, but proportionally small volume.

The charging station is located nearly in the centre of the district, near the Bastille, that is, beyond the city limits, and working with fully-loaded engines, sends out the current to substations, which are proportionally divided in the secteur. These substations consist of storage batteries and the charging current required by them, has the same strength as that delivered by the central station current. They are all connected in series, which makes necessary the high tension employed. The batteries which are to be discharged, are disconnected from the high-tension system, and connected with the secondary illuminating circuits; another set of batteries takes the place of the one discharging, or the latter is merely cut out. By this arrangement the outgoing current is independent of the charging current, and accidents in the central station do not have a sudden influence on the illumination; the security of the operation is therefore increased.

The question is frequently asked as to the economy of this Paris plant. As is well known, we can express the efficiency of a storage battery by the following formula:

$$\eta = \frac{\int c\,\delta\,dt}{\int C\,\Delta\,dt}$$

which represents the quotient of the discharging and charging work. In this equation

c represents the discharging current. ;
C " " charging current;
δ " " discharging potential;
Δ " " charging potential;
t " " time.

This formula applies to any case, no matter how the batteries are connected, whether in series or parallel, and is also applicable in this instance. If

n equal the number of substations;
Δ, the average of the charging tension needed for each substation,
v, the whole drop in the line,

then the central station must produce a tension:

$$V = n\,\Delta + v.$$

Call the intensity of the charging current C, then the work, done by the central station is

$$W = C\,V.$$

Further, if H is the time of operation in hours, then is $\frac{W\,H}{746} = E$, the number of horse power hours, which are delivered into the charging circuit from the central station. With the arbitrary supposition that all the substations will be discharged simultaneously and completely, that is, down to the lowest limit of the drop of potential, we can calculate the work of discharging.

In the Paris plant the maximum volume of the discharging current is the same as that of the charging current; the batteries are so designed, that one could increase the discharging current, but that has not been done up to the present. We therefore want first the value of the discharging potential. All the substations are fitted out with regulating cells, with which the potential can be kept at the same point, designed by δ. Hence the discharging work is:

$$w = n\,\delta\,C.$$

If charging and discharging intensity is the same, then the time in both cases is about the same. The number of horse power hours taken out of the substations is then:

$$e = \frac{w\,H}{746}.$$

We therefore get the economy as follows:

$$\eta = \frac{e}{E} = \frac{w}{W} = \frac{n\,\delta}{V} = \frac{n\,\delta}{n\,\Delta + v}.$$

As the value of $n\,\delta$ is fixed, η, the efficiency is dependent upon V. But Δ again is dependent upon the peculiarities of the accumulators employed; while the drop v is a maximum if all batteries are charged simultaneously, as we assumed by adopting the term n. Both expressions, Δ and v will never exceed the calculable or known maximum measure. We can therefore say, that η will never be subjected to such unfavorable fluctuations, at would bring it beyond the bounds of predetermination. The conjecture made by many that the electric efficiency of the Paris plant, which is not known up to the present, is not very high, is not justified and this the more, as the circumstances which make a proper calculation possible, rarely, if ever, exist.

It is the nature of an electric central station, that the load varies; this is the case here and therefore the assumption is not quite valid, that all batteries will be discharged within H hours and with the intensity C. The discharging current rather will be smaller and therefore the time of discharge longer than H. This includes also temporary changes in the time of charging. All these features cannot be expressed very well in figures, and their influence on the efficiency of the plant cannot be justly estimated. But we can suppose that a very big variation from the theoretical result will not be the consequence. It is wrong and unfair to inquire about the electric efficiency of this plant, and to compare it with other storage battery plants of the usual style; for it is certain that the losses in an ordinary plant with accumulators in parallel, are less, and the efficiency higher. But to get an idea of the efficiency of the Paris Popp plant, it is only right to compare it with other plants, which have to work under similar local circumstances.

I add here some data on the Paris plant.

The central station is located about in the middle of the illuminated district, and is operated by steam. Four upright triple expansion engines of Weiher, Richmond & Co., each of 300 h. p., running at 135 revolutions per minute, are coupled on both sides to dynamos of the Desroziers type, with the well-known disc armature; the connection is effected by means of the Raffard elastic coupling. These dynamos have a capacity of 250 amperes at 400 volts, with the above number of revolutions, and are all connected in series except two of them, which are now serving as a reserve till the circuits are completed. The fields are separately excited by means of eight small Rechniewsky 100-volt dynamos, which are driven by belts from the fly wheels. Each group of machines has its own connecting board, and all the manipulations of connecting and disconnecting can be done there.

The current at present delivered by these machines is 250 amperes at a potential of 2,400 volts, in the charging system (primary network). The latter is laid in underground conduits and consists of a very good insulated cable. To avoid soldering joints the cable is drawn in one continuous length from substation to substation and, besides, is laid double, so that there may be no interruption in case of accident to one of them. The diameter of the conductor is about 0.63 inch. The number of substations is at present 25, but will be increased on 32. They are distributed at proper points in the city—in cellars, stables and similar places—where rent is cheap. From these the secondary conductors are led out which carry the consumption current. They radiate in all directions, are not inter-connected except, of course, at the battery board, and are only 250 metres long (about 800 feet). The diameter of the conductors, like that of the primary cables, is 0.63 inch, and this is a great convenience in laying the circuits. The maximum current passing through this secondary cable is 100 amperes, and the drop at full load 5 volts. Owing to the circumstance that the secondary cables are never longer than 250 metres, the maximum distance between two substations is 500 metres. In most cases, however, they are located much nearer, because the current density per unit section is very great, especially in the interior parts of Paris. The substations are fitted out with two storage batteries at least, each consisting of 53 main cells and three regulating cells, therefore delivering about 105 volts. These batteries are of the Laurent-Cely type and built by the Societé pour le Travail Electrique des Métaux. They have a capacity of 14 watt hours per kilogramme of plate and require a charging current of 0.7 ampere per kilogramme of plate, but can deliver at the rate of 1.5 ampere per kilogramme. This discharge has not yet been called for. There was a possibility of getting along with only one battery in each substation; charged in series it could be discharged parallel with the secondary conductor with 105 volts. But then there would always have been the danger that the high tension could come on the consumption net, and, moreover, the whole independence of the central station would have been lost. This was the reason why two batteries were put in notwithstanding the most careful insulation of the batteries.

To the end that one can connect each battery with the charging or discharging circuit during the operation of the plant there are switchboards in each substation, and with a very practical switch arrangement, including compensating resistances by which every combination can be made easily and without interrupting the current. All the substations are built in the same way and all manipulation is strictly prescribed by the central station; the probability of the assistants in the substations making any mistake is therefore very small.

To indicate how many batteries and during what time they must be charged daily, there are in every substation recording meters, registering the consumption of current, a report of which is sent in the central station every night. From there the superintendent issues orders as to which batteries must be charged the next day, and how long. The man in the substation has no other work but to put the battery from the discharging on to the charging circuit at the prescribed hour, to do the opposite with the second battery, and to interrupt the charging at the time specified. In this way the central station is also prepared for the required power.

As is well known, the E. M. F. must be increased during the charging. The regulating of this is very simple, the central station merely keeping the current of 250 amperes constant, without regard to the voltage.

Finally it must be stated that the whole number of lamps installed now aggregates about 22,000. In this, however, must be included three compressed air substations having a capacity of about 500 h. p., which also furnish current. The entire length of the conductors, working at present, is about 55 miles.

It would be very interesting to know something more definite of the financial aspect of this system, but on this point the writer is unfortunately in the dark.

GOVERNING WATER WHEELS—A SUGGESTION AND AN INQUIRY.

BY A MECHANICAL ENGINEER.

AMONG the problems which have been presented to the mechanical engineer as the result of the rapidly-increasing use of electric transmission, is that of the means of governing water powers so that they shall furnish a constant speed under widely and suddenly varying loads. This question has, until lately, been kept somewhat in the background by a variety of circumstances which, briefly stated, are about as follows: When the mechanical production of electricity first made its appearance among our industries, nearly all the water powers of any consequence in cities or their vicinity were already utilized for manufacturing purposes. As long as only electricity of low tension was used the powers more distant from towns were useless except when, as in the magnificent example at Rochester, N. Y., they were used for arc lighting. In such cases the load, while varying slightly, only did so under the direct control of the engineers, and the changes were gradual and could be cared for. With the arrival of the alternating system of lighting came a wider use of distant powers, but still the load was one varying by slow and small degrees, and the ordinary water-wheel governor could do excellent work.

With the advent of high-tension power distribution, however, and the rapid and enormous increase in its use for railroad work, came a new set of conditions which the old methods failed to meet. When a load varies from maximum to minimum in a few seconds, we have the most severe test to which a governor can be put, and in the use of water for power we have, in addition other factors to increase the difficulty.

On an electric railroad plant the first effect of increased load is naturally to diminish the speed and thus to drop the E. M. F. of the dynamos. The cars all slow down, but the drivers keep the regulating levers where they were, or even throw them further to keep up the speed, giving the water-wheel gates plenty of time to open wide to supply the extra current called for, and then, as the cars rapidly rise in speed, or are thrown off, the generators are relieved of load and the water-wheel speed rises to an extent far beyond what it would, could the E. M. F. have been maintained more nearly constant. So governor after governor is tried and yet none is found satisfactory.

There have been several complaints against the mechanical engineer for not inventing for water wheels a quick-acting governor such as is used on steam engines, but these complaints are founded, I think, upon a misconception of the facts and conditions to be met in the two cases. With steam, we are handling a fluid which has comparatively no weight or viscosity, and which, being under strong compression, will instantly flow wherever it is permitted. We can therefore check and release it as suddenly as we please with no danger, and with the perfect assurance that it will do as we desire. It is by no means easy to make the perfect governor which shall hold a steam engine to absolutely normal speed under wide variations of load, but there are many close approximations and a few well nigh perfect ones.

With water, on the other hand, we are dealing with a fluid which has great weight and viscosity and slight compressibility. Any one who suddenly closes a stop cock in a water pipe while the water is flowing and hears the jar which follows, can easily realize what would be the blow struck if such methods were tried on a pipe six feet in diameter with twenty or thirty feet head. Again, any one who has seen a water pipe burst when under pressure without flow, may have noticed the perceptible check after the first gush until the body of water in the pipe has had time to get into motion. Both these effects can be seen well exhibited in the ordinary hydraulic ram.

To make matters worse and still more widely different, these same properties allow us with steam to get the benefit of placing the governor right at the point where the fluid does its work, while the nearer our governor is to the water wheel, the greater the strain is upon it, owing to the heavier pressure and greater body of water to be handled.

There is no difficulty in making a quick-acting governor which shall shut off the gates as sharply as wanted, and were it feasible to locate these gates at the point where the water enters the flume, we should be so far all right, since the greatest load which could be brought upon them would be only the head necessary to cause the water to flow into the flume, and about fourteen pounds per square inch additional which would be thrown upon them, should we shut the gates so suddenly as absolutely to expose the under side to a vacuum. What kind of commotion would be created in the flume by this I leave my readers to imagine; but besides this, the water already past the gates would still act on the wheel in a very uncertain manner owing to the varying effects of vacuum, momentum and quantity of water.

Is there any other way in which we can solve the problem? Let the electrical engineer decide. So far most of the water powers are ample for the maximum load upon them, and if this load could only be kept constant they would work well. As there is a surplus of water this would practically not cost anything. In one case it is reported that this is done in a minor degree by having a man sit by a brake wheel with his eye on the ammeter, and throw on and off the brake according to the variations of the load, and if this could be done automatically it might pay to do it. Now, many years ago—in 1874, I think—the writer, when studying with Dr. R. M. Ferguson, in Scotland, was familiar with a small dynamo on Ladd's principle, which was used in lectures on electricity. It was a small series-wound machine fitted with a Siemens "H" armature which had two coils at right angles. One coil (the smaller) was used to excite the fields coupled in series with it; the larger to supply the external circuit. When working the machine by hand, it could be driven to a high speed, the total effect of the small armature not being enough to overcome the power. When both coils were put in series, with the fields, however, the machine could only be run slowly, the dynamo "building up" so much under increased speed as simply to hold back against any force which could be applied. It was very curious to start the dynamo from rest and see with what perfect ease it could be run until the critical speed was reached, and how no amount of power could get it above that speed.

This machine and this experiment were exhibited, I believe, before the Royal Scottish Society of Arts, and the writer well remembers Dr. Ferguson, on more than one occasion, calling attention to the fact that it would form a model railroad brake for descending inclines if attached to the axles of the cars, since there was absolutely no danger of "skidding" the wheels, while a certain constant and predetermined speed would be maintained, the only thing to be taken care of being the heat generated. Of course, an additional brake would be required to completely stop trains, since this electrical brake would not possess any power below the speed at which it was meant to begin to act, but this suggestion was made at a time when continuous brakes were very little known and in a country where even to this day the old hand brake is in the large majority.

Now, can we not use a similar device as an automatic load maker? Suppose we take a series-wound dynamo, or a number of them, large enough to absorb the whole power of the water wheels without injury, and belt it to the main shaft. Build this dynamo so that its critical speed shall be reached when the main shaft runs a few turns above normal, and that it shall not begin to build until a few turns below it, using "teaser coils" on the fields if necessary, which teasers can be charged from the main generators or a special machine, if desired. Make the dynamo waterproof and put it in a tank of water, or put it in a tank of insulating oil and keep that cool by water circulation. If this is done, commutators and all can be plunged bodily in.

Now, see what will take place. The moment cars are thrown off, the main shaft, lightened of its load, begins to speed up, and that moment the series dynamo builds up and puts load on until the total equals the former load, and the shaft keeps its speed. Throw load on the generators and the shaft slows a trifle, when the series dynamo dies out and no load is on the shaft but that of the generators. The same amount of electricity is always generated, but the amount from the main generators which passes to line, and the amount from the regulator dynamos used to heat water are constantly varying—that is all. The regular governor will take care of small changes.

Now, let the electrician figure out whether he can build such a dynamo, and if he can, he should have no difficulty in persuading, say, the Neversink Mountain Railroad, at Reading, Pa., to try the device. Of course, I expect to find that the device is patented or has been tried and will not work. If so, I would like to be informed when and where. It would certainly be interesting, as I have never seen or heard of such a device except from Dr. Ferguson in the days which now seem so very long ago—the days when "Gramme's" dynamo was the wonder of the age and the electric light a curiosity to be exhibited in lectures and entertainments.

AURORAL AND EARTH CURRENTS.

BY

THERE can be little doubt, as Mr. D. B. Grandy suggests in the last issue of THE ELECTRICAL ENGINEER, that a comprehensive and systematic course of observation on the part of telegraphers during the periods of auroral disturbances would add much to our knowledge of the nature and cause of earth current phenomena.

The average operator, however, cannot be said to possess the electrical knowledge or the analytical ability necessary for a clear and intelligent appreciation of the circumstances attending these phenomena; and it is extremely doubtful whether it would be found either practicable or profitable to undertake his scientific education on these points, especially in the manner proposed by Mr. Grandy. The operator would be called upon, for instance, to discriminate between the auroral and ordinary signaling current effects; to know exactly the polarity as well as the strength of current actuating his relay; and to understand many other points more or less technical in character, before his judgment could be accepted as having any definite value.

It is highly probable, moreover, that any attempt on a large scale to define the polarity and ascertain even approximately the strength of earth currents by simply noting their effects upon the relay armatures, would tend to develop widely different and anomalous results among the various observers and drive to the very verge of despair the local electrician who might try to restore order out of such chaos.

There is, fortunately, a simpler way in which the ordinary operator can aid the cause of science during these disturbance periods, and that is, by carefully noting the circuits that are *absolutely unaffected* by the passing storms. The direction of such circuits will show the equipotential planes, which are known to be at right angles to the direction taken by the disturbing forces, which are believed to have their origin in sun spots. It is beyond question that the effects noted at such times are *not* the result of local causes, for it invariably happens that telegraph wires in every section of the globe are affected simultaneously with the appearance of unusual solar activity.

The principal points to be observed in case of further disturbances of this nature are as follows:

(1.) Note the times of appearance and disappearance of the phenomena, as well as the periods of maximum intensity.

(2.) Make a record of the differences of potential shown between the terminal grounds of the circuits affected, and,

(3.) Ascertain the geographical direction of the wires most affected as well as of those least affected by the earth currents.

The ordinary operator can be of considerable assistance in determining (1) and (3), but the measurements and calculations involved in (2) can only be accurately made by those having some technical knowledge and skill, and equipped with the necessary apparatus for making such tests.

THE MANUFACTURE OF HIGH VOLTAGE INCANDESCENT LAMPS.

BY

Henry E. Viening

I HAVE noticed from articles that have recently made their appearance in THE ELECTRICAL ENGINEER, that the attention of lamp makers is now being concentrated on the manufacture of high voltage lamps, by which I mean lamps of 150 to 300 volts, and a short consideration of the subject will be found profitable to companies and other individuals to whom economy is of importance in the use of the electric current for purposes of lighting.

The benefit to be derived from a high voltage lamp is at the present moment almost incalculable, and the field for such enormous, for by its application to existing central stations, the capacity of their mains would be doubled, and in many cases trebled ; and it would also enable those who generate continuous currents to extend satisfactorily, and with increased profit, their present limit of service from 40 to 70 per cent. at an enormously reduced first cost for copper.

The recent article of Capt. A. de Khotinsky, wherein he deals with the difficulties of manufacture, and the increased cost of the lamps, and also suggests the feasibility of doubling the length of a 10 c. p. 100-volt filament in order to produce a 200-volt lamp, shows me that he has studied the subject closely, and understands the details of manufacture well, and the experience which I have gained from close experiment in the same line some few years ago, leads me to agree with him, in his statement that the brush effect developed on the pumps in high voltage lamps is due entirely to the resistance of the joints and the vacuum.

Furthermore, the quality of the glass is an all-important point in the manufacture of incandescent lamps, and fully 90 per cent. of the troubles of a lamp maker's life are due to inferior glass; and the quality of the finished product depends upon the quality of material used in this respect, whether 50, 100, 200 or 300 volt lamps.

There is no doubt that it is possible to make lamps of a high voltage by the apparently simple process of lengthening the filament, but as to whether they can be successfully produced by this method so as to sell at a reasonable price is open, in my mind, to grave doubt on account of the enormous loss in carbonizing and the treatment the filaments have to undergo previous to insertion in the lamp bulb. The only fibrous material of which a filament can be made successfully for a high voltage lamp is bamboo. Now the length of clear fibre, that is, one without knots, to be available for a filament, is limited to about seven inches, for if this length is exceeded the product becomes very doubtful. Again, if the filament is lengthened, it becomes necessary to use a third support to prevent vibration, which must of necessity increase the cost of production, and nearly, if not quite, counterbalance the money saved in copper.

Lately I have succeeded in making a number of lamps of a voltage ranging from 200 to 280, with a life of over 500 hours, at 3.6 watts per candle power, without having to lengthen the filament or to resort to any device other than the ordinary process now in use for 100-volt lamps, with the exception of the chemical treatment of the fibre previous to carbonization, which treatment of itself is inexpensive, an outlay of $1 being sufficient to treat 1,000 fibres.

The features of a high voltage lamp thus made are many, and a brief enumeration of them may not be out of place here, in order to impress on the minds of those who are now ignorant of the value of the lamps, points that they will easily recognize when they refer to the lamps now in general use.

Blackening.—The blackening common to ordinary lamps is almost done away with in lamps of 150 to 200 volts, 16 c. p., after 500 hours at 3.6 watts per candle.

Uniformity.—The higher the voltage the greater the margin of resistance within which the lamps are practically the same candle power, rendering, therefore, a greater percentage of the make of uniform candle power.

Fall of Resistance.—During exhaustion, the fall of resistance of the filament is 50 per cent. less in proportion to lamps of lower voltage.

Regarding the brush discharge mentioned above, I have found that this can be done away with by nickel-plating or carbon-plating the joint as in the majority of modern lamps, instead of using cement.

The conclusions which I would draw from the above are that lamp makers who are now grappling with the subject of high voltage lamps will find the solution of the problem in the chemical treatment of the fibre, rather than in the use of mechanical devices.

THE VIBRATING ELECTRIC HELMET FOR NERVOUS DISEASES.

AMONG all the methods, more or less curious, applied to the treatment of nervous diseases there is certainly none which is more original than that which has been applied for some time at the Salpetrière Hospital, in Paris, by Prof. Charcot. It is a treatment by means of mechanical vibrations, which have been shown to have a marked effect in soothing the nerves. This vibration cure has for some time been specially studied by a pupil of Prof. Charcot, Dr. Gilles de la Tourette. With the assistance of two colleagues, well versed in electro-therapeutics, MM. Gautier and Larat, he has constructed an apparatus for the treatment of headaches and similar nervous affections of the brain. It is termed the vibrating helmet. It resembles an ancient helmet and is, in fact, constructed of sheets of steel which permit the top of the head to be thoroughly encased, as shown in Fig. 1. The interior construction will be readily understood by referring to Fig. 2. Mounted upon this helmet is a small alternating current motor making about

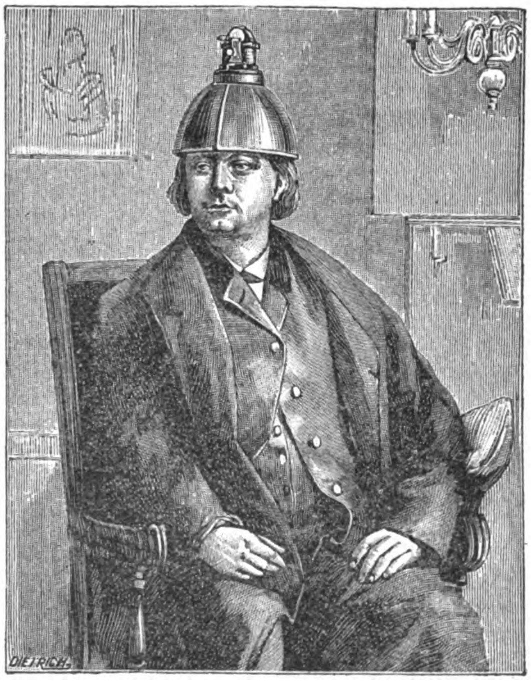


FIG. 1.—THE VIBRATING ELECTRIC HELMET.

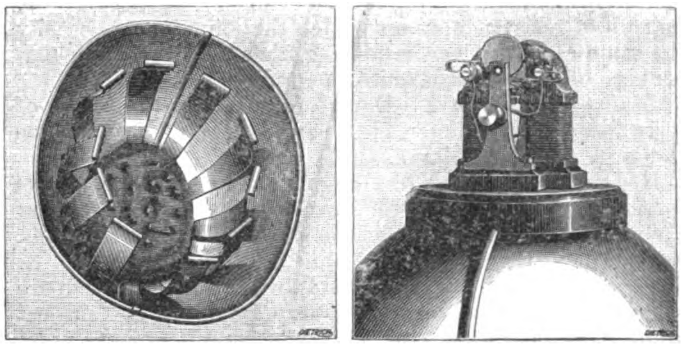
six hundred revolutions per minute. At each revolution a uniform vibration is transmitted to the metallic springs and is communicated to the skull against which they are pressed. The walls of the skull are thus vibrated in their entirety, and these vibrations naturally are transmitted to the cerebral structure. The sensation is not disagreeable and the number and intensity of the vibrations can be varied according to the patient treated. The machine produces a rumbling sound which contributes to benumb the faculties. At the end of some minutes the patient experiences a general lassitude and a tendency to sleep, putting nervous people and those afflicted with insomnia into a salutary repose. The vibrating helmet has already been applied in a large number of cases of neurasthenia and similar diseases, and in the majority of cases with good results. The process is also successful in the case of headache, and as this is a widespread complaint, against which there is no sure remedy, it is possible that the vibrating helmets will become quite the fashion; something that no home or family can dispense with.



FIGS. 2 AND 3.—THE VIBRATING ELECTRIC HELMET.

THE NEW YORK STATE BUILDING AT THE WORLD'S FAIR.

A STRIKING feature of the building will be its exterior illumination by electricity. The belt course marking the second story will be strung around three sides with incandescent lights of different colors, and about the entrance, above which the seal of the State of New York is set, a myriad of fiery diamond jewels. A second line of these lights will deck the entablature of the main building, while a third and fourth line will set off the cornice of the upper deck, and define and outline the arches, angles and cornices of the two belvederes. Finally a cluster of lamps will illuminate the base of the flagstaffs, surmounting the belvederes.

A NEW PROPERTY.

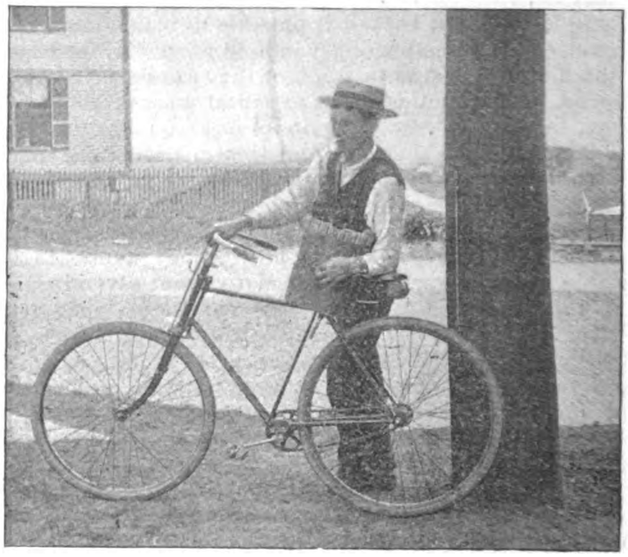
IN an investigation on the properties of lamellar bimetallic conductors under the influence of electromagnetic induction, says the London *Electrical Review*, MM. Ch. Regnier and Gabriel Parrot have reported to the Paris Academy of Science that they have obtained an arrangement recalling the well-known "Faraday's disc," by substituting for the usual copper conductors thin plates of a certain constitution. These plates are composed in the direction of their thickness, of a very magnetic and highly conducting metal, and so placed that the lines of force of the electromagnetic field are perpendicular to this direction of thickness. The flow of induction which proceeds from the north pole is divided into several sheets of parallel lines, which are very close together, and which only traverse the metallic portions of the bimetallic conductors, the tubes of force becoming cylindrical. In this arrangement of conductors MM. Regnier and Parrot found that the available energy increases at a rate which is practically proportional to the height of the conductors. They constructed a small machine on this principle, and obtained with a load of 750 kilogrammes and a velocity of 500 revolutions, 32,000 watts; and this they found worked out to an output of 42 watts per kilogramme of the machine. Further details of this newly discovered property of lamellar bimetallic conductors may may be found in a paper in the *Comptes Rendus*, August 8th.

ANTIMONY IN ELECTROLYTIC COPPER.

HERR W. HAMPE states in the *Chemiker Zeitung* that all the specimens of electrolytic copper which he has examined contained a small proportion of antimony ranging from 0.007 to 0.02 per cent. The precipitation of antimony from the copper ore might be checked if the sulphuric acid were not used for so long a time, and thus did not become so highly charged with impurities, but except for laboratory purposes the extra expense involved in the increased consumption of acid would not be proportionate to the advantages gained by the elimination of the antimony.

A BICYCLIST LAMP TRIMMER.

IN our issue of August 24, we illustrated the central station of the Concord Gaslight Company, at Concord, N. H., and in the article, mention was made of the fact that the lamp trimmer used a bicycle in the pursuance of his daily occupation. We are now enabled to present to our readers an engraving showing the trimmer, Mr. James Urquhart, standing beside his bicycle all ready to begin work. The bicycle is a Grendon safety, manufactured by the Grendon Iron Wheel Company, of Toledo, O., weighs 47 pounds, and is geared to 58 inches. In all there are about 65 lamps to be trimmed on two circuits measuring together about 16 miles, the two lamps furthest from each other being about 2¼ miles apart. On a pleasant day it takes about eight hours to trim the lamps, and after the lamps are started, Mr. Urquhart goes over the circuits once more to make sure that all the lamps are burning properly, occupying about 1½ hours in the operation. The bicyle has proved quite a success in Concord, and saves a large amount of time and labor, and could well be applied to other cities.



A BICYCLIST LAMP TRIMMER.

Letters to the Editor.

ON THE PROSPECT OF STORAGE BATTERIES FOR ELECTRIC TRACTION.

One of the great questions of the present day to which almost every citizen is giving particular attention, is that of solving the rapid transit problem in such a manner as will best meet the interests of the public generally. Of course every one looks (and justly) to electricity as the power by which the problem is to be solved. To a considerable extent it has done so already in shape of the much discussed and freely abused trolley system. It is a well-known fact that up to the present time, as viewed from a commercial standpoint, the trolley system is the cheapest and best. From the standpoint however of public favor, it is very far from the ideal we look for and expect. It is needless to reiterate the main reasons for the public disfavor of the trolley system beyond the statements that as regards appearance, comfort and safety, it is not now, and is never likely to be the system which the public requires and is looking for. If there were no prospects whatever of anything better, there might be some excuse for those who recommend householders to suffer the disfigurement of their streets, the extra noise of the trolley cars, and the risk of their lives. But now comes the question, Is there no prospect of anything better? Those financially interested in overhead railroad systems will either answer: "No, no prospect whatever," or keep discreetly silent. But the answer of the unbiased and unprejudiced naturally is—"Yes there are prospects of better systems." Confining oneself to the electrical field there is the underground traction system, and last but not least the storage battery system. Of the two prospective systems the public look with the greatest favor and hope toward the latter. A successful underground system is decidedly better than the overhead; but a successful storage battery system would undobtedly be the best of all. Advocates of both the overhead and underground systems are in the habit of stating that there is no prospect whatever of a successful storage battery system or, at least, so remote is the prospect that it is unworthy of present attention. The statement is very freely made that every attempt so far has proved an unmitigated failure. There is undoubtedly a great deal of truth in this statement; but not so in the statement of there being little or no prospect of future success. Those who have given special study to this industry and have a practical experience in the actual working, together with a thorough technical knowledge of the requirements and capabilities of storage batteries of various types, do not agree with the pessimists of the electric storage systems as applied to street cars. There are moreover at the present time some very mistaken ideas amongst the public in general as regards the true state of the art, and also as regards the direction from which ultimate success may be first expected. One is accustomed every now and then to see a long and elaborate description of some *new system* (so called) under some such head as "The Problem Solved," "A Successful Electric Storage System for Cars," "The New Battery for Storage Cars," "Most Successful Experiments," "The System to be Universally Adopted by the —— R. R. Company," etc., etc. Under some such heading one finds a long description of a beautifully painted, decorated and electrically equipped car, possessing a number of novel features. We are informed how some dozen or so railroad men and experts, etc., mounted the said car, and under the guidance of a driver of no electrical knowledge (as no such knowledge is required, everything being so simple and under perfect control), they were piloted over a road of some four or five miles. We are told how they mounted several grades on which they stopped and started with perfect ease; how they were propelled at the rate of 12 to 15 miles an hour without any apparent injury to the battery. Upon their safe return these experts are stated to have commented most favorably upon the excellent mechanism, the enormous power stored, the smoothness of the motion; and finally gave it as their unanimous verdict that the experiment was a most pronounced success, and to the best of their belief the first and only success in this line. In many cases beyond the fact of offering stock for sale, etc., one hears no more of this particular and successful new system These demonstrations may be all very well in their way as far as maintaining the public interest in the matter is concerned; but they have the unfortunate tendency to spread the opinion (especially amongst purchasers of stock) that another failure has been added to the list. Now the public should be apprised of the fact that there is no question whatever at the present time, and has been no question whatever for years but what storage battery cars can run as smoothly; be as easily handled; attain the same speed; mount equal grades; stop, reverse, and in fact do all and everything equally well, and sometimes better than any other electrical system either overhead or underground. A great deal is made out of the fact of the great extra weight. It is upon the strength of an enormous reduction of this said weight, that inventors and advocates of the numerous so-called "entirely new and improved storage systems" attract their patrons. In some cases a certain reduction of weight may be made, but it is usually at the sacrifice of stability and strength. As a matter of fact this subject of reduction of weight is not nearly so important as the public are led to suppose. A reduction of 50 per cent. of battery weight would on an average mean a saving of 10 per cent. of total weight upon a car capable of seating from 30 to 40 passengers.

Now those who have practical and technical experience in this business know that the extra cost of operating, consequent upon the additional ten per cent. of weight, is very far from a serious item, but an item, in fact, which can be very easily exceeded by extra cost of depreciation consequent upon reduction of strength and stability in attaining the 10 per cent. reduction of weight. It is true a firm roadbed as well as good rails should be used when extra heavy cars are run; but neither the roadbed nor the rails have to be of superior construction or more expensive nature than should be the case with every well-built street car line. A great deal is made of the total extra weight to be carried on a car which, without said battery and with forty passengers, would weigh, say, 20 per cent. less. What car line is not in the habit of allowing an excess of 20 per cent. of weight of passengers over its seating capacity. As they represent five cents apiece nothing is said about the extra weight. Even 20 per cent. extra weight does not so seriously effect the extra cost of operating expenses as some would like the public to suppose. Thus with the facts before us that a storage battery car can do all and everything as well and perhaps better than any other electric car, that the weight is an overrated objection, it may be justly asked, Why have they not been successful? The answer to this is very simple. Because hitherto the cost of operating—in consequence of the depreciation of the batteries themselves—has been too high. The cost of prime motive power is less with storage batteries than without. Now, the only way of proving the success of any storage car system is in the first place for the owners to make a contract with some good representative street car company, by which said owners undertake to operate and maintain their batteries in proper working order upon a fair number of cars at a fixed price per car mile.

If such a contract is taken at a price satisfactory to the car company, this is the first step towards the required proof. If at the end of the first term the contractors are prepared to renew said contract on same or equally satisfactory terms, having by their previous operation given sufficient satisfaction to the car company to warrant such renewal, then we come to the second and very important step towards the final proof. The last and most important step is for the contractors to prove that they are operating on a profitable basis. This can be shown by their books or by their willingness to take further contracts upon the same terms. Numerous contracts of the above nature have been made and started upon. Some have resulted, so far as they went, in the satisfaction of only one party to the contract; usually the car company. In others, again, there has been general dissatisfaction all round. In all cases, however, difficulties and disagreements have arisen at the second or third stage of the drama, namely, the renewal and extensions of the contracts. Numerous excuses have been made, the principal of which is lack of funds. For ample funds there must be ample faith. It is the lack of faith that has produced the lack of funds. All these contracts, however, no matter how short a time they may have lasted, have resulted in some good, namely the acquiring of practical experience as to requirements in actual working. Each so-called experiment has been one step ahead. It is from those who have been thus steadily working ahead in this field that the long-wished-for result must be looked for. Those who have devoted many years of study and close attention to this special subject as a rule do not expect to see the sudden solution of the problem arise from some great and unexpected discovery. Of course it must not be denied there is a possibility of something new and unexpected suddenly coming to the front; but the possibilities of such appear greatest to those who have the least knowledge and experience in this branch of science. Most scientists will probably agree that it is to the developments and improvements which have resulted from continued study and experience of present systems that we must look for the solution of the problem. Storage batteries as applied to electric lighting began to come forcibly before the public some ten years ago. For many years they met with little or no financial success. The subject was carefully studied and the business practically developed until at the present time (in Europe especially) the electric accumulator as applied to electric lighting is a financial success. It was not, however, until substantial guarantees were given and carried out by the manufacturers for operating and maintaining storage batteries at a fixed price (as is now being done in many instances in Europe) that their success was assured beyond question. Electric storage batteries as applied to traction purposes are going through the same course of development, and it is from those who have been continually working in this field and who have achieved the practical results so far attained, and by whom the experience has been gained for making the nececessary improvements, that we must look for the success which is to be. The probabilities are greatly against the solution of the problem from the sudden inspiration of one who has but quite recently given attention to the subject; one who has probably forsaken his calling and business to become a full fledged inventor and electrician and make a great discovery. Such discovery usually upon inspection is found to be only a case of history repeating itself; a device in fact which was originally discovered many years ago, and has been steadily and unfailingly rediscovered many times every year since It is not from such as these, of which the number is legion and still increasing that the public will in all probability see the hoped-for result.

If such a discovery should be made at all it is much more likely to come from one of those who has given continuous and close study to the subject. These are the very ones, however, who agree in thinking the problem is much more likely to be solved by some of those now engaged in the practical development of systems in which already the principal obstacles have been overcome, and in which it is merely a matter of time when the final goal will be reached. As a last question which the patient public may justly ask: How soon may this long-looked-for and long-wished-for result be expected? It may be stated in reply that in all probability even the next few months may show some decidedly encouraging advances. There are at present in different quarters of the globe some of the most practical undertakings in this line being developed. Contracts such as described above have been entered into by experienced and substantial firms. The contracts are now entering upon the second stage—namely, that of renewal and extensions. These are being watched with the utmost interest as apparently at no previous occcasion have the contractors been in a more substantial position and with a better knowledge of their subject than at the present time. Results so far give every promise in the very near future of a practical proof beyond all question that the storage system is bound to be *the* system by which the problem of rapid transit will be solved.

GAUTHEROT.

NEW YORK, Sept. 7, 1892.

THE HAMMER EFFECT OF LOCOMOTIVE DRIVING RODS.

IN Mr. Sprague's admirable inaugural address before the American Institute of Electrical Engineers, he thinks "it fair to say that the so-called hammering effect on the rails said to take place in the ordinary locomotive driver where the weights are counterbalanced, exists more in imagination than in fact."

Mr. Sprague does not seem to understand that the unbalanced feature of the locomotive of which a great deal has been said is not so much in the driving wheels or connecting rods as it is in the driving rods. In the absence of any practicable plan, locomotive builders do not pretend to put them in running balance; the result is, the machine rocks and noses around, and delivers trip-hammer blows to the rails at each revolution of the drivers. In electric locomotives, Mr. Stephen D. Field and the writer have independently demonstrated certain advantages, and the practicability of driving connecting rods from their centres without intervening driving rods; we have all of the advantages of the connecting rod, (some of which are important ones) and at the same time avoid the destructive effects referred to which have haunted locomotive builders for the past seventy years.

JOHN C. HENRY.

NEW YORK, Sept. 3, 1892.

A CANADIAN POWER TRANSMISSION PROJECT.

WHAT will probably be the first attempt to use power from Niagara on a large scale and at long distances is likely to materialize here very shortly.

A company has been formed with a capital of $3,000,000 to construct some 200 miles of electric railway in distances of 25 to 60 miles, and to supply light, heat and power to the towns and cities along each line. It is intended to make Hamilton the centre of the system and bring the power here at a very high voltage, possibly 25,000, which is recommended by Messrs. Brown, Boveri & Co. after their experience at Lauffen Falls.

The company will, as far as possible, use existing roads, fencing off what is required for single tracks and using large trolley cars and trailers. The lines have been partly surveyed and it is expected that the whole system can be completed early next summer. Considerable attention will be devoted to the supply of power for manufacturing, and they will also endeavor to introduce it largely for cooking and heating.

JOHN PATTERSON.

HAMILTON, ONTARIO, Aug. 30, 1892.

HOW TROLLEY ACCIDENTS HAPPEN.

IT was on a Back Bay car. At —— street she stopped the car, and, upon reaching the crowded platform, attempted to get off on the wrong side. "The other side, madam," said the conductor. "I want to get off on this side," she insisted. "You can't do it, madam," was the reply. "Conductor!" she exclaimed indignantly, "I want to get off on this side of the car." Whereupon the polite official of the West End, in a loud voice, remarked, "Gentlemen, please stand aside and let the lady climb the gate." —*Boston Transcript.*

Street Railways; their Construction, Operation and Maintenance. A Practical Handbook for Street Railway Men. By C. D. Fairchild. 426 pp. 9 x 11½ inches. Price, $4. Illus. New York: 1892. *The Railway Publishing Co.*

THE transportation of passengers from point to point within the limits of a city in a convenient manner and at a cost which will enable all to avail themselves of the facilities offered is by no means a problem easy of solution. The fundamental principles, indeed, are simple enough, but the comparatively recent adoption of street railways shows that it required considerable hardihood on the part of their promoters to convince the public, and especially the investing public, of their financial feasibility. It is scarcely thirty years ago that the first street railway or tramway, in the true sense of the word, was put in operation, yet we need only point to the record of work in this country alone to illustrate the favor with which street railways are looked upon by the public at large. But thirty years have also brought about a remarkable change in the engineering character of street railways. The horse road, which for over twenty years practically had no competitor, is gradually being supplanted by other systems, and a record of the conditions of the art as it exists to-day presents a most varied and interesting picture. In the work before us the author has treated the subject in the broadest sense, giving first a very comprehensive view of the actual methods employed, and then entering into many details of the construction and the management of roads, which are here probably brought together for the first time.

The importance which the electric system of street car propulsion has now attained probably justly entitles it to first consideration, and hence we find the author introducing his work directly with a description of this system in a very brief but clear outline of the principles underlying the generation of the electric current in the dynamo. This is followed by a description of the machines most generally employed for that purpose at present, and he then takes up the method of conducting the current from the power house to the car. There is also introduced a description of the various types of poles and overhead construction. The return circuit also receives very thorough treatment, the author describing the various methods of bonding with the different types of rail employed. That most important detail, the overhead line, is next taken up in order and the various types of insulators and brackets for the suspension of the overhead system are very fully described, together with the method of their erection.

The author then turns his attention to the various types of motors in general use and their method of mounting on the truck, with the electrical connection generally employed. At this point, also, is introduced the subject of storage battery traction, the main features of which are described. The author then passes to the power house, giving a full description of the methods of construction adopted in some of the best stations in the country, including both the motive power and the switchboard arrangement. This chapter is very appropriately brought to a close by an excellent résumé of the proper methods to be adopted for maintaining an electric railway in good condition, a subject which ought to be thoroughly impressed upon all electric street railway managers. In this section on electric traction the author is naturally limited by space to the enumeration of the most essential details. but it would seem that a mention, however brief, of the work accomplished in conduit railways, such as that now in operation at Budapest would have added to the completeness of this chapter. But the author had to "shut down" on new copy at some point or other.

In the chapter on cable traction which follows we find a very thorough discussion of the methods of street railway construction which have proved most successful; and which is followed by that important detail, the grip. The cable itself is next taken up and the various methods of splicing are described. The driving machinery is very thoroughly treated, and some of the arrangements adopted in the largest cable installations are described. The other details which go to make up successful cable traction, such as the type of rope, etc., are given, and the chapter closes with a brief review of the cost of cable road construction and operating expenses, which affords a basis for interesting comparison with similar data in electric railway work.

But while electric and cable traction are rapidly supplanting all other methods the author has not lost sight of the fact that there are still a large number of horse roads in operation, and hence their consideration in this work is eminently proper. Special stress is laid upon the proper selection of animals, and the results of long experience in this particular field are given by the author. He then passes on to the best method of feeding, stabling and general care of the animals, and the proper design of car houses and stables. Steam, air and gas motors are next taken up and described in a short chapter, in which we find the most important of these types of locomotives described. Following this are chapters on inclined planes, rack rail inclines and elevated roads, in which various details of construction of these types are very fully dealt with. The author next devotes considerable space to the subject of car building, a most interesting chapter, and one which is full of practical hints and suggestions. The roadbed or track construction, upon which the success of every type of road must depend, has justly been accorded a chapter by itself, in which we find descriptions of the principal types of rails employed and the method of their laying on roads of different types. The subject of curve construction and crossing is also gone into with considerable fullness. Discipline and rules and the book-keeping and classification of railway accounts form the subject-matter of the next two chapters, and, if thoroughly carried out, will benefit both the stockholders of the railway as well as the traveling public. For those intending to enter into the field of street railways, the chapter on charter, franchise, stocks and bonds will prove exceedingly valuable. The work is brought to a close with a large number of illustrations of the leading types of cars now in general use, and with a description of the thousand and one auxiliary appliances required in the equipment of street railways, such as track tools, fare registers, car heaters, lamps, brakes, etc.

It has evidently been Mr. Fairchild's aim throughout to place the subject-matter before the reader in such a manner that even those little versed in technical matters will be able to gather a correct understanding of the various systems, and to form an opinion of their relative merits viewed from both a mechanical and a commercial standpoint. The illustrations throughout are admirable, and, together with the lucid text, make this the best compendium on the subject extant. Mr. Fairchild and his publishers are to be congratulated.

Fourth Annual Report of the Department of Public Safety, City of Pittsburgh. Year ending Jan. 31, 1892.

A most interesting volume, full of valuable statistics and data as to city work.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED AUG. 30, 1892.

Accumulators:—

Secondary Battery, W. W. Griscom. Haverford College, 481,560. Filed Nov. 16, 1891.

Employs plates having perforations extending therethrough, and having two opposite concave walls.

Alarms and Signals:—

Auxiliary Fire Alarm System, J. Sachs, New York, 481,590. Filed Mar. 29, 1892.

A system by means of which an alarm can be sent from an auxiliary box at any distance from the street fire alarm mechanism.

Signal Timing Apparatus, H. A. Chase, Boston, Mass., 481,618. Filed May 11, 1892.

Employs a recording apparatus situated in a local circuit controlled by a relay included in the main line circuit.

Electric Door Alarm, M. W. Bessey, Waterville, Me., 481,711. Filed Nov. 14, 1891.

Fire Alarm Telegraph, A. J. Coffee, Portland, Ore., 481,847. Filed May 12, 1892.

Employs an automatic and permanent lock for the auxiliary box mechanism of a fire alarm system.

Electric Guest Call, F. Benner, Minneapolis, Minn., 481,919. Filed Oct. 26, 1891.

Conductors, Conduits and Insulators:—

Pipe Insulator, G E. Dixon, Chicago, Ill., 481,899. Filed Mar. 1, 1892.

Conduit for Electric Conductors, A. Noll, Mt. Vernon, N. Y., 481,912. Filed Aug. 28, 1892.

Consists of metallic tube sections enclosed in coverings of insulated material, there being tubular insulated material forming the connection between each tube section.

Conduit for Electric Conductors, A. Noll, Mt. Vernon, N. Y., 481,913. Filed April 28, 1892.

Similar to 481,912.

Electric Circuit Connection, A. Noll, Mt. Vernon, N. Y., 481,914. Filed Apr. 28, 1892.

Employs tubular metallic conduits enclosed in insulated material junction boxes and metallic clips for receiving the ends of the conduits, and electric connections to such clips.

Distribution:—

Electric Lighting System, P. Cravath, Whitewater, Wis., 481,785. Filed May 31, 1892.

Employs a main circuit leading from the source of energy, a series of branch circuits each containing lamps, and a multiple switch between the main and branches by means of which the number of branch circuits in use is limited.

System of Electric Lighting, E. Huber, New York, N. Y., 481,904. Filed Oct. 7, 1891.

Relates to a system of distributing electric power throughout a system of light or motor circuits in such a way that the energy used up in the circuits is reduced to a minimum with a maximum effect.

Dynamos and Motors:—

Electric Fan, F. H. Beers, Newark, N. J., 481,646. Filed Feb. 26, 1892.

Claim 1 follows:

An electric fan having the blades attached to a revolving shell, encompassing the driving motor.

Electric Motor or Dynamo-Electric Machine, R. Lundell, Brooklyn, N. Y., 481,701, Filed Mar. 14, 1892.

Claim 1 follows:

An electric motor having a rotary armature and two overlapping field magnet poles all surrounded by a single field magnet coil,

Electric Motor and Regulating Device therefor, F. J. Sprague, New York, 481,739. Filed Apr. 29, 1889.

Employs two regulating commutators connected in multiple arc, each provided with contacts and circuits for varying the mechanical effects of the motor.

Device for Removing Armatures, S. H. Sharpsteen, Honesdale, Pa., 481,833, Filed May 6, 1891.

Consists of a track extending between the field magnets of the dynamo and two connected hangers adapted to travel upon the track and to engage with the armature shaft.

Dynamo-Electric Machine, W. S. Andrews, New York, and T. Spencer, Philadelphia, Pa.; reissue, 11,266 Filed July 11, 1892.

Claim 1 follows:

In a dynamo electric machine, the combination of the armature, the generating coils thereon, the field magnet and the external stationary coils supported upon said field magnet and wound so as to oppose the magnetizing effect on the armature core of said generating coils.

Galvanic and Thermo-Electric Batteries:—

Galvanic Battery, W. J. Engledue, Byfleet, Eng., 481,664. Filed Mar. 23, 1892.

A reversible galvanic battery having a liquid-tight case and a locking device therefor.

Lamps and Appurtenances:

Duplex Arc Lamp, C. E. Scribner, Chicago, Ill., 481,677. Filed July 3, 1888.

Employs a single electromagnetic device for controlling a cut-out with its coil included in circuit, with one set of carbons and its armature and back stop in circuit with the other set.

Extension Chandelier, F. Overholt, Harlan, Iowa, 481,814. Filed May 31, 1892.

Measurement:—

Voltameter, F. A. La Roche, Ph., 481,573. Filed Sept. 1, 1891.

Operated by means of repulsion between two electromagnet cores magnetized by the passage of the current to be measured.

Miscellaneous:—

Apparatus Generating Ozone, C. C. Sharp, Chicago, Ill., 481,676. Filed Sept. 18, 1891.

Consists in applying one terminal of the generator to the body, maintaining the other terminal out of contact with the body, generating ozone at the non-conducting terminal and closing the circuit between the ozone generating terminal and the body by the current of ozonized air.

Method of and Apparatus for Extracting Gold and Silver from their Ores, J. W. Aylsworth, Orange, N. J., and A. C. Payne, Elizabeth, N. J., 481,683. Filed July 3, 1891.

Electric Cigar Lighting Lamp, W. J. Eastman, Waterville, N. Y., 481,692. Filed Feb. 8, 1892.

Electrically Driven Machinery for Cutting Coal. L. B. Atkinson and C. W. Atkinson, London, Eng., 481,775. Filed Aug. 18, 1891.

Employs a revolving ring carrying the cutting tools and having beveled geared teeth in combination with two rigid bearing plates covering the beveled teeth and between which the tool ring is journaled.

Electrically Controlled Stop Motion for Knitting Machines, V. S. Clute, Cohoes, N. Y., 481,726. Filed Oct. 28, 1891.

Rheostat, C. E. Carpenter, Minneapolis, Minn., 481,781. Filed Feb. 18, 1891.

Employs a rib base plate provided with a coating of enamel in which are embedded the resistance coils.

Electric Central Clock, N. Prokhoroff, Kiev, Russia, 481,916. Filed Sept. 4, 1891.

Railways and Appliances:—

Trolley Carriage for Conduits, S. L. Platt, Elgin, Ill., 481,817. Filed June 18, 1891.

Consists of a wheeled carriage adapted to be engaged by the car hanger and a contact wheel journaled in spring pressed bearings held in the carriage.

Magnetic Brake, A. de Bovet, Paris, France, 481,842. Filed Oct. 24, 1891.

Electric Railway, R. M. Hunter, Philadelphia, Pa., 481,905. Filed Sept, 21, 1891.

Employs a slotted conduit and current-collecting device, having a rearwardly extending pivoted arm making connection with the under side of the conductor.

Switches and Cut-Outs:—

Lightning Arrester Cut-Out, J. P. Freeman, Washington, D. C., 481,617. Filed Dec. 24, 1891.

Employs a magnetic needle alternately opening and closing the connection between the main line and the ground.

Ceiling Rosette Cut-Out, J. Pass and A. P. Seymour, Syracuse, N. Y., 481,-624. Filed Mar. 21, 1892.

Has for its object to simplify and cheapen the construction of cut-outs, etc., and provides means for the renewal of the fuse without the necessity of detaching any of the parts.

Safety Attachment for Electric Conductors, R. Furgang, Boston, Mass., 481,665. Filed Jan. 18, 1892.

An automatic cut-out for overhead trolley systems.

Safety Attachment for Electric Conducting Wires, R. Furgang, Boston, Mass., 481,666. Filed Jan. 25, 1892.

Similar in its object to 481,665.

Telephones and Apparatus:—

Multiple Switchboard Telephone Exchange System, C. E. Scribner, Chicago, Ill., 481,678. Filed Nov. 22, 1889.

Invention relates to bridging the annunciator across the two sides of the metallic circuit and to a switch in the circuit of the test battery; the circuits and connections being so arranged that when a plug is lifted the test battery will be connected to indicate the busy test.

Telephone Exchange, C. E. Scribner, Chicago, Ill., 481,679. Filed Nov. 16, 1891.

Employs branch circuits each including a retardation coil and a set of plugs with double stranded cords for each branch circuit and a clearing-out annunciator and condenser in a bridge wire between the strand of each set of cords.

System of Telephony, Elihu Thomson, Swampscott, Mass., 481,878. Filed Feb. 15, 1892.

Employs an alternating current of such low rate of alternation as not seriously to interfere with speech, in place of a continuous current.

Coin Signal Sounding Device, C. W. Holbrook, Windsor Locks, Conn., 481,903. Filed Nov. 28, 1890.

A sounding device for "nickel in the slot" telephones.

TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

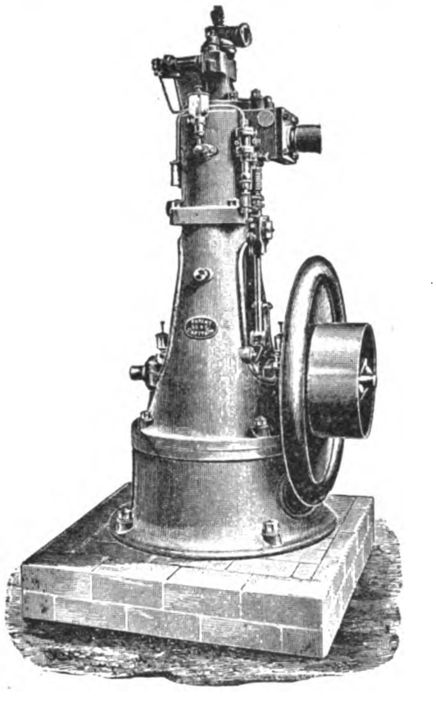
Advertising is rapid transit between buyer and seller.

THE GROB PETROLEUM ENGINE FOR ELECTRIC LIGHTING.

CONSIDERING the extent to which electric lighting increases every year, it may be of some interest to learn of a new type of engine which, through its special qualities, is rapidly coming to the front to drive dynamos.

The Grob engine is operated by ordinary petroleum, and has numerous advantages, particularly in regard to its application as an electric lighting engine.

The engine, which is illustrated in the accompanying engraving, is of comparatively small size, and therefore requires very little floor space, and is especially adapted for private residences and shops. Although being exceptionally light, so that it may be set up anywhere without special foundations, it is of solid and simple construction and massively and neatly built. The regulation is effected automatically, and in a very economical way.



THE GROB PETROLEUM ENGINE.

The motor does not require any special attendance, and is absolutely safe.

Special attention may be called to two important advantages of this motor; the easy operation without any strain and the quiet running, which both make this engine appropriate for using it in private houses as well as in other places, where vibration is not permissible. As the motor is able to work without belt, it is as a rule directly attached to the dynamo. Another important advantage is the fact that no licensed engineer is required to take care of the engine.

The cylinder is kept very cool with a small supply of water by application of a novel ventilator-refrigerator.

The engine, as constructed by J. M. Grob, of Liepzig, varies from 1 to 10 h. p; the dimensions of the 4 h. p. machine are as follows:

Height...	5 feet 10 inches;	diameter of pulley,	12 inches.
Breadth...	3 " 10 "	breadth "	5 "
Depth.....	3 " 7 "	number of turns per min.,	300

The weight of the whole motor, including all spare parts and packing, is about 1,980 lbs. The running expenses are exceptionally small and depend naturally on the price of petroleum. Based on a price of 10 cents per gallon, these expenses per 1 h. p. per hour amount to ¾ cent.

The engine will, in all probability, be exhibited at the World's Columbian Exposition at Chicago, and full information regarding it can be obtained from Mr. Maximilian Mintz, the agent for it in this country.

THE DARKY AND THE SOCKET.

MR. L. S. GREENSFELDER, vice-president of the Ries Electric Specialty Company, of Baltimore, Md., relates an amusing incident which occurred a few weeks ago. While sitting in the lobby of one of the principal hotels in the South, where the incandescent light was directly over the desk, at which he was writing, he quietly slipped a Ries regulating socket, which he had attached to a plug, into the old-time socket which was in use. He then called the porter, and told him to "please turn that light down a little, it is too bright and hurts my eyes." The colored porter smiled in delight and answered—"Boss, you ain't up to the times, dat ain't no gas light, dat is 'lectricity! and you can't turn it down, like gas." Mr. Greensfelder then politely said: "Coon, you are crazy, why of course you can turn it down," and no sooner said than done, Mr. G. arose and turned the key of the Ries socket down a peg or two and had a very nice light to suit his eyes. When the colored porter saw this, he said: "Look yar, boss, is you a magic man, or is dat a new kind 'lectricity?" Mr. G. then explained the new device. The colored porter smiled and said, "Look yar boss, I is going to make some money out 'a dat, I gone to go and get the head waiter, and bet him I can turn dat light down like gas. He of course will take the bet and I will take his money." Whereupon the porter silently went to look up the poor head waiter. Now comes the fun. While the porter was gone, Mr. Greensfelder withdrew the Ries regulating socket and plug from the old-time socket, putting them in his pocket, and replaced the lamp in the old socket which was in regular use at the hotel. In a few minutes the porter strutted in with his innocent prey (as he thought), the head waiter. "Look yar, Silas, I bets you forty cents I can turn dat 'lectric light down same as gas!" Whereupon the head waiter said, "Mose, you is gone crazy." "No, sir, I is not crazy, put up your forty cents and I shows you if I is crazy." The head waiter felt that he had a snap and put up his forty cents. Whereupon Mose tried to turn the light down as Mr. Greensfelder had done with the Ries regulating socket, and to his utter dismay, he of course turned it out every time; as nothing else can be done with the old-time sockets. Well, he tried time andtime again, but with no better results. He then turned about six shades whiter, and said, "Silas, I done lose de money. I guess dat man (meaning Mr. Greensfelder) only mesmerize me before, and make me believe I see him turn it down." Mr. G. then states that he quietly pulled the lamp out of the old socket, while the two colored gentlemen were arguing, and slipped his plug and Ries regulating socket again into the old socket, and the slick waiter was asked if he would bet again. He said, "Why, boss, dat is a snap." Mr. G. said, "Put up your money, Silas." When Mr. G. slowly with the aid of the regulating socket, turned the light up and down; poor Silas looked in dismay, and said to the little crowd which had gathered, "Gem'men, I'se done up, no tellin' what 'lectricity is gone a do for this world yet."

This little incident, however, caused the hotel proprietor to adopt the Ries regulating sockets throughout his house, he stating at the same time, that it was exactly what he had long been awaiting. Thus ended a little joke, by making a very nice sale.

THE BOYNTON BICYCLE RAILROAD.

AT the annual meeting of the Boynton Bicycle Railroad, the following board of directors was elected: Dr. James B. Bell, George Haseltine, D. C. Reusch, E. M. Boynton, William A. Stephens, David Wallace, W. H. Boynton, James D. White, C. A. Varney, F. H. Osgood, I. B. Watkins, H. W. Mawhinney, E. L. Sanborn, I. B. Newcombe, R. D. Evans, George Hagerman, W. H. Thurber, F. W. Dunton, M. C. Baker, O. M. Wentworth and Gen. O. O. Howard.

E. Moody Boynton was re-elected president and treasurer, and the other officers chosen were Dr. James B. Bell and F. H. Osgood, vice-presidents; W. H. Boynton, secretary, and D. C. Reusch, assistant secretary.

President Boynton in his report said that during the year patents had been obtained for seven inventions that will be used by the road, and among them were one for an electric locomotive and others for bicycle passenger and palace coaches. A general electric company was formed during the year with a capital stock of $5,000,000 under the control of the bicycle company and with the same officers.

The object of this company is to furnish this system of road with electricity as a motive power. The report further showed that during the year several companies had obtained charters to operate roads of this character in different parts of the country. The president assured the stockholders of the ultimate success of the principle of locomotion which this company is endeavoring to introduce.

One of the roads referred to is between Brooklyn and Bellport, L. I., and the other is between Aurora, Ill., and Chicago.

PURITY OIL FILTER MANUFACTURING COMPANY.

THE summer dull season has no terror for Mr. Albert C. Darragh, the general manager of the Purity Oil Filter Manufacturing Company of Pittsburgh, Pa. Mr. Darragh reports the following list of people to whom, among others, he has made sales during the month of August alone:

Homestake Mining Co., Lead City, S. Dak.; Tennessee Manufacturing Co., Nashville, Tenn.; Union Mill Co., Nashville, Tenn.; House of Refuge, Glens Mills, Pa.; E. H. Kellogg & Co., New York City; Farmers' Union and Milling Co., Stockton, Cal.; F. & R. Lazarus & Co., Columbus, Ohio; Southern Pacific Railway Co. Shops, Sacramento, Cal.; Victoria Brewing & Ice Co., Victoria, B. C.; Alaska Treadwell Gold Mining Co., Alaska; Leland Stanford, Jr., University, Mayfield, Cal.; Santa Cruz Electric Light & Power Co., Santa Cruz, Cal.; Mt. Pleasant (Pa.) Electric Light Co.; T. H. International Electric Co., London, Eng.

The success of the Purity Oil Filter Manufacturing Company, and the satisfaction given by its Ideal steam oil refiner can perhaps be no better shown than by the increasing number of voluntary testimonial letters being received by the company. Among recent letters of this nature is the following:

DOYLESTOWN, PA., August 18, 1892.

PURITY OIL FILTER MANUFACTURING Co.,
Pittsburgh, Pa.

Gentlemen.—We are very much pleased with the Ideal steam oil refiner purchased of you. It does all you claim for it.

Yours truly,
(Signed) JOHN YARDLEY,
Secretary Doylestown Electric Co.

GRAMME ARMATURES IN STATION GENERATORS.

WITH regard to Mr. L. E. Marple's article in THE ELECTRICAL ENGINEER of August 31 on "Some Advantages of Gramme Armatures in Station Generators," Mr. F. A. Scheffler, the superintendent of the factory of the Brush Electric Co., writes us:

"This article bears out fully the operation of Gramme ring armatures, such as have been used by the Brush Company ever since its existence. As this company has never made any other kind of an armature the results obtained by them with the Gramme armature show conclusively that it is only because the armature can be and is so thoroughly ventilated as to produce a long life in the bobbins of armatures. There are hundreds of armatures in daily use of this type which were made ten years ago and are still running with the same winding on them. I know of no other type of armature which can show such a record as this. All generators manufactured by this company also have this form of an armature. The bobbins on same have very few layers of wire, and are, therefore, easily repaired should an accident occur. The fact of there being very little wire on the armatures per bobbin also permits quick radiation of heat, and the life of the insulation is greatly prolonged thereby."

Mr. H. F. Parshall, of the Thomson-Houston Electric Co.'s factory, at Lynn, writes:

"The remarks of Mr. Marple do not apply to the style of drum winding at present used by this company. The drum armatures with the bifurcated end conductors are more easily ventilated, easier to repair and less liable to give trouble than the Gramme type of armature. The use of the bifurcated end conductor makes it possible to replace any particular bar without disturbing any other. It also leaves these conductors thoroughly ventilated on both sides since there is a good-sized air duct between the end conductors and the core of the armature. The core of the armature is ventilated by means of several ducts arranged in planes perpendicular to the axis of the armature. By experiment it has been found that the ventilating capacity of an armature of this construction has been doubled over that of the ordinary Gramme construction. I should say, therefore, that qualifying terms should be used in this article to distinguish between the new and old types of drum winding."

NEW YORK ELECTRICAL ENGINEERING CO.

THE contract for the construction of four miles of electric railway in Montgomery, Ala., has been awarded to the New York Electrical Engineering Company of 206 Broadway, New York City. Westinghouse apparatus will be used. The New York Electrical Engineering Company's contract is for the complete installation and equipment of the road.

AN OLD COMPANY IN A NEW HOME.

THE STEUBEN LAMP WORKS, formerly of Hornellsville, N. Y., are now settled in their new factory at Canisteo, N. Y. The new home of this company is a modern building with a frontage of 96 x 80 feet, and has an isolated flashing house and storeroom. The main building is three stories high, with unexcelled light and ventilation. They have just placed in position three large steel boilers of the Erie type, and two 75 h. p. high speed automatic engines and have a capacity of 1,500 lamps per day. The company are in a position to make prompt shipments of all orders with which they are favored. They are, also, not only willing but anxious to send free sample lamps to all responsible persons desiring them.

NEW YORK NOTES.

THE BISHOP GUTTA-PERCHA CO., 420-426 East Twenty-fifth street, this city, have just issued a new illustrated catalogue and price list of their insulated wires and cables for all classes and conditions of service. The record of the company is a long and honorable one. They started in 1847, and yet some of their earliest work stands to this time, just as some of their work of to-day promises to be in use forty five-years hence. Not only does the catalogue contain all the necessary data as to Bishop, Balata, etc., but it embodies a variety of useful information. It also includes a number of striking testimonials as to the high qualities of these wires and cables in submarine, overhead, central station, underground and all other branches of work. There can be no question that as regards, for example, high tension underground work, the Bishop cables have stood up most remarkably in New York, Philadelphia and other cities.

MR. GEORGE A. FORD, of the Ford-Washburne Storelectro Co., of Cleveland, O., has been spending the week in New York City in connection with storage battery business. The remarkable results shown by their battery have called attention to it very generally. Its robust construction, as evidenced by an ability to give up 300 and 400 amperes on short circuit a number of times without any injury whatsoever, is regarded as opening up a new and better era in electric storage traction. It is claimed that the battery does what was impossible with the old plate, by virtue of its great capacity and its remarkable endurance, and that it is the desideratum in its field.

THE ELMIRA ELECTRIC ILLUMINATING CO. are building a new plant at Elmira, N. Y., and have placed the contract for the iron roofs with the Berlin Iron Bridge Co., of East Berlin, Conn. The dynamo-room will be 66 feet wide by 177 feet long, covered with the Berlin Company's patent anti-condensation corrugated iron roofing—the floor space being controlled by a ten-ton traveling crane. The boiler-room will adjoin the dynamo-room and will be 82 feet wide by 75 feet long. When completed, this will be one of the finest electric light plants in New York State.

THE SPERRY ELECTRIC CO. have opened offices at 29 Broadway to introduce an electric motor and trolley system which is said to have given remarkably good results at Youngstown, O., where it has been in operation for nearly a year. The car has but one motor, flexibly suspended, quite noiseless, and there are various improved devices in the trolley arrangements.

MR. EDWIN G. REYNOLDS, until recently the steward of the New York Electric Club, has assumed charge of the Eastern office of the *Street Railway Gazette*, in the Electrical Exchange Building, Liberty street. He will represent that paper in the East, and needs no introduction to electrical circles.

MR. THOMAS ROBINS, JR., the patentee of a novel form of conveyor belt for concentrating plants, is now established at 120 Liberty street, this city. Some of the belts invented and sold by Mr. Robins have been subjected to the severest tests, and all, so far as heard from, are giving perfect satisfaction.

P. CLAUS & CO., the electrical engineers and contractors, dynamo builders, etc., have equipped a factory for constructing their dynamos and motors, etc., at 357 West Fortieth street, where they will also have their offices. They are very busy, and are getting plenty of new orders.

DR. SCHUYLER S. WHEELER and his wife have recently been touring in the north of Germany, and it will be a great relief to their many friends to know that they have been heard from in Switzerland and are well. They start at once for home, and will receive a warm welcome.

NEWTON L. SCHLOSS AND G. J. SCOTT of the Ries Electric Specialty Co. were New York visitors last week and favored this office with a call.

CANADIAN NOTES.

THE CANADIAN GENERAL ELECTRIC COMPANY, LIMITED, has acquired the business and interests in Canada of the Edison General Electric Company, the Thomson-Houston International Electric Company, and the Toronto Construction and Electrical Supply Company. The Canadian General Electric Company will now have control of the entire Edison systems, including the Edison factory at Peterboro, the Wood arc light system and the systems controlled in Canada by the Thomson-Houston International Electric Company. To meet the extensive requirements of such a consolidation, this company has applied to the Canadian Parliament for authority to increase its capital from $1,000,000 to $2,000,000.

HARRISBURG IDEAL ENGINES.

The Harrisburg Ide and Ideal engines built by the Harrisburg Foundry and Machine Works, Harrisburg, Pa., are in demand among the electrical and manufacturing interests of the country. The following engines are being prepared for shipment in the next few days: One 16 x 16, one 13 x 12, one 10 x 10 Ideals for Chillicothe Electric Railway; four 12 x 12 Ideals to be used in connection with the Wadell-Entz Electric Co., in New York; three 12 x 18 standard Ide engines for Hartford, Conn.; one 11 x 12 and one 7 x 10 for the Racquet Club, New York; two 16 x 16 Ideals for a New York City apartment house; one 14 x 20 standard Ide for Perth Amboy, N. J.; one 9 and 15 x 12 Ideal compounds for California; two 9 and 15 x 12 Ideal compounds for the Pennsylvania State Insane Hospital; one 9 and 15 x 12 for the Mt. Pleasant Steam Printery. These engines are all for shipment in the next 10 days or two weeks.

They are also just shipping ten 100 h. p. steel return tubular boilers for a hollow ware company. These boilers are equipped with the Weitmyer furnace, which will increase their efficiency at least 10 per cent. The company have just furnished ten 100 h. p. boilers for the Central Iron Co., Harrisburg, equipped with the same furnace. They are also setting two large boilers for the Alexandria Street Railway Company. Besides these orders, the company have work ahead for some three months and are compelled to work night and day.

WESTERN NOTES.

The "Electra."—On Saturday evening, Aug. 27, Gen. C. H. Barney, the manager of the Electric Launch and Navigation Compady, of New York, invited the representatives of the electrical press of Chicago to take an evening sail on the lagoons of the World's Columbian Exposition on the electric launch "Electra." Several ladies were among the party, and the "Electra" performed its work to perfection, showing the superiority of electricity as a motive power for launches, and every one was charmed with the boat. During the two hours' sail light refreshments were served, and a most enjoyable evening was spent by all.

The General Electric Company have recently secured a contract, against keen competition, whereby they are to supply to the Cass Avenue Street Railway Company, of St. Louis, Mo., 85 cars, each equipped with two 25 h p. motors of the well-known Standard W. P. type, three 800 h. p. direct-coupled railway generators at a speed of about 90 revolutions. By this purchase by the Cass Avenue Company, the entire system of electrical railroads in St. Louis is now solely equipped with apparatus manufactured by the General Electric Company.

The Midland Electric Works, of which Mr. Ray Griggs is president, and Mr. C. F. Sammis, secretary and treasurer, are doing a general electrical construction and repair business at No. 224 East Washington street, Chicago. They also make a specialty of model and experimental work of electrical devices and machinery of all kinds, and have excellent facilities for giving the best satisfaction in work of this class.

The Chicago and St. Louis Electric Railroad Co., which proposes to operate a road between the two cities with 15 ton cars at a speed of 100 miles an hour, has issued an elaborately illustrated folder, giving pictures of the proposed road, terminal depots, and apparatus. This company's bold project has already been described in The Electrical Engineer, and its progress will be watched with intense interest.

The Electrical Appliance Company have just received their first consignment of security cleats which are meeting with ready sale. The Security cleat and Security insulator are the latest specialities in the direction of higher grade electrical construction, and will receive a hearty welcome from every electrical engineer who is looking for improvement in the present methods of electrical installation.

George A. McKinlock, treasurer of the Central Electric Company, nothing daunted by cholera reports, has gone abroad for a month on his vacation and will visit Ireland and Scotland, besides going to London and Paris in a semi-business capacity for his company.

Prof. G. D Shepardson, of the electrical engineering department of the University of Minnesota, was married, on August 31, at Kings Mills, Ohio, to Miss Harriet Bowker King, and has now returned with his wife to Minneapolis to resume his work at the university.

Mr. R. Fleming, electrical engineer with the Rockford Electric Manufacturing Company, of Rockford, Ill., visited Chicago during the past week, and found time to drop in at the Western office of The Electrical Engineer.

The Central Electric Company are doing a very brisk business in all lines of general electrical supplies and Okonite wire is having a run as usual.

The Acorn Lamp.—The high grade that has been maintained by the Sunbeam Incandescent Lamp Company in their Sunbeam lamps has been shown very conclusively by the large and increasing business the company are doing. Attention is called to the announcement in our advertising columns this week of their "Acorn" lamp made in all colors for display lighting.

NEW ENGLAND NOTES.

S. C. Nightingale & Childs, of Boston, have recently furnished a quantity of their well-known Magnesia sectional covering to the Edison Electric Illuminating Company of Boston, for a rather novel purpose. The Edison Company had occasion to use insulated cables underneath one of the many bridges crossing one of the steam railroads of Boston. These cables connecting their regular underground system on either end of the bridge, were exposed to the escaping steam and hot gases from locomotives which are in the habit of standing directly under the bridge, and were in danger of having the insulation entirely melted or burned off. Recently the cables were all covered with Magnesia sectional covering, which has completely obviated all danger, and thoroughly prevents any of the steam or hot gases from coming in contact with the insulation.

The Beacon Vacuum Pump and Electrical Company, of Boston, are calling the attention of the trade to their new and revised price list recently issued. The demand for the Beacon lamp has been constantly increasing all summer, and a recent visit to their factory showed that they were manufacturing as many lamps as their floor space would allow, and presented a very busy and interesting scene. It is expected that within a very few weeks much larger facilities will be procured, and the Beacon lamp will be manufactured in even larger numbers than before.

The Shawmut Fuse Wire Company, of Boston, have issued a neat little catalogue of their manufactures, calling the attention of electrical dealers to their tested fuse wire and links, and presenting in an interesting way a lot of valuable information regarding the fusing point of fuse wires. The pamphlet is well illustrated and brings out the necessity for using an accurately tested fuse wire for good and safe work. It will be found very useful to all constructing electrical engineers as well as central station managers and electrical supply dealers.

The Bradbury-Stone Storage Battery Company, of Lowell, Mass., are extremely busy with their fall business, and are receiving large orders for their well-known storage battery for use in phonograph, lighting, signaling and all kinds of work where electricity is required. Their battery appears to have given immense satisfaction in phonograph work, and they are in receipt of many letters from users giving the warmest kind of unsolicited testimonials, of which they may be justly proud.

The Westinghouse Electric and Manufacturing Company, through their Boston office, have closed a contract for the electric equipment of the street railway of the Sanford Electric Railway Company, of Sanford, Me., the railroad to be in operation by October 20th, 1892. The equipment consists of one 100 h. p. generator, two passenger cars and one electric locomotive for hauling freight.

Messrs. Brown & Sharpe's illustrated catalogue for 1892 contains about 250 pages of descriptive matter concerning their well-known specialties. The book is of a convenient size, 5¼ by 3¼ inches, and as usual, contains a great quantity of valuable information on mechanical and engineering subjects.

PHILADELPHIA NOTES.

The Helios Electric Co. recently incorporated under the laws of Pennsylvania for the manufacture of electrical apparatus, supplies and appliances, is composed of some of the best-known electrical men in the East. Its incorporators are: D. C. Spruance, Frank S. Marr, Thomas Spencer, John C. Corbit, Jr., and Thomas J. Johnson. They will start in business with a well equipped factory occupying the entire sixth floor of the new Clark & Dunlap Building, 13th and Filbert streets. It is understood that they will make a specialty of a new arc lamp.

Mr. C. L. Crosby, well known in electrical circles, has associated himself with the Commonwealth Electric Co. He will devote most of his time to soliciting and outside work.

The Gibson Gas Fixture Co. has, in order to accommodate its rapidly increasing Western trade, established a Western branch at 171 South Canal street, Chicago, Ill.

☞ ***Departmental items of Electric Light Electric Railways, Electric Power, Telegraph, Telephone, New Hotels, New Buildings, Apparatus Wanted, Miscellaneous, etc., will be found in the advertising pages.***

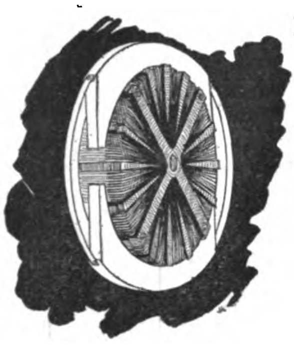
THE
Electrical Engineer.

VOL. XIV. SEPTEMBER 21, 1892. No. 229.

THE GENESIS OF THE MODERN DYNAMO: ANTONIO PACINOTTI.—I.

BY

Franklin Leonard Pope



OF the dynamo-electric machine, using the term in its broadest signification, as defined by Silvanus Thompson—that of a machine for converting energy in the form of mechanical power into energy in the form of electric currents, or *vice versa*, by the operation of causing conductors to rotate in a magnetic field[1]—it is not too much to say that it seems inevitably destined in the future to occupy a position in the industrial world, certainly not less important, possibly far more important, than does the steam engine at the present day. The historic experiments of Faraday, interpreted in the light of the mathematical researches of Maxwell, and still further elaborated by the persevering and painstaking investigations of Crookes, have proven almost to a demonstration that the whole vast universe is filled with an all-pervading ether, and that the phenomena of light and heat, electricity and magnetism, force and motion, and possibly even matter itself, are but the protean manifestations of this infinite essence. If it is true, as the researches of Crookes apparently show, that the molecular forces inherent in the ethereal fluid are incomparably greater than any of those which have as yet been subjected by man, so that perhaps millions of horse-power may be contained within the circumscribed limits of an ordinary room, the time may come, nay almost certainly will come, when we shall discover—as Tesla expresses it—how to "hook our machinery on to the machinery of nature."[2] Should that day dawn upon us, it may well be that the steam-engine and the water-wheel will be relegated to the limbo of historical curiosities, while the dynamo-electric machine will reign supreme as the sole immediate source of power for industrial uses throughout the world.

While the dynamo-electric machine, as it exists to-day—perhaps in respect to its economic efficiency, the highest type of machine ever devised by the mind of man—is the result of a well-defined and continuous process of evolution, almost every step of which has been made within the memory of men of middle age now living, yet when we study attentively the history of this process of evolution, we shall find, as in all similar instances, that among the many successive advances of lesser importance, there are a certain few which the progress of events has demonstrated to have been radical and fruitful innovations upon preexisting practice, and which form, as it were, conspicuous landmarks of progress along the path of invention. First and foremost among these, beyond all question, is the discovery of magneto-electric induction, first made known to the world in the autumn of 1831 by Faraday,[3] but as later researches have shown, independently discovered by Henry at a somewhat earlier date.[4] This was almost immediately followed by the construction of the well-known alternating magneto-electric machine of Pixii,[5] to which the same inventor soon applied a commutator for rectifying or "straightening" the alternate currents.[6] A host of subsequent inventors labored zealously upon this machine, vastly improving it in many of its details, but for a long time developing no new principle of importance. In 1848, Brett made the important and fruitful suggestion that the magnetic intensity of the permanent field-magnets might be augmented by surrounding them with helices of insulated wire through which the current developed in the armature was made to pass.[7] For many years, however, this conception, which we now know to have been the virtual key to the whole problem, lay dormant,

Antonio Pacinotti

and as a necessary consequence, the magneto-electric machine remained little more than a philosopher's toy. In chronological order, the next important step in advance was made by Pacinotti, in the machine constructed by him at Pisa, of which the first description was published in 1864, in which the armature coils were for the first time arranged in parallel in a closed circuit, for the production of a continuous uni-direction current.

Next, in progress of time, rapidly followed the rediscovery and practical application, in 1866, of the principle of auto-excitation first suggested by Brett, but worked out independently and almost simultaneously by Farmer in the United States[8], Varley[9] and Wheatstone[10] in England, and Siemens in Germany[11], and finally the armature construction of Pacinotti—which had, meantime, been independently rediscovered and introduced by Gramme in France in 1871—and the self-excited field-magnets were combined in one machine by Hefner-Alteneck in Germany in 1872,[12] giving to the world the modern direct-current dynamo, with all its wonderful capabilities.

We can clearly see therefore, in the light of the knowledge of to-day, that the essential and fundamental discoveries, which converted the feeble and inefficient magneto-electric machine of the last generation, into the magnificent dynamo-electric machine of to-day, have been really but two in number; first, the endless winding of the armature coils, rendering possible the production of a continuous direct current, and second, the excitation of the field magnets by a current derived from the armature working in the self-same field produced by these magnets.

The story of the first of these achievements has, so far as the writer is aware, never been fully told. It is well worth the telling.

The University of the old Italian city of Pisa is remarkable, not merely for its venerable antiquity, but for the eminence which its scholars, by reason of their researches and discoveries, have attained in the annals of literature and science. In a church not far from the University is still to be seen the suspended lamp, the oscillations of which, according to tradition, served to place in the mind of the illustrious philosopher Galileo, the germ of the conception of the true relation and movements of the heavenly bodies. Near at hand, moreover, is the famed leaning tower of Pisa, which proved to be so singularly well adapted to his needs in the prosecution of his subsequent researches made with the aid of the pendulum.

It would seem eminently in accordance with the fitness of things, that the very locality renowned throughout the world as the scene of the labors of the illustrious founder of experimental philosophy, and the greatest of astronomers, of physicists and of mechanicians, should receive added lustre in the annals of physical science as the birthplace of the continuous current dynamo-electric machine.

In a scientific journal published in Pisa, under the title of *Il Nuovo Cimento*, there appeared in June, 1864, a remarkable article entitled "Descrizione di una Macchinetta Elettro-Magnetica; del Dott. Antonio Pacinotti" (Description of an Electromagnetic Machine of Dr. Antonio Pacinotti.) The historical importance of this communication justifies its reproduction in full, with copies of the original illustrations. We therefore present the following, which is a careful and accurate translation from the original:

In 1860 I had occasion to have a model of an electromagnetic machine of my invention constructed for the Cabinet of Technological Physics of the University of Pisa. This instrument I have now concluded to describe particularly, in order to make known a peculiar kind of electromagnet used in its construction. Besides its novelty, it seems to me suitable for obtaining greater regularity and constancy of action in such electromagnetic machines, while its form appears to be a convenient one for collecting all the induced currents of a magneto-electric machine.

In ordinary electromagnets, even when provided with a commutator, the magnetic poles always remain in the same position, while with the commutator attached to the electromagnet to be described, the poles may be made to move along in the iron subjected to magnetization. The form of the iron in this electromagnet is that of a circular ring. To facilitate a conception of the direction and mode of action of the magnetizing current, let us suppose a copper wire covered with silk wound around our iron ring, as follows: When the first layer of convolutions is completed, instead of continuing the helix by forming the second layer on top of the first, we close the metallic wire by soldering together the two ends. In this way we cover the iron ring with a closed insulated spiral having everywhere the same direction. Now, if we connect two points sufficiently far apart of the metallic wire of this helix with the two poles of a battery, the current will divide itself into two portions and will traverse the helix in parallel between the points of connection. The directions it assumes are such that the iron will become magnetized and present its poles where the current enters and leaves. The right line joining these poles may be called the magnetic axis. By changing the points of connection with the battery this axis may be made to assume any position whatever transverse to the iron

ring, which I would therefore call a *transverse electromagnet*. The two pieces of magnet placed at the extremities of the right line (in our machine the diameter) joining the points of entrance and exit of the battery current, may be considered as two opposing semi-circular electromagnets, with the poles of the same name together.

In order to construct on this principle the electromagnet with which I provided the little electromagnetic machine, I took a ring of turned iron fashioned like a gear-wheel with sixteen equal teeth, as indicated in Fig. 1. (See Plate IV.) This ring is braced by four brass radii (spokes), *a a a a*, Fig. 4, which unite it with the axle of the machine. Between the teeth little triangular prisms of wood, *m*, Figs. 1 and 4, leave depressions, in which I inserted as many well-insulated electro-dynamic helices or clews, made by winding silk-covered copper wire around them. In all these bobbins, some of which are marked *r* (Figs. 3, 4), the wire is wound in the same direction, and each one consists of nine turns. Every two consecutive bobbins, like *r r'*, are separated by an iron tooth of the wheel and by a triangular wooden prism, *m m* (Figs. 1, 3, 4). Passing from one bobbin to make the next, I left free a loop or stirrup of copper wire, which I fastened to the wooden separator, *m*. I then conducted all these loops, each of which is the end of one bobbin and the beginning of the next, towards the axle, *M M* (Fig. 3), of the wheel, causing them to pass through holes conveniently situated in a wooden collar on the same axle, and attaching each one to the commutator, *c* (Fig. 3), also centered on the same axle. This commutator consists of a small, low, box-wood cylinder, with two rows of mortises around the edges of its cylindrical surface. In these mortises are inserted sixteen bits of brass, eight above and eight below, arranged so as to alternate. Their surfaces are concentric with the wooden cylinder, a little projecting, and separated by the wood. In the representation, *c*, of the commutator, the brass pieces are indicated by the shaded spaces. To each of them is soldered a corresponding loop connecting two bobbins. In this wise all the bobbins are connected, each being united with the next by a conductor, of which one of the pieces of brass in the commutator forms a part. Connecting, then, two of these brass pieces with the poles of a battery by means of two metallic rollers, *k k* (Figs. 3, 4), the current dividing itself into two branches, will traverse the helix on both sides of the points where the loops separate which unite the two commutating parts, and the magnetic poles will appear in the iron ring at *N S*. Upon these poles, *N S*, act the poles of a fixed electromagnet, *A B*, and produce a rotation of the transverse electromagnet around its axis, *M M*; but, even when it is in motion, the poles continue to occupy the same position, *N S*, which corresponds to the connection with the battery.

This fixed electromagnet, as is shown in Figs. 3 and 4, consists of two iron cylinders, *A B*, joined together by an iron cross-piece, *F F*, to which one of them is screwed fast, while the other is secured in its place by a screw, *G*, placed beneath, which permits it to slide along a slot when it is desired to make the poles of the cylinders, *A B*, approach the teeth of the wheel or recede from them. The battery current, entering at the binding screw, *h*, passes through a metallic wire to the binding screw, *l*, thence to the roller, *k*, circulates through all the bobbins of the wheel, and returns through the binding screw, *l'*, whence it passes through another copper wire into the helix surrounding the cylinder *A*. Upon issuing from the latter it traverses the helix of the cylinder, *B*, and connects by means of another copper wire with the binding screw, *h'*.

I found it advantageous to attach to the two poles of the fixed electromagnet two soft iron armatures, *A A A*, *B B B*, each of which embraces more than one-third of the circumference of the wheel which forms the transverse electromagnet. They are placed quite near to the teeth of the latter, and are held together by means of brass braces, *E E*, *E E*, as is seen in the horizontal projection (Fig. 4). These armatures are not represented in the vertical projection (Fig. 3) of the machine, because they would have hidden the bobbins and the teeth of the wheel too much. The machine works even when the current passes through the circular electromagnet alone, but it has much less power than when the current passes through the fixed electromagnet also.

I made a few experiments to determine the mechanical work produced by the machine and the corresponding consumption in the battery.

These experiments were conducted according to the following method:

The shaft of the little electromagnetic machine carried a pulley, *Q Q* (Fig. 3), communicating with a rather large wheel by means of a cord, and causing it to turn when the machine was in motion. The axle of this wheel was horizontal and wound up a cord carrying a weight. At one end of the horizontal axle of this little windlass was a brake, which was made to bear down until the weight to be raised was almost sufficient to set in motion the whole apparatus, including the electromagnetic machine, not traversed by the current. With this arrangement, when the machine is set in motion, the mechanical work expended in overcoming friction is equal to that employed in raising the weight, and to obtain the total work performed by the electromagnetic machine we have only to double that obtained by multiplying the weight by the height to which it was raised. To find out the consumption in the battery necessary to produce the work thus determined, a voltameter of copper sulphate was inserted in the circuit, and the plates of copper were weighed before and after the experiment.

I will report the numbers obtained in one of these experiments with the transverse electromagnetic machine. This machine had a wheel thirteen centimetres in diameter, was set in motion by a battery of four small Bunsen cells, and raised a weight of 3.2812 kilogrammes, including estimated friction, to a height of 8.66 metres; the mechanical work was therefore 28.415 kilogrammetres. The positive copper of the voltameter lost 0.224 gramme, while the negative copper gained 0.235 gramme, so that the mean chemical work in the voltameter may be called 0.229 gramme. This number, multiplied by the ratio between the equivalents of zinc and copper, and by the number of cells of the battery, gives 0.951 as the weight of zinc consumed. Hence, to produce one kilogrammetre of mechanical work, 33 milligrammes of zinc were consumed in the battery. In another experiment, made with five cells, the consumption was 36 milligrammes per kilogrammetre. Although these results do not show the new model to be notably superior to other electromagnetic machines, they do not seem to me to be unfavorable, when it is considered that there exist in it defects of construction which do not occur in other machines of this kind. Among these, it should be noted that the commutator is made of brass and not well centered on the axle, so that the contact is not always sufficiently good.

The reasons which led me to construct an electromagnetic machine arranged as described, were the following: (1.) In the arrangement adopted, the current never ceases to circulate in the helices, and the machine does not move by a series of impulses succeeding each other more or less rapidly, but by a couple of forces which act continuously. (2.) The circular shape of the rotating magnet, assisted by the preceding mode of successive magnetization, gives regularity to the motion, and reduces the loss of *vis viva* in shocks and friction to a minimum. (3.) There is no attempt made to effect instantaneous magnetization and demagnetization of the iron in the electromagnet, which would be opposed by the extra currents and by the coercitive force, which we can never get rid of entirely in the iron; but it is required only that every portion of the iron in the transverse electromagnet, subjected continually to the proper electro-dynamic forces, shall pass successively through the different degrees of magnetization. (4.) The enlarged armatures of the stationary electromagnet embrace a considerable number of the teeth of the magnetic wheel upon which they act, and, therefore, do not cease to influence them so long as any magnetism remains in them. (5.) The sparks are increased in number, but much diminished in intensity, there being no strong extra currents on breaking the circuit, as the latter may remain continually closed. Only while the machine is in action is there a continuous induced current in a direction contrary to that of the battery current.

It seems to me that the value of this model may be increased by the fact that it may easily be converted from an electromagnetic to a magneto-electric machine with continuous current. If, instead of the electromagnet, *A B* (Figs. 3, 4), we substitute a permanent magnet, and cause the transverse electromagnet to rotate, we should have in fact a magneto-electric machine furnishing a continuous induced current always in the same direction. In order to find the most suitable points for tapping the commutator, in order to collect the induced current, we should observe that opposite poles are induced in the movable electromagnet at the extremities of the diameter presented to the poles of the stationary magnet. These poles, *N S*, maintain a fixed position even when the transverse electromagnet rotates on its axis. As regards the magnetism, and consequently the induced currents also, we may therefore consider, or suppose, that the bobbins of copper wire revolve around the circular magnet on which they are strung, and that the latter remains stationary. In order to study the induced currents developed in these bobbins, let us examine one of them in the various positions it may assume. Going from the *N* pole (Fig. 2) to the *S* pole, there will be developed a current in one direction until we reach the middle point, *a*, where the direction is reversed. Proceeding from *S* towards *N* until we come to the middle point, *b*, the currents will preserve the same direction they had between *a* and *S*; beyond *b* the direction will change again to that observed between *N* and *a*. Now, as all the bobbins are connected with each other, the electromotive forces in a given direction may be added together, and will give to the total current the arrangement indicated by the arrows in Fig. 2. In order to collect it, the most convenient positions will be at *a*, *b*; in other words, the commutator is tapped at right angles to the line of magnetism of the electromagnet. The induced current may have its direction changed by changing that of the rotation. When the commutator is tapped at the diameter corresponding to the line of magnetism, no current is obtained, though the electromagnet be in motion. On tapping it to one side of this diameter, the current obtained is in a direction contrary to that it would have had if the commutator had been tapped on the other side of this diameter.

To develop an induced current by the machine thus constructed, I brought near the magnetic wheel the opposite poles of two permanent magnets, or magnetized the stationary electromagnet it contained by means of a current, and then caused the transverse electromagnet to rotate on its axle. With both methods I obtained an induced current continuously flowing in the same direction, which indicated a moderate intensity in a galvanometer, even after passing through copper sulphate or water acidulated with sulphuric acid. It is evident that the second method cannot be convenient; but it remains easy to put a permanent magnet in the place of the temporary one, A F F B, and then the resulting magneto-electric machine will have the advantage of furnishing cumulative-induced currents, all in the same direction, without the necessity of mechanical appliances for separating them from others in opposite direction, or for making them conspire together. This model also shows very well that the electromagnetic is the opposite of the magneto-electric machine; in the former the current entering the binding screws, *l l'*, and circulating around the bobbins, produced motion of the wheel and mechanical work, while the latter applied mechanical work to make the wheel turn, and so obtained from the permanent magnet a current in the bobbins, which is conducted to the binding screws *l l'*, whence it may be introduced into any substance we desire to act upon.

The careful reader will note certain inconsistencies in the minor details of the above description. For example, it will be found in Fig. 1 that the contact-rollers are shown as having been placed opposite the respective poles of the stationary electromagnet, whereas, to produce an effective operation of the apparatus, they should of course have been placed in a plane at right-angles with a line joining these poles. An oversight of the draughtsman is also apparent in Fig. 2, in which the arrow between N and *b*, indicating the direction of one portion of the current, is made to point in the wrong direction, as a reference to the text clearly shows. In the actual machine, of which a careful drawing is given in Fig. 5, the contact-rollers will be seen to be in their proper angular position. The error first noted may perhaps have been due to an oversight on the part of the author, rendered explicable by the considerable length of time that had elapsed between the construction of the actual machine and the preparation of the description, some three or four years, or what is more probable, it may have been due to an accidental misplacement of the parts, which the draughtsman, from want of familiarity with the principle of the machine, failed to notice and to rectify.

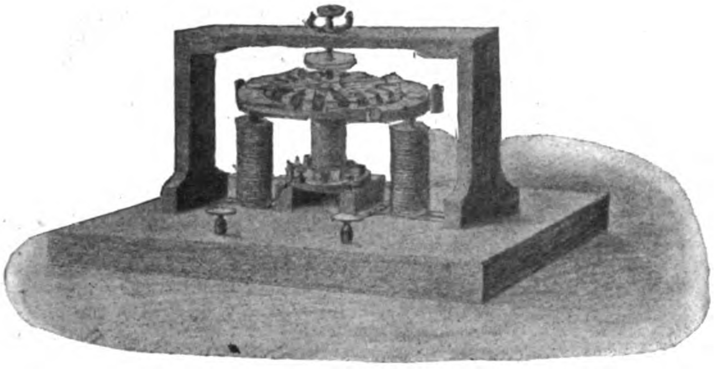

FIG. 5.—PACINOTTI MACHINE OF 1860.
(From an original drawing.)

The importance of Pacinotti's work appears to have been almost wholly unappreciated until after the labors of Gramme and of Hefner-Alteneck had demonstrated the industrial possibilities growing out of the conversion of mechanical into electric energy.

A TUBULAR ELECTRIC RAILWAY FOR PARIS.

AN underground tubular electric railway of the Greathead type, from the Bois de Boulogne to the Bois de Vincennes has been sanctioned by the municipal council of Paris. The tubular tramway will be constructed of metal. As the tunnel is driven ahead cast iron plates will be bolted together, forming a solid and durable wall.

ON THE CONDITIONS AND REQUIREMENTS OF A PRACTICAL CONDUIT TROLLEY SYSTEM.—I.

BY

R J Hewett

THE writer has studied the above subject with a view to designing a practical conduit trolley system applicable to the various conditions which may have to be met. In looking into these conditions and requirements, the writer has endeavored to be guided by practical affairs as far as possible. The following is submitted as being some of the more important requirements of the case. Many things are mentioned which might be considered as commonplace and well known, but they all aid us in arriving at useful results.

The first and most serious question is that of drainage. That the conduit should be provided with ample sewer inlets at all low places has been well recognized. But we must not expect too much of this alone. The street itself should have careful attention. The sewer inlets of the street should be ample to carry away excessive rainfall so as to avoid overflowing the entire street and conduit. All sewer inlets both in the conduits and on the street surface should be carefully inspected at proper times, and in case of heavy rainfall inspectors should be despatched to all low and dangerous places to look out for obstructions at sewer inlets. Thorough street cleaning will do much to obviate this difficulty. The matter, therefore, seems to open up the question of responsibility, and co-operation of the municipal government who should certainly do their share of the work. The street and sewer departments should cooperate with the street car companies in perfecting the surface drainage of the streets so as to avoid overflowing the conduits. In many cases additional sewer inlets may be required.

Where the grade of the conduit is sufficient, cleaning can be effected by flushing out with water from the street mains, permanent connections being established at the higher points for this purpose. The connections with the mains should be ample so as to admit a large quantity of water. A large quantity of water flowing a short time will do more cleaning than a small stream flowing continually. On levels where the flow of water is not sufficient to carry away the dirt, scrapers will necessarily have to be used as is now the practice with cable roads.

As to the size and shape of the conduit, it is obvious that the larger it is, the better. The shape and width should be such as to permit the supply wires to be placed as far from the slot as possible. The bottom of the conduit should be shaped so as to facilitate flushing out with water. Regular cable conduits are well planned for this purpose, but unfortunately they have never been able to realize much advantage from their good shape for the reason that the tar which drops from the rope forms a very adhesive and obstructive mass in the bottom of the conduit and cannot be flushed out with water. Fortunately, electric conduits do not have this difficulty to contend with.

As to the material and method of construction, we have an excellent precedent to follow in cable railway conduits. In these the body of the conduit is constructed of concrete in a continuous manner, the whole forming a monolithic structure from end to end of the road. This construction, although possibly more expensive than others, gives more strength and durability to the entire permanent way, there being little or no repairs to the line after it is once properly laid. Aside from this it is possible to take advantage of the fact that there is ample space available in the body of the concrete mass in which to construct feed wire conduits and thus avoid the expense of separate conduits for this purpose.

The insulation of the supply conductor is a matter almost equal in importance to the drainage of the conduit. Insulation supports in conduits loose their efficiency through two causes, namely, moisture, which exists in all kinds of weather both wet and dry, and dust which finds its way into the conduit in dry weather and adheres to the more or less moist surface of the insulator. The situation is much worse than is the case with ordinary out-door insulators. The latter have a decided advantage in getting washed off every time it rains. The conduit insulator is never washed off. From these considerations the writer concludes that it would be a good plan to place manholes at each insulator so that they can be cleaned. A special form of oil insulator which cleans itself automatically, invented by the writer, was described in The Electrical Engineer of March 30 and May 18, 1892.

The next question is, How to deliver the current to the car; whether by means of one conductor or two; by bars or simple trolley wires; by underrunning or overrunning contacts? In deciding these questions we should look at the future requirements and possibilities of the case. We should consider the possibility of extensive electric conduit systems with crossings and turnouts, as well as the crossing of cable lines, and plan everything so as to provide as simple devices as possible for all the conditions to be met.

The two-conductor plan has the advantage of entirely isolating all parts of the conductor system from the street and is therefore least dangerous, and as the wheels and rails form no part of the conducting system the presence of dirt or ice on the rails has no effect on the electrical part of the system as is the case with a single conductor. It also has the advantage of an insulation resistance twice as high as with one conductor, the same insulating device being used in both cases. The disadvantages of the double-conductor system are that the outlay for copper is doubled; the moving contacts, frogs and crossings, are double and therefore somewhat more complicated and liable to cause trouble.

The single-conductor system has all the advantages of simplicity and cheapness of the overhead trolley wire but has the disadvantage of only half the insulation resistance and also of having one side of the system, the track and slot rails, exposed to contact. By placing the supply conductor entirely out of reach of meddlesome boys, and providing proper protective appliances for workmen when handling the trolley device, the question of danger need not be serious; the main question is that of insulation. The single conductor plan has a great advantage in the copper outlay, due to the fact that the track return has a valuable auxiliary in the slot rails and yokes. By laying the slot rails so as to break joint with the track rails it will hardly be necessary to bond the rail joints. This has had practical proof in the case of cable roads which have been changed to the electric overhead trolley system.

As to the form of the conductor we note that in nearly all of the conduit work done so far bars have been used. This plan necessitates expansion joints and insulating supports at closer intervals, with consequently increased leakage due to the increased number of insulators. The simple trolley wire plan has the advantage of taking care of its expansion by means of the sags, and the insulators can be spaced further apart.

In determining the distance below the surface of the street at which the supply conductor is to be placed, we must consider the position of cables to be crossed, and place the supply conductor a sufficient distance above the cable to avoid fouling the running contact at the crossing.

As to the moving contacts, an underrunning contact will require wide gaps in the conductors at crossings and junctions to permit the passage of the bar which carries the underrunning device and seems to be objectionable on this account. The overruning device will have almost all the simplicity of the overhead trolley system, and can be removed from the conduit more easily than the underruning contact. The contact device should be so designed as to always keep in contact with the supply conductor and to pass turnouts, crossings and cable gaps of considerable width without displacement.

The trolley device should be adapted to run in either direction without readjustment and should be easily attached and detached from the car so as to provide for through traffic between conduit and overhead systems. It should be easily removable from the conduit so as to provide for the transfer of rolling stock from one track to another in case of fires or other causes and slot rail gates should be provided for this purpose at suitable points on the line. In a subsequent article will be given a description and plans of a practical conduit trolley system designed in accordance with the requirements just enumerated.

THE SPERRY ELECTRIC RAILWAY APPARATUS.

A great deal of interest has been aroused in the Sperry electric railway apparatus, the invention of the accomplished young electrical engineer, Mr. Elmer A. Sperry, and now being introduced by the Sperry Electric Company, of New York City. This apparatus has, it is stated, now been in use for nearly a year at Youngstown, Ohio, with very good results. We illustrate it herewith in Figs. 1 and 2.

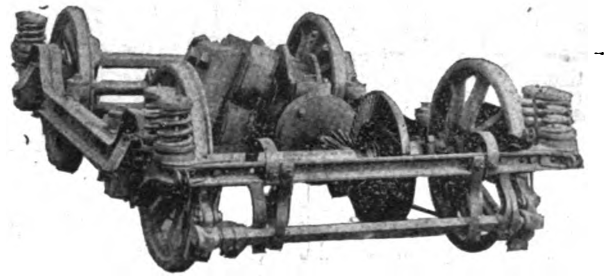

Fig. 1.—The Sperry Electric Motor—Showing Bevel Gear.

The equipment consists of a single motor, flexibly mounted on the truck, the armature running lengthwise of the truck, having a hollow shaft through which runs the pinion shaft driving both axles through bevel gears. Between this pinion shaft and armature shaft is a flexible gear. The motor is a 40 h. p. single reduction, with a slow speed armature. The gears are a special design, with broad face and very strong. The housings for these gears, forming the bearings for the pinion shaft, are likewise very strong and of particular design, and have proved in practice to be admirably adapted for the purpose. The gears on the original equipment running to-day at Youngstown are in splendid condition and have not been running in oil, though all equipments now manufactured have gear covers, allowing the use of oil on the gears. By this method of flexible support and flexible connections it is claimed the Sperry Company obtain the maximum tractive effect with a minimum expenditure of power, having a single 40 h. p. motor with one armature, instead of two 15 h. p. motors having two armatures, giving the total weight on the wheels for traction and having the minimum weight on the wheels, without springs. The Sperry Company also control the use of devices intended to protect life and property in the event of a breakage of the trolley wire.

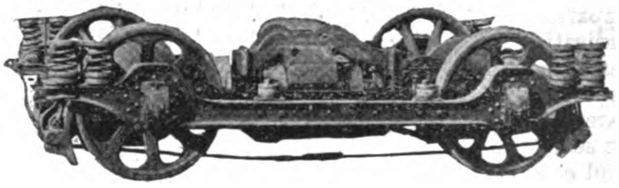

Fig. 2.—The Sperry Electric Street Railway Motor—Side View.

A BIOGRAPHICAL SKETCH OF THE KHOTINSKY ACCUMULATOR.—II.

BY

Capt. A. de Khotinsky

In the spring of 1881 much talk was heard of the discovery of M. Camille A. Faure with reference to accumulators. This rumor caused the laboratory of *l'Electricien*, under the direction of Messrs. Planté and Hospitalier, to have a large battery of Planté accumulators made to prove that the Planté accumulators had more capacity per kilogram of lead than the accumulators of Faure. I took no active part in these proceedings, but preferred, on account of practical experience, which I had already gained with Planté accumulators in Russia, not to let myself be carried away by other people's influence. I had set myself the task of constructing an accumulator, by which the defects could be avoided that were peculiar to the experiments I had made with the Planté system.

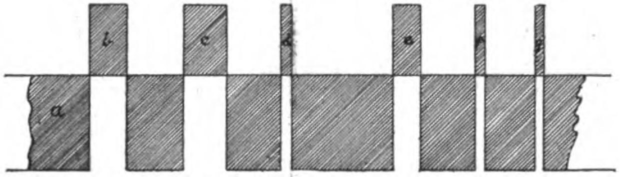

FIG. 10.

Next I considered how it would be possible to prevent short-circuiting inside, caused by the falling off of oxide from the surface of the positive electrodes. When the loosened oxide fell down in powder and scales I was satisfied with the construction adopted in 1874, of parallel plates, to avoid short-circuiting. Since therefore, as experience showed, the oxide in layers loosened from all over the positive plates, the distance of the positive from the negative plates in the accumulator should have been as great as the height of the positive plate itself, but this arrangement was not practicable. A remedy for that was to make separating walls to prevent the falling oxide scales touching the negative plates, or else to make the positive plates so that only scales of small size could fall off; and this size of the scales must be such, that the falling could take place without touching the negative plates; or else the oxide must be made to fall off only in the form of powder.

A great disadvantage, peculiar to the Planté accumulator, was noticed in its short life as a producer, and this short life as a producer was by no means in proportion to the amount of work necessary to form it; and after this comes total exhaustion together with useless existence. In this it resembles a paralytic, who, indeed, takes nourishment but is unable to exert energy.

The above diagram shows clearly the run of life of accumulators made of common lead plates. This diagram is to be compared with the life of a strong spirit in a weak and sickly body. The spirit spontaneously flourishes and may do great things, but its physical power is soon exhausted.

After having taken rest, recreation and care, we see a new start, but—the first spurt can now no longer be repeated—weakness of body and exhaustion makes itself still more perceptible. Later attempts and renewed efforts for a last trial for work only prove useless and unprofitable and the spirit and body sink in lassitude and lethargy.

The part below the line which intersects the diagram, Fig. 10, shows the work required for the bringing up of the accumulator, and the care expended for its recovery; that below the line shows what the Planté accumulators are able to return in work. The first part *a*, under the line, which is about twenty times as large as *b*, is the bringing up, the forming, of the accumulator. *b*, above the line, marks the first activity of life; after the finishing of the forming process. *c*, above the line, marks the first spontaneous display of the will power, the highest point of capacity.

d, hasty exhaustion of the weak bodily powers; the first falling off of oxide. *e*, beginning of fresh activity after having had care and recreation, after long-repeated charging. *f*, bodily weakness is more perceptible; the falling off of whole scales of oxide.

g, after renewed care—entire cleaning of the cells, new arrangements—later attempts to work, but all is useless and unprofitable and the spirit and body sink in exhaustion and indolent lethargy—the accumulator takes the charge, but returns no energy.

From all that has been said it follows that in the nature of this accumulator, this principle underlies: That when it reaches the highest point of formation, then also begins its degradation. From this it will be seen that the very formation which gives power is the cause of its ultimate failure.

Hence came the necessity of adopting a construction, which either made the forming totally unnecessary, or at least that only a short period of formation should be necessary for the highest attainable capacity per kilogram of weight. For this purpose I worked to get out of the same weight of lead the largest possible surface in order to have the same weight of oxide, but distributed in proportionately thinner layers; because for the production of thicker layers the time required varies as the square, and for still deeper oxidation, as the cube.

The larger spreading of surface of the same weight of lead has the further advantage that the oxide carrier becomes much thinner. Thereby the falling off of oxide from the support is avoided, because the thinner the oxide carrier is, the easier it can expand with the oxide. With a thicker carrier its expansion is difficult or impossible; the expanding oxide must according to the laws of nature, therefore necessarily loosen and fall off from its immovable supporter.

All this led me to produce a type of accumulator, of which I gave Mr. N. de Kabath a description, and I authorized him to take out a patent for it in his name as an acknowledgment for his permission to let me work in the laboratory of *l'Electricien*, and as an indemnification for financial aid which he had given me for this work. This accumulator, shown in Fig. 11, is known under the name of "accumulateur gaufré N. de Kabath."

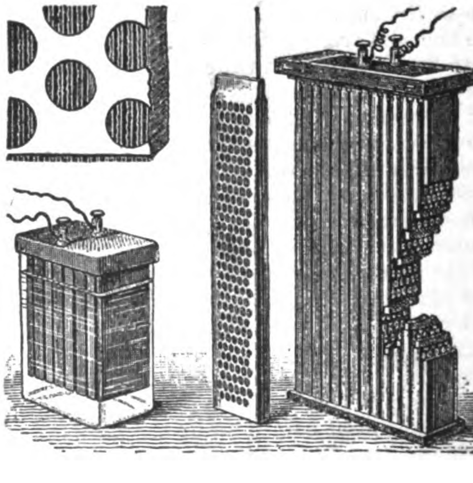

FIG. 11.

In constructing this accumulator lead strips were used, 0.1 mm. in thickness, one-half being directly cut in the required length of 36 cm., the other half originally 56 cm. in length being reduced by corrugated rollers. These flat and corrugated strips to the number of 180 or 190 were laid alternately one upon another, and the whole fitted in a thin covering which was perforated on the side, and was bound closely around the strips. This covering resembled a very long envelope perforated on both sides, 38 cm. in length, 9 cm. broad, 1 cm. thick and 1 kilogram in weight. At the narrow end was fixed a lead strip, and the covering was perforated with rows of small holes, so that in the complete battery the liquid could circulate freely.

In the year 1881, the Paris Electrical Exhibition was held. During my stay in America, the American Maxim Company with which I was connected invited me to assist in establishing their great exhibition in the Palais d'Industrie, where the exhibition was held. For lack of time for further investigation and development of the above described "gaufré accumulator," I gave the charge thereof to one of my employees, Mr. Bernardos. In September, 1881, several batteries of these accumulators were finished and sent for the purpose of practical experiments to America, England and Spain.

My duties in the exhibition were various. Subsequently the contract for lighting a part of the great opera house by means of Maxim glow lamps was given to me. From this resulted the sale of the patent on Maxim incandescent lamps for France to the Jablochkoff Company, on condition to deliver 100,000 incandescent lamps within six months. I established then a manufactory for the purpose at No. 17 Rue des Martyres, and was consequently so much occupied that it was impossible to personally supervise the further development of the gaufré accumulator.

THE COMPARATIVE EFFICIENCY OF THE COMMUTATED FIELD AND THE EXTERNAL RESISTANCE CONTROLLING RAILWAY SWITCHES.

BY

Thorburn Reid.

So far, the prevalent practice in the speed control of street car motors employs a change in but two elements, viz., resistance of the main circuit and field turns. Of the two methods mentioned in the title, the one varies the resistance only, the other varies both the resistance and the field turns.

For purposes of comparison, we will assume that the resistance, turns in field, speed, current, etc., are the same in the two methods when all the external resistance is out of the circuit in the one and all the field turns are in parallel in the other. This assumption is both necessary and proper. Proper because there is nothing inherent in either method to necessitate a difference in these conditions and whatever change in them increases the efficiency of either will be of advantage also to the other. It is necessary also because a comparison of the efficiency of two methods of regulation is sought and to make this comparison it is necessary that all extraneous conditions should be the same in both.

The loss by hysteresis and eddy currents may be neglected, since although it may be appreciable in some cases, the difference in its value due to the two methods is negligible.

We will inquire then what effect increasing the number of turns in addition to increasing the external resistance (for the purpose of reducing the speed) will have on the loss of energy in the motor and in the controlling device. Before proceeding with this comparison, note that the number of turns in the field equals the ampere turns divided by the current through the armature. In other words, two or more turns in parallel count only as one, for as far as their effect is concerned the turns in parallel with each other could be replaced by one turn carrying the sum of the currents which were in parallel.

For simplicity we will use numbers rather than letters of the alphabet for the quantities involved, showing as we go along the general application of the principles brought out.

Starting then under the conditions mentioned above, assume the resistance in circuit to be 10 ohms, the current to be 10 amperes, the line E. M. F., as usual, 500 volts, and the speed 10 miles an hour. Suppose now the resistance is doubled. The current would immediately be reduced thus reducing the torque. The speed would then commence to decrease, thus reducing the counter E. M. F. and increasing the current again. As the speed decreases the torque required to drive the car becomes less and less and the torque furnished by the motor increases with the current. This process will continue until the torque furnished by the motor equals that required to drive the car at the speed to which it has been reduced. The speed will then remain constant at this lower value. It thus becomes evident that the value of the current that will flow under these new conditions depends only on the variation of the torque required to drive the car with the speed, and on the variation of the torque furnished by the motor with the current. Let us first examine the variation of the torque with the current. By the well-known formula the work furnished by the motor equals the current multiplied by the counter E. M. F. The counter E. M. F. (the number of armature turns being constant) is proportional to the field strength and speed. The work is therefore proportional to the field strength, the current and the speed. Torque being proportional to work divided by speed is proportional to the field strength and the current. To arrive at this in another less mathematical way, the torque may be considered as due to the force exerted upon each other by the poles of two magnets, the one the field magnet, the other that armature considered as a magnet, whose poles are always nearly in the same position relatively to the field magnet poles; the distance between these poles remaining very nearly constant, the attraction or repulsion between them will vary very nearly as the products of their strengths, or with the field strength multiplied by the armature strength, the latter being proportional to the current flowing through the armature coils. The field magnets of street car motors are in present practice very highly saturated and a change in the ampere turns does not change the field strength in anything like the same proportion. Consequently the torque, instead of varying as the square of the current, as would be the case if the field strength varied directly as the ampere turns, varies more nearly as the first power of the current. Thus reduction in torque requires a larger reduction in the current when the field magnets are highly saturated than when the saturation is low.

The variation in the torque required to drive the car at different speeds is not very great between the limits used on street railways and the torque is generally assumed to be constant, an assumption which is not inadmissible when we consider the diverse conditions of track, load, lubrication, etc. Such an assumption will make our reasoning much simpler without vitiating the conclusion finally arrived at, since our purpose is to compare two methods of regulation and whatever the torque may be at different speeds, it will be the same for both methods of control at the same speeds.

To return then, what will be the effect of doubling the resistance in circuit? Since by assumption, the torque required remains constant, the current will have finally the same value as before and will require twice the E. M. F. to drive it through twice the resistance, or 200 volts. The counter E. M. F. is reduced to 300 volts and the speed, which is proportional to the counter E. M. F. if the current (and therefore the field strength) is constant, is reduced in the proportion of 400 to 300, or to seven and a half miles an hour.

Next, without changing this resistance, double the number of turns on the field. The current will immediately be reduced on account of the increased counter E. M. F. due to increased field strength. Suppose the field strength were thus increased 20 per cent. The counter E. M. F. would thus be increased to 360 volts and the current reduced to seven amperes. The torque would then become .7 × 1.2 = .84 of its former value and the speed would commence to decrease. This would decrease the counter E. M. F. and increase the current, thus increasing the torque until it reached the value required by the car at the lower speed. Now to get back to the speed we had before the turns were increased it is necessary to decrease the resistance in circuit. Thus for the same speed both the current and the resistance are reduced, and therefore the *C R* loss[1] is reduced, by increasing the number of turns on the field.

Again, if enough resistance were inserted to reduce the counter E. M. F. to less than half the applied E. M. F., an increase in the field turns would increase the torque (see foot note) and speed and resistance would have to be added to bring the speed down to its former value, but that the loss of energy would still be less can be shown as follows: The work given out by the motor at any speed is the same for either method and equals the current times the counter E. M. F. The current is reduced by increasing the field turns. Therefore the counter E. M. F. must increase if the work is to remain constant and *CR* must decrease. Therefore the loss, which equals *CR* times the current, must be less since both *CR* and the current are less.

The reduction in the current is also of further advantage in that the loss in the line and in the dynamo at the power station is also reduced, thus increasing the total efficiency of the plant.

This reasoning has shown that the commutated field is more efficient than the external resistance method after the speed has become constant; but in street railway practice a large part of the energy of the motor is expended in accelerating the speed of the car, and it remains to show the relative efficiency of the two methods under these conditions.

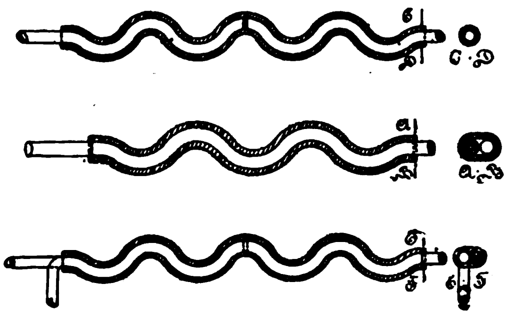
We may consider the resistance to acceleration or the inertia of the car as an additional load put on the motor, but one which is continually changing as the speed of the car changes. A glance at the above reasoning will show that the load was one of the conditions which was assumed to be the same in the two methods. Further, it was proved that at each speed and torque the loss of energy was less with the commutated field method than with the external resistance method, and with equal torque and speed the resistance to acceleration, or the "inertia load," would be the same in both, and thus the above reasoning applies to this condition also.

Finally, it must be remembered that we have considered the comparative efficiency of these two methods, and that only from an electrical point of view. As to their mechanical efficiency, their adaptability to the end in view, their cost and ease of repair, nothing has been said in this article, because these are matters only to be determined by experience, and a discussion of them would be beyond the scope of this paper. I have only tried to answer a question about which there seems to be much confusion. Even practical men of long experience express a doubt as to which takes the most current, a car controlled by the commutated field method or by the external resistance method. To this question the above reasoning gives the answer that a car controlled by the commutated field method requires the least current.

The fact is also brought out that for the same speed and torque the resistance is also less when the counter E. M. F. is greater than one-half the applied E. M. F. The amount of this difference in the efficiency depends on the saturation of the field magnets and on the length of the field gap. In other words, it depends on the saturation curve of the motor. The higher the saturation the less is the difference. The exact amount of the difference could only be ascertained by means of a saturation curve of the motor, and since that would require a complete and somewhat lengthy analysis and would then be a rather distant approximation to the actual difference of efficiency that would be obtained under the rough conditions of street railway practice, I have not considered it worth while to undertake it, at least in this article. That the difference would be considerable can be seen from the argument. That is the most important point and an answer to the main question at issue.

CONZ'S WIRE JOINT.

In this joint, described in the *Elektrotechnische Zeitschrift*, short tinned metallic tubes or sheets are slipped or wound on the wires. The point of juncture is then given a wave-like form. The engraving, Fig. 1, shows two wires joined in this manner with their ends abutting. Fig. 2 shows a joint in which the wires are placed side by side. Fig. 3 is a combination of both, showing the method of taking off a branch wire.



FIGS. 1, 2 AND 3.—CONZ'S WIRE JOINT.

Our contemporary states that it has examined these joints, which throughout exhibit such close contact between wire and enclosing shell that soldering seems unnecessary. Should the latter be desirable, however, it can be easily affected, as the tubes are tinned. The new joint is the invention of Mr. Gustav Conz, of Hamburg, Germany.

BRAIN'S PROPOSED UNDERGROUND CONDUIT FOR ELECTRIC CAR LINES.

Mr. C. T. Brain, of Liverpool, has recently proposed an ingenious form of closed underground conduit for electric car lines. His idea is to build the conduit with a comparatively wide slot, and then to cover this opening with a stout iron rail, lying flush with the surface of the street. To enable the collector attached to the car to come in contact with the cable, this rail is raised from its seat as the car goes, by rollers beneath it, which are carried on U's attached to the car. After the car has passed the cover rail falls back into its place. Thus at any time the conduit is open only under the car, being completely closed both before it and behind it by the cover rail. The wide slot which can be used with this system enables the collector carriers to be made of ample strength, and by removing the cover rail of any section the cable and its supports can be easily got at for repairs, no taking up of the roadway being required. The cover keeps the conduit free from dirt, which would injure the insulation of the conductor.

---

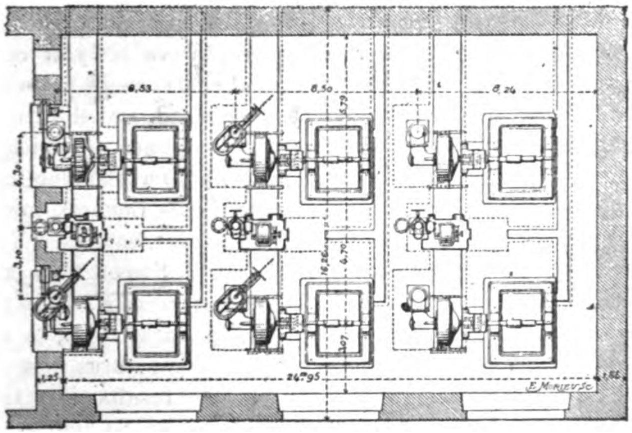
[1] This reasoning only applies as long as the counter e is less than ½ the applied E, which is usually the case in street car motors, except when they are starting from rest. This can be shown as follows: If T = torque, N = field strength, S = armature turns, n = revolutions per second and e = counter—E. M. F. we have $T = NC = N\frac{E-e}{R} = N\frac{E-SNn}{R}$ $\frac{dT}{dN} = \frac{E}{R} - \frac{2SNn}{R} = \frac{E-2e}{R}$. This expression is negative when e is greater than ½ E and positive when e is less than ½ E. That means that any increase in the field strength will decrease the torque when e is greater than ½ E and increase it when e is less than ½ E. That the field strength must necessarily increase with increase in the field turns can be negatively proved as follows: If the field strength either remained constant or decreased, counter e must either remain constant or decrease, and the current therefore must either remain constant or increase, and in either case the field strength would be increased, which is contrary to the hypothesis. Therefore the field strength must increase when the number of field turns is increased.

HIGH-TENSION POWER TRANSMISSION BETWEEN TIVOLI AND ROME.[1]

As our readers are aware, the city of Rome has for several years past had an alternating current station in operation, installed by Messrs. Ganz & Co., of Budapest, and operating at 2,000 volts, with steam power. This station has been increased from time to time, but, the demands continually growing, it was finally decided to utilize the Falls of Tivoli, at a distance of about eighteen miles from Rome. This distance naturally made it necessary to increase the potential in order to avoid serious losses, and for that purpose the E. M. F. employed at Tivoli was raised to 5,000 volts. This potential is carried to the outskirts of Rome, where it is lowered by means of step-down transformers to 2,000 volts. This potential is carried into the city and distributed to the local transformers, which finally reduce it to 100 volts in the distribution circuits.

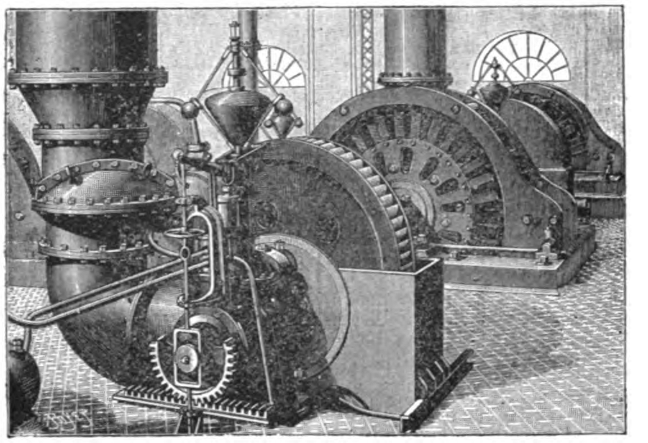
The generating station at Tivoli is placed beside a waterfall of 110 metres, of which 10 metres are utilized for local industrial installations. This fall has an available capacity of 3,500 litres per second. The station is a solid structure on the side of a very picturesque hill, the main machine-room being 25 metres long and 15 metres broad. Nine turbines are employed, as shown on the plan, Fig. 1. The nine turbines form three groups, each of which is composed of two turbines of 330 h. p., and of a small one of 50 h. p. All these turbines are of the Girard type with horizontal shaft and part gate, the automatic regulators being of the Ganz type, the arrangement being shown in Fig. 2. The two turbines of each group are directly connected to and drive an alternator furnishing 42 amperes at 5,100 volts at a speed of 170 revolutions per minute. The armature is 2.2 metres in diameter and has 30 pole-pieces, giving a frequency of 42.5 periods per second. The small turbine of each group operates a four-pole exciter and at a speed of 375 revolutions per minute delivers 150 amperes at 180 volts, this current being sufficient for the excitation of three alternators.

All the alternators are coupled in parallel and also the exciters, which considerably simplifies the regulation ; and rheostats have been introduced into the exciting circuit of each alternator. But the regulation proper is effected by means of two Blathy automatic rheostats acting on the field current of the exciters and regulating their current in such a manner that the potential of the alternating current is maintained constant at Rome, the losses in the line being compensated for by a potential equalizer. The main switches consist of ebonite cylinders containing mercury, in which contact rods dip.



Plan of Main Dynamo Room at Tivoli.

The line from Tivoli to Rome traverses the deserted Roman Campagna, and consists of four copper cables of 12 strands, each of 2.6 mm. in diameter, corresponding to a section of 100 sq. mm. and having a total weight of 100 tons. At full load the loss on the line is about 20 per cent. The cables are supported on heavy oil insulators at points 35 to 40 metres apart. The poles to which the insulators are attached consist of two T-beams, 21 centimetres wide, placed side by side and riveted together. The pole-line also carries two silicon bronze wires, 2 mm. in diameter, designed for telegraph and telephone purposes.



Alternators Driven Direct by Turbines at Tivoli, Italy.

The high potential line is carried to the sub-station at the Porta Pia, Rome, arriving there at a potential of 4,000 volts. Here it is reduced to 2,000 volts by means of 32 transformers of 25 kilowatts each. One group of 16 transformers transmits 2,000 volts alternating, to a concentric system of cables serving for the general distribution of current in Rome. The second group of 16 transformers is employed to furnish current for arc lamps. Each transformer feeds 45 lamps at 14 amperes. There are 14 transformers in service, which correspond to 600 lamps ; the other two remaining transformers act as a reserve. An automatic rheostat receives the circuit of each series of lamps and maintains the current constant at 14 amperes by introducing or cutting out resistances; but in order to reduce the losses as much as possible the secondaries of the transformers can be coupled so as to produce 500, 1,000, 1,500 or 2,000 volts. In this way the potential can be changed very easily during the run. The total energy transmitted amounts to about 1,200 h. p.

[1] *La Nature.*

HOW TO SPEAK WITH MARS BY THE MORSE SYSTEM.

I INFER, from the astronomers, writes the Rev. Mr. Haweis, in the English newspapers, that a signal on our earth about six miles in size, of the nature of a bright light, could be seen by the inhabitants of Mars, who by all accounts seem to be making the most systematic and herculean efforts to communicate with us by flashing triangular signals of presumably electric light. Why cannot we answer those signals by something which would resemble the lighthouse intermittent signal? Here is the method. London every night presents an area of at least 12 miles square brilliantly illuminated. That illuminating power might be enormously increased with only a few additional centres of powerful electric light. But without *any additional expense*—a little co-operation on the part of the gas companies—it would suffice to alternate darkness and light at intervals of five minutes over the whole of London between certain hours when traffic is more or less suspended. If only tried for an hour each night some results might be obtained. The citizens would have lights in their houses, the vehicles would still have their unimportant and shielded lamps, and as every five minutes the lights would be simultaneously turned up, no very extensive burglaries or outrages could be committed. Into the details and mechanism of such a scheme I need not enter. If the lights in the Albert Hall can be simultaneously extinguished or lowered, so could the lights in a street or a thousand streets.

EDITORIAL ANNOUNCEMENTS.

Addresses.—*Business letters should be addressed and drafts, checks and post-office orders made payable to the order of* THE ELECTRICAL ENGINEER. *Communications for the attention of the editors should be addressed,* EDITOR OF THE ELECTRICAL ENGINEER, 203 *Broadway, New York City.*

Communications *suitable for our columns will be welcomed from any quarter. Discussions of subjects relating to all branches of electro-technical work, by persons practically acquainted with them are especially desired. Unavailable and rejected manuscripts will be returned only when accompanied by the necessary postage.*

Advertisements.—*We can 'entertain no proposition to publish anything for pay, or in consideration of advertising patronage, except in our advertising columns. Our editorial columns will express our own opinions only, and we shall present in other columns only such matter as we consider of interest or value to our readers.*

VOL. XIV. NEW YORK, SEPTEMBER 21, 1892. No. 229.

Great as are the triumphs of the present century, we may well believe they are but a forecast of what discovery and invention have in store for mankind.—Lord Rayleigh.

THE DAY OF THE ELECTRIC LAUNCH.

AS a matter of fact, the electric launch is an unknown thing in this country. One or two boats have been built and put into commission, but at the present time there is hardly half-a-dozen of them. In Europe, however, these launches have become widely known. On the upper Thames, for example, it is impossible to spend an hour or two on the water without seeing several of them; and the number used by Londoners is rapidly on the increase. They are certainly preferable to the fussy little steam launches with their ugly "wash," and have not proved costly to build or maintain. Perhaps one reason for the rarity of electric boats in America has been the extreme popularity of naphtha launches, whose name is legion; and another reason has undoubtedly been the greater length and width of our inland waters, rendering navigation by small craft more or less risky. A third reason may have been the comparative rarity of charging stations, but in view of the great use made of the incandescent light at our pleasure resorts along the water, this trouble lessens every season. It will be a long time before the Hudson, for instance, has the density and continuity of population that the Thames and Seine have; but even now its shores from New York to Albany are fairly well dotted with places where it should be possible to obtain a supply of current.

Moreover we believe that with the unquestionable growth in popularity of aquatic sports and pastimes in America, there is to be found encouragement for the formation of local launch companies, such as that which is to carry passengers at the World's Fair. Just two years ago, Mr. Fred. Reckenzaun, an authority on this subject, published in these pages a careful and exhaustive article on the subject, and gave it as his opinion that a complete charging plant, with 12 launches each capable of running 60 miles at six miles an hour, could be equipped, all expenses for land, etc., in-included, for $32,050. These boats could be run for five months in the year for $905 apiece, making a total run each of 9,000 miles in that time. If these boats carried about 10 passengers each trip, the investment would be profitable, at the low rate of a cent per mile. The figures seem to us quite reasonable, as they do not take into account any special hiring of the launches,—a very profitable class of business; and we would greatly like to see the experiment made.

This subject of storage launches is brought up again by the successful trip of the "Vashti" of which an account is given on another page. It is late to begin storage battery launch work for this year; but it is none too early to begin mapping out a programme for next year, when Mr. Astor, with his new storage launch, bids fair to set the fashion in this field. He will be very extensively imitated.

TESTS THAT MEAN NOTHING.

RADICAL improvements and innovations in the older engineering branches are now of such comparatively rare occurrence that the societies devoted to these branches are largely given to the discussion of modifications of older and well-established work, and the civil engineering societies especially have their meetings taken up by the reading of papers on current work, which, though frequently exhibiting great constructive ingenuity, does not possess that novelty of character which similar productions, presented to societies devoted to the more recent developments of engineering, may lay claim to. It is not strange, therefore, to note the occasional reading of a paper on work accomplished some years ago, but which through lack of opportunity had not been brought out at the time of its completion. This tardy recording of the results obtained in a permanent structure, for instance, would, as a rule, be of no serious consequence. But when a paper treating of a new art and read before a representative body of men, fails to point out the progress in the art made since the time of its writing, it is very apt to mislead, and thus to do an injustice to many workers in the branch of which it treats. We are led to these reflections in glancing over the advance copy of a paper by Mr. Louis Bonnett, junior member of the Society of Civil Engineers, entitled "Test of Power Required to Drive Electric Street Cars and Total Efficiency of Motor." These tests were made on the Seashore Electric Railway at Asbury Park, N. J., in the summer of 1889, on a road equipped by apparatus now obsolete, and operating at 220 volts! The results show that the efficiency of the motor varied between 24 and 56 per cent. Granting even that the tests were properly carried out, their publication at this time, and their presentation before the American Society of Civil Engineers, without reservation, is an injustice. The author has not taken the slightest pains to explain that since that time electric railway apparatus has been vastly improved; nor that the motor efficiencies obtained at present are considerably higher; nor that even at the time at which the tests were made there were roads in operation in which the efficiencies were higher than those found by the author of the paper; nor that a higher and much more economical voltage is now universally used. We feel it our duty to thus point out these facts in order to guard many civil engineers from obtaining a wrong estimate of the efficiency of electric railways, an error into which they would be very apt to fall upon the perusal of the paper referred to. As to the ability or standing of Mr. Bonnett, we have no word of criticism. We believe him to be an able and competent engineer. But all the same, these tests are not fair to the electric railway either of to-day or in 1889, and we cannot let them pass without protest.

COPPER VERSUS NICKEL AS A CONDUCTOR.

It is acknowledged to be a difficult task to impart to a large number of new workers in the field of electricity that knowledge which is essential to the proper carrying out of details of electrical construction; and, indeed, it is too much to hope that the general public can share a knowledge of the management of even the most simple electric installations. The hopelessness of this task is again forcibly brought to our attention by the apparent absolute inability of many to distinguish between the relative conductivity of metals. A striking example of this is shown in a recent instance which has come under our notice in which a search for trouble on an electric circuit developed the fact that the regular fuse wire had been replaced by two five-cent nickels, each clamped in the fuse screws and contact being formed by the mere butting of the nickels. When we consider that the specific resistance of nickel as compared to that of copper is as 8 to 1 it is incomprehensible why the genius that inserted the nickels did not employ copper pennies. On the score of expense alone, it should have occurred to the merest tyro to have used them in preference. It is strange, indeed, that since the question of expense seems not to have been taken into consideration, trade dollars were not used for the purpose. The conductivity of silver exceeds even that of copper, and the color of the metal resembles very closely that of the fuse wire. It is apparent that the public needs more knowledge as to the conductivity of trade dollars, nickels and penny pieces.

THE DEADLY FAN MOTOR.

We would suggest to our esteemed contemporaries of the daily press in this city that just by way of variation on their weary cry against the "deadly trolley," they begin a crusade against the deadly fan motor. It has long been known that when thoughtful people stick their fingers near a revolving electric fan, the careless motor goes on, and flippantly slices part of their fingers off. But now comes a Washington paper which reports that a young man who never before knew what sickness was, has died suddenly after "contracting pneumonia from sleeping within reach of the breeze from an electric fan." Now, as the deadly trolley itself has never killed anybody, and as here is a direct case of murder on the part of the fan motor, how much more "deadly" must the fan motor be! There is an old legal decision reported by Cowper, in one of his poems, as to the dispute betwixt eyes and nose, in which it was ruled that when the nose put spectacles on, eyes must be shut. Very much in the same way, it would be fitting for the daily papers to decide that when people fall asleep near fan motors, the motors must stop. That is the only way to prevent these outrageous murders, unless we stop the fan motors altogether. Perhaps that would be the best thing for the public welfare and safety.

ELECTRIC TRACTION OTHER THAN BY TROLLEY.

In the last issue of The Electrical Engineer we ventured, even while defending the trolley from the reckless and foolish aspersions cast upon it, to express the belief that the time would eventually arrive, or might even be at hand, when both the storage battery car and the conduit car would make a place for themselves. The remarkable letter signed "Gautherot" went to prove our assertions and support our hopes, in regard to the storage car. This week we have an excellent article from Mr. R. J. Hewett, of St. Louis, discussing the lines upon which a practical conduit system must be laid down, and in the observance of which success would be found. None of the conditions that Mr. Hewett names embodies a serious or insurmountable difficulty; and that being the case, such a system as will embrace the necessary requirements must sooner or later be hit upon. Meanwhile the demand for operative methods of either kind, that shall obviate the need of resorting to the overhead trolley, grows daily louder and more urgent.

The Utilization of Station Exhaust Steam.

No little discussion has lately gone on as to the profitableness or advantage of utilizing the exhaust steam of central stations for a steam heating service; and although we have produced the evidence showing that it is worth while for stations to go into this line of work, some critics have advanced a number of able arguments against the scheme. Be their contention what it may, we are glad to note the fact that the Springfield, Ill., Electric Light and Power Co. is so well pleased with its exhaust steam enterprise that it has now contracted for an extension of its system, and will put in half a mile more of six-inch mains. A full description of the plant in question, by Mr. W. F. Collins, appeared in our issue of June 1, and we see in this new contract no ground for the withdrawal of any of the points then urged as to the economy, efficiency and profitableness of the plan adopted.

Antonio Pacinotti.

While Italy is not prolific in great electricians, she still can boast of Volta, Galvani, Pacinotti and Ferraris as her sons. These are illustrious names, and yet of one member of the quartette it has remained for The Electrical Engineer, twenty-eight years after his discovery and invention of the continuous current dynamo, to tell, for the first time, the interesting story of his life and work. To most electrical engineers Pacinotti has been but a great name, and it will amaze them to learn that he still lives. The story of his career and of his connection with the genesis of the modern dynamo, has been prepared for this journal by Mr. F. L. Pope, and the opening instalment appears in this issue.

CONNECTING SEVERAL TELEPHONE STATIONS BY A SINGLE LINE WITH AN EXCHANGE OFFICE.

BY ED. ZETSCHE.

MR. ELSASSER in 1883, and myself at various times, have published diagrams, showing the use of call signals invented by Kettell as well as Wittwer and Wetzer (*Dingler's Polyt. Journal* 1892, p. 283, Vol. 38) which enables the connection of several substations with the central office over a single line. Again, in 1885, Messrs. Grassi & Beux (*La Lum. Elec.*, Vol. XV, p. 530) have published another plan by which three substations may be called over one line. Lately the same subject has been taken up by J. J. Carty in his well-known bridging bell arrangement (New York EL. ENG. Vol. X, p. 330; also Vol. XI, p. 420). Another solution of the problem has been found by a gentleman residing in Luettich who has sent me his arrangement, which I shall presently describe in detail.

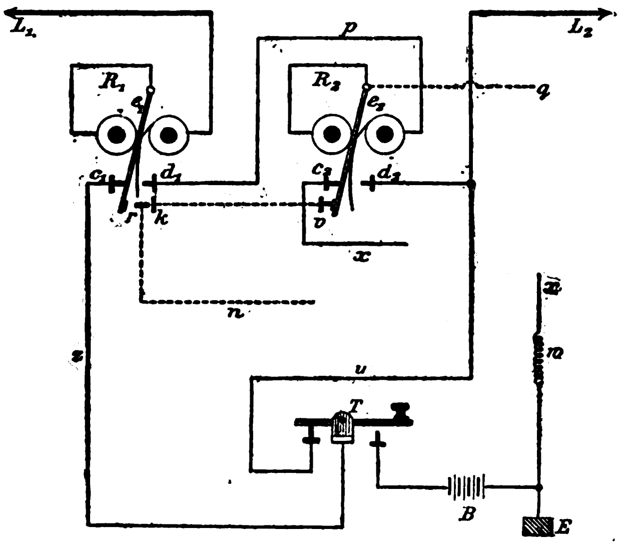

FIG. 1.

Assuming that telephone engineers are well acquainted with my prior devices (diagrams of which are shown in Figs. 1 and 2,) I desire to state briefly that in the arrangement I proposed *none* but the *subscriber called* received the call and the central station was obliged to use as many different strengths or graduations of current as there were substations on the line. This I achieved by means of two polarized relays at the substations, each responding to a different strength of current, so that whenever the central office sends a certain calling current of predetermined strength over the line, only that relay which, by means of its construction is adapted to respond, would operate. In operation this relay by its first motion cuts off the call current, establishing a new path for the conversation current through the telephone. At the same time the stations beyond the one called are automatically disconnected. The line resistance, which is thereby considerably decreased, is brought back to its original value by the introduction of a resistance coil. Means are also provided for the ringing of the alarm at the station called until the subscriber removes the telephone from the supporting hook.

In Fig. 2, the alarms W, are included in the line L_1 L_2, but only one polarized relay R is required. In this arrangement, the call is simultaneously heard by all substations, and an individual signal must be used for each subscriber. The central office employs for calling purposes currents of equal strength of such a direction, or polarity, that the armature *e* of the relay R is held against *c*. The station called presses the key T, sending a current of the same direction; moves the telephone F from the automatic switch U, thus changing the lever U from its resting contact *i* to *q*, and cutting off from L_1 the coil of the relay R as well as those of all stations beyond it, while at the same time grounding the line by means of F. The central station now sends a current of the opposite direction which in all stations up to the one called moves the armature *e* from point *c* to *d*, cutting off T and F. When the conversation is finished, the amatures swing back to *c*.

After this brief description of my prior arrangements, I will now describe the plan of Mr. M. J. of Luettich, reference being had to Figs. 3 and 4. The characteristic feature of his arrangement consists in placing the several substations in multiple, instead of in series, as has heretofore been customary. There are two ways of calling the subscriber. All relays may be wound to equal resistance and a different resistance placed in the circuit of each relay; thus the calling current is split up into several branch currents of different strength; but, as each of these branch currents affects its relay differently, only the instrument desired will respond.

All relays may be wound to a different resistance R, but the auxiliary resistances W_1, W^1, etc., are so constructed that the sum of R and W_1 is the same for all substations. In this case the calling current splits up into branches of equal strength, which currents become operative in relay coils wound to a different current strength. Consequently only a given number of substation relays will respond.

The arrangement for telephone installations, using a single conductor, is shown in Fig. 3, more especially the first substation I beyond the central office. It is to be noted that a somewhat sluggish galvanometer is included in the circuit of line L_1, L_2. Again the convolutions of the galvanometer G are connected with the spindle of the needle, which plays between two contacts V according to the direction of current passing through the galvanometer coil. A second line *l* leads from these contacts and passes seriatim all other substations included in L_1, L_2. Finally at I there is a derived circuit *q*, which, passing through a resistance *w'* connects the line to ground. This resistance, however, must possess a sufficiently high self-induction to prevent an injurious leakage of telephone currents.

At each substation at *j* a conductor is led from line *l*, which passes through a resistance w_1, the relay coils R_1, and thence to ground. The amount of auxiliary resistance W, as well as the number of convolutions of the relay is to be determined for each substation. From L_1, L_2, at *x*, a conductor is taken to the spindle of the relay armature *e*, thence to the contact screw *c*, (the resting point for the armature when positive currents pass through the relay and its customary position), thence through the telephonic apparatus S_1,

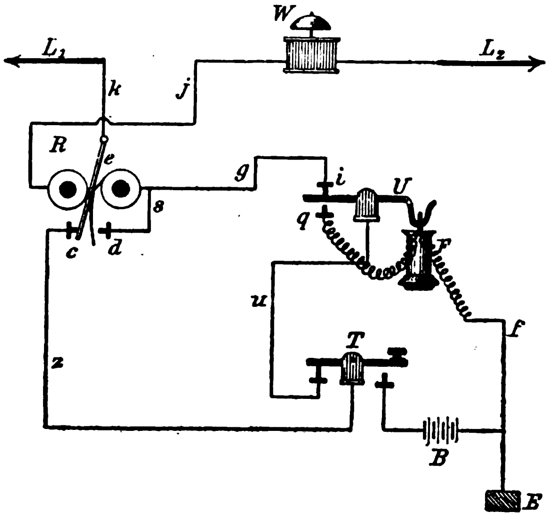

FIG. 2.

through a resistance W_1 over s to ground. The resistance W_1 must receive a well-determined value so that only infinitesimal portions of current may pass over x, e, c, W_1, s to ground. This resistance is only included in the circuit when no conversation is going on, which is accomplished by so connecting the resistance with the automatic switch that the act of removing the telephone short-circuits the resistance.

It will be seen that at all stations the relays are in derivation with line l, while the telephone apparatus S, of the substations usually are included serially in the line L_1 L_2 which terminates at the exchange. The call currents produced by a magneto machine have no effect upon the galvanometer G, and are thus prevented from passing through G to the relays R at the substations.

Generally the armatures e of all relays R_1 (see Fig. 3) make contact with c. If the exhange desires to call the nth substation, a negative current of such strength is sent into L so as to attract the armatures e of all relays R. The current passes first through S_1, but does not actuate the alarm at the substation, always supposing that alternate currents have been employed. It deflects, however, the needle of the galvanometer G, thus finding a path over v to the relay R_1 and to ground. This path is that of the least resistance, because behind s there are the large resistances W, and as soon as the levers leave c, the apparatus S1 at each station is cut out. Next the exchange transmits a positive current of predetermined strength, say of the value n. This current at first finds no earth ; consequently a ground through w^1 is needed. It is true that this current affects the needle of G, thus introducing at all substations the relays R, but by reason of its strength at this moment it can move only the relay armatures which are at the n stations back from d to c.

Finally the exchange sends a negative current of $(n-1)$ strength to line to replace the armatures e upon d. Thereafter at substation n only the telephonic apparatus S is included in the line and no other station can interrupt the conversation. Upon the close of the conversation the exchange throws the armatures of all the other relays upon c which is accomplished by sending a positive current of sufficient strength over line L_1 L_2. A visual signal may be provided by attaching a small disc to the armatures e.

If a subscriber desires to call the exchange, he proceeds exactly in the same manner as a subscriber having a private line. The call currents enter the exchange without splitting over the other substations, being prevented by the large resistances interposed at the branching points. At the calling station this resistance is removed by means of a key which the subscriber presses while giving the call. If two subscribers on L_1 L_2 desire to communicate, the exchange connects them in any customary manner.

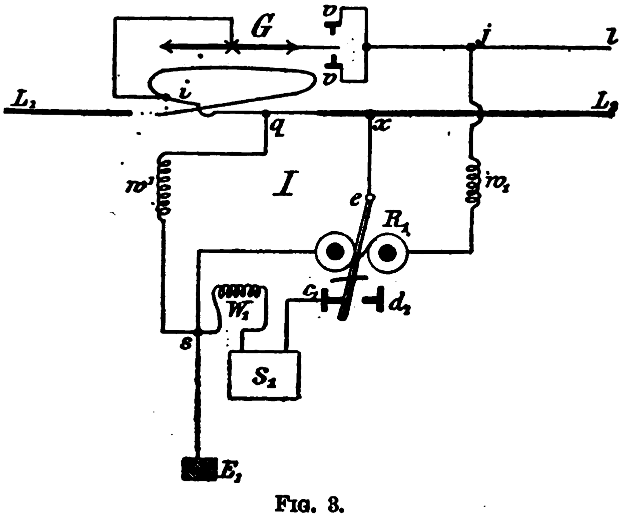

FIG. 3.

In exchanges using complete metallic circuits, G, l, and W_1, Fig. 3, are omitted, while the relays are of identical construction. A light contact spring opposite c must be added to the armature e to ensure the continuance of contact to effect the placing of the armature upon d. In Fig. 4, L_1, L_2, and L^1 L^2 are the metallic line, S the telephone apparatus, and w should be placed between x and n. All substations are similarly arranged. A small key T is added to the axis of the armature e, short-circuiting R, and when pressed, grounding e by means of m. This is necessary whenever a subscriber desires to call. The exchange calls by sending a negative current over L_1 L_2. This current throws all armatures e upon d. Next a positive current of strength n replaces in all n substations the armatures upon c and finally by a negative current of $(n-1)$ strength the $(n-1)$ armatures e are drawn back upon d.

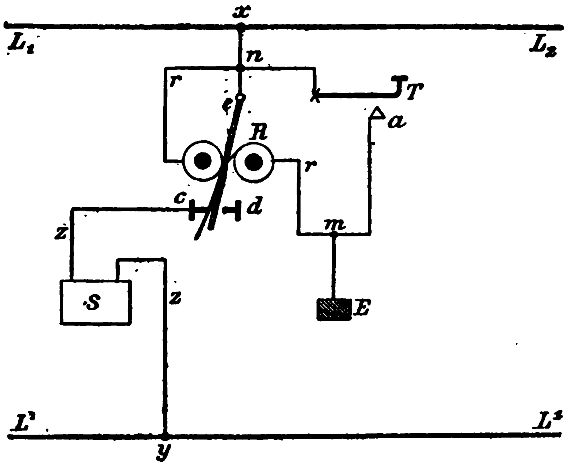

FIG. 4.

THE LIVERPOOL ELEVATED ELECTRIC RAILROAD.

THE *Railway World*, of London, in an account of the car shops of Brown, Marshalls & Co., of Birmingham, prints the following description of a 45-foot passenger car, with an electric motor, now building at those shops for the above-named road: "Each train to run upon the new line will consist of two cars coupled together, and mounted respectively on two four-wheeled bogie trucks of the ordinary American pattern. Upon the truck at each end of the train will be fixed an electric motor of sufficient power (70 to 100 h. p.) to propel the train; but the rearward motor for the time being will alone be in action. The car bodies are 45 feet in length and 8 feet 6 inches wide, the centres of the trucks being 32 feet apart. The truck frames are of pressed steel, and solid wheels, 2 feet 9 inches diameter, are employed, with wrought iron spokes and naves and steel tires. The buffers are placed centrally, as in all American rolling stock, combined with a self-acting car coupler. The motor axle boxes are of cast steel. The car bodies are framed of oak and teak, with side doors, and are separated into two classes only, first and second. The cars are lighted with electricity and are efficiently braked by a mechanical screw brake to every wheel, in addition to the Westinghouse automatic. Each car holds 56 persons; and at one end, immediately above the electric motor, is placed a very neat little cab for the 'motoneer,' with electric regulating switchboard, brakes, etc., close at hand, so that everything is under control."

THE PROFITABLENESS OF UTILIZING EXHAUST STEAM.

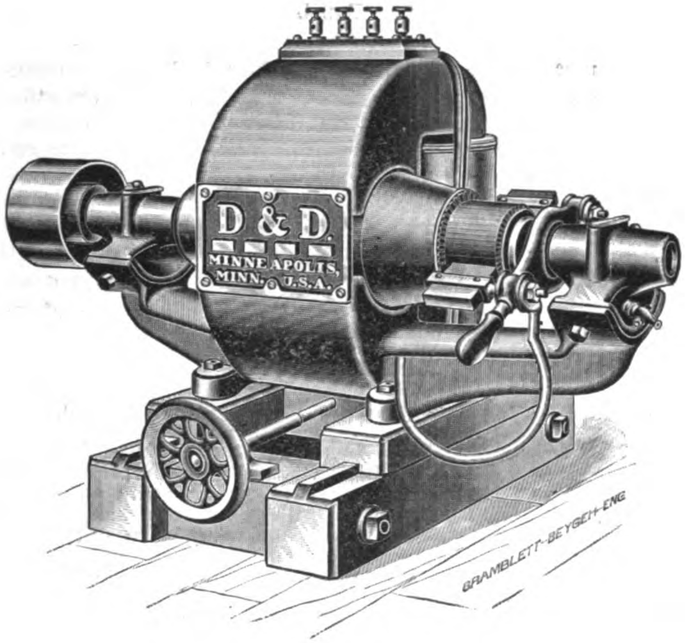
IN its June 1st number THE ELECTRICAL ENGINEER published an illustrated article by Mr. W. F. Collins upon the subject of "The Utilization of Exhaust Steam for Heating by the Springfield, Ill., Electric Light and Power Company."

In support of what was therein said in favor of this plan of turning a waste product into money, we learn that the Springfield Company is so much pleased with its exhaust steam enterprise that it has contracted to have built an extension of its underground steam mains, consisting of one-half mile of six-inch protected iron pipe for further service in disposing of its surplus exhaust steam. The work of construction is being done by the American District Steam Company of Lockport, N. Y.

THE "D. & D." DYNAMOS AND MOTORS.

The appearance of a new dynamo or motor is always interesting to the electrical engineer, not only because of the features of design it may embody, but because it is an evidence of activity in the great field of electric light and power. To-day, particularly, it is felt that a new machine is built to sell on its merits. In the earlier days, pretty well any machine would serve as a basis for the stock jobbing operations then so much in vogue, but at the present time, the new dynamo or motor that would win must appeal for general favor strictly on the ground of superiority in design and efficiency.

This idea has been in the minds of the D. & D. Electric Manufacturing Co. of Minneapolis, Minn., who have recently come upon the market with dynamos and motors of the design and form illustrated in our engraving. These machines, which are well worthy of attention and study, are of the single field magnet type, with a Siemens drum armature, presenting a very substantial and compact appearance, and promising high efficiency. The field magnet which has only two joints, is of wrought iron wound with the best double-covered wire. The pole-pieces, as will be seen, are very heavy. The arms which support the bearings are cast in one piece with the base, and thus secure great stability and strength. The commutator is made of hard copper, with a liberal diameter and width, reducing the wear to a minimum. The insulation is also ample and carefully done. The armature shaft is of the best machine steel. The bearings of these machines are made interchangeable. They are of bronze in the form of a sleeve, turned to gauge. They are also self-oiling. Thorough lubrication is insured by a brass ring, which hangs loosely on the shaft and turns with it. The under part swings through the oil reservoir in its revolution, constantly picks up the oil and feeds it to the bearing; and in due course the oil returns to the reservoir for further indefinite use. The reservoir very seldom needs refilling. The brush holders are of simple design, as will be noted, and are made to carry multiple end-on carbon self-adjusting brushes, so constructed as to give perfect contact between the commutator and each individual carbon block. The centre of gravity in the machine is quite low, so that there is practically no vibration at all in running.



The D. & D. Constant Potential Dynamo.

These dynamos and motors are now wound for 110, 220 and 500 volt constant potential circuits. They are furnished with switchboards for the lighting plants, the boards including double-pole switch, resistance box, fuse blocks, lightning arresters, ground-detector voltmeter and pilot lamp. With each motor is supplied a rheostat or switch box, finished with polished brass switches, binding posts, fuse blocks, etc. It may be stated that the figures of the 500-light dynamo are: 52 inches high; 72 by 48 inches floor space; pulley, 15 inches diameter by 12 inches width; weight 7,090 pounds and speed 800 revolutions. The one-horse motor is 15 inches high; occupies 24 by 14 floor space; has a pulley 3 by 2½ inches; weighs 240 pounds and runs at a speed of 2,500 revolutions.

CALCULATION OF WEIGHT OF COPPER WIRE FOR LONG-DISTANCE TRANSMISSION.

BY

W. F. Hasson.

It is frequently desirable to calculate quickly the weight of copper necessary to transmit a given power to be utilized at the end of the line. This may be done by the following formula, in which

D = distance in miles.
E = E. M. F *at motor* in hundreds.
$H.P.$ = horse power *at motor.*
l = per cent. line loss in units.
W_1 = weight of two copper wires for given distance.

Then

$$W_1 = 267 \times \frac{D^2 \times H.P.}{E^2} \times \frac{100 - l}{l} \text{ lbs.}$$

In order to show the application of the formula, let us take the following example:

To transmit 300 h. p. 15 miles; voltage at motor, 3,000; line loss, 20 per cent.

$$W_1 = 267 \times \frac{15 \times 15 \times 300}{30 \times 30} \times \frac{100 - 20}{20} = 80{,}100 \text{ lbs.}$$

This formula would be quite correct if standard sizes of wire were to be ignored. To find a wire of standard gauge that will meet the above requirements, a table is appended sufficiently accurate and comprehensive for ordinary purposes.

$$\text{Weight of wire per mile} = W_1 = 133.5 \frac{D. \times H.P.}{E^2} \times \frac{100 - l}{l}.$$

Size of wire.	Weight per mile.	Size of wire.	Weight per mile.
Diameter = ½ in.	3,994 lbs,	No. 1 B. & S...	1,337 lbs.
No. 0000 B. & S...	3,381 "	" 2 "	1,061 "
" 000 "	2,682 "	" 3 "	842 "
" 00 "	2,127 "	" 4 "	666 "
" 0 "	1,686 "	" 5 "	529 "
		" 6 " ...	420 "

In the case given above

$$W_1 = 133.5 \times \frac{15 \times 300}{30 \times 30} \times \frac{80}{20} \times 2670.$$

This corresponds to No. 000 wire; and W_1 corrected becomes 2682 × 30 = 80,470 lbs.

In these examples no allowance is made for sag.

THE LOVE ELECTRIC CONDUIT SYSTEM IN CHICAGO.

There is considerable public interest in conduit electric railway systems at the present time, with very little to satisfy the curious or to stimulate the energies of the hopeful. In fact, we believe that the only conduit system that is "operative" in the United States to-day is the Love, under trial on the North Chicago street railroad. The Love Electric Traction Co. is a Chicago corporation, which last February equipped a loop about 1½ miles long for the North Chicago road. We are indebted to the *Railroad Gazette* for the details as to the conduit there used, as shown in Figs. 1 and 2. The construction of this conduit road is quite similar to that of the usual cable road. It has cast iron yokes spaced about 4 feet apart and a cast iron conduit about 9 inches wide and 15 inches deep. The top cover of the conduit consists of rolled steel angles having a deep vertical flange on the side next to the slot. These flanged rails are cut into lengths of about 30 feet each and are so constructed and laid that they can be taken up at any time, giving free access to the interior of the conduit for purposes of repair or for the removal of dirt or other obstructions that may fall into the conduit. The slot rail is made to serve a two-fold purpose; it defines the slot and protects the copper wire conductors from outside interference. There are two copper wires about ⅜ inch diameter spaced about 6 inches apart for carrying the current. The trolley bar is a very simple device. The trolley wheels are slightly smaller than those used in overhead roads, and are so suspended from the trolley bar that they admit of all necessary vertical and horizontal motions due to the irregularities of the line and in passing curves. The trolley bar is so constructed that it can be readily detached from the car or replaced.

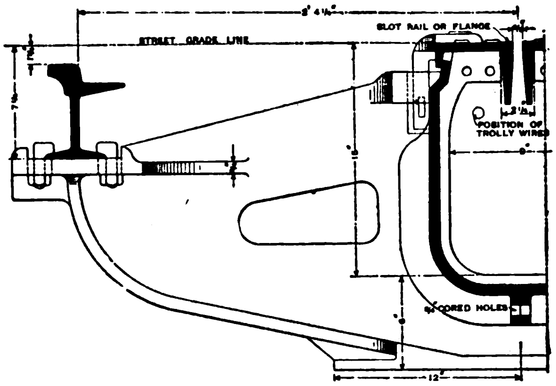


Fig. 1.—Love Electric Conduit for Street Railroad—Cross-Section.

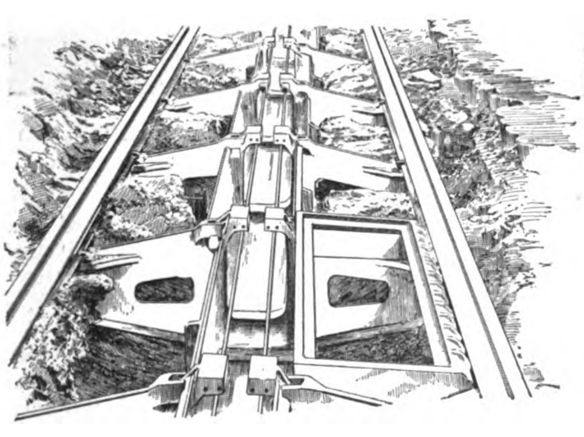

Fig. 2.—The Love Electric Railway Conduit.

During the heavy rainstorms in Chicago in the months of May and June this road was severely taxed, as in some places the streets were covered to a depth of three or four inches with water, filling the conduits. Notwithstanding the presence of water in the conduits, the running of the road was not interfered with. This road was put in as an experiment, but it has been so successful that the North Chicago Street Railway Co. has bought it, being well satisfied with the service rendered. Nineteen miles of this electric conduit system is negotiated for in Washington and Baltimore this year, and it is expected to have the lines in running order within six months.

The plant in Chicago for generating the current consists of one Edison dynamo, and a high speed "Ideal" engine. The two motor cars are equipped with Westinghouse motors. These two cars supersede about 110 horses, 60 being on the line constantly. The per diem cost for fuel and help at the power station is said to be very low. The repairs to trolley and other details have been reasonable so far.

THE ELIHU THOMSON PRIZE.

At the last prize contest instituted by the city of Paris for the best electric meter the prize of 5,000 francs was awarded to Prof. Elihu Thomson.

With the desire that this sum should serve for the development of the theoretical knowledge of electricity, he has requested the undersigned, general manager for Europe of the Thomson-Houston International Electric Co., to offer a prize for the best work on a theoretical question in electricity, and to organize a committee who should propose the subjects, examine the productions and award the prize.

The following gentlemen have been chosen, and have kindly consented to act as members of the committee: J. Carpentier, president of the Société Internationale des Electriciens; Hippolyte Fontaine; E. Hospitalier, professor in the School of Physics and Chemistry of the city of Paris; E. Mascart, member of the Institute; A. Potier, member of the Institute, examiner; B. Abdank-Abakanowicz, consulting engineer, secretary of the committee.

The committee has decided that the prize should be given for an investigation on one of the following subjects:

1. The heat developed by successive charges and discharges of condensers under different conditions of frequency, nature of dielectric and quantity of charge.
2. It has been shown theoretically that when the two surfaces of a condenser are connected by a conducting body, the condenser becomes the source of alternating currents as soon as the resistance of the conducting body decreases below a certain limit. The formula that permits calculating the period of this oscillation has not yet been completely verified. This period of oscillation should be investigated experimentally under conditions such that the exact measure of resistance, capacity and coefficients of self-induction may be possible, in order to arrive at a complete and precise verification of this formula.
3. When a condenser made with an imperfect insulating material has been charged and then left to itself, the charge is gradually dissipated. The time necessary for the charge to be reduced to a given fraction of its initial value depends only on the nature of the insulating material. It is proposed to investigate whether, as certain recent theories would seem to indicate, analogous phenomena do not present themselves in metallic conductors, and whether these can be shown experimentally.
4. It is proposed to arrange and systematize our present knowledge of the graphical solutions of electrical problems, and deduce from them some general methods as in graphical statics.

The theses presented may be written in any one of the following languages: English, French, German, Italian, Spanish or Latin. They may be in manuscript or printed.

Each thesis presented must be signed by a pseudonym and accompanied by a sealed envelope bearing the same pseudonym on the outside, and with the name and address of the author inside.

The papers must be sent before the 15th September, 1893, to B. Abdank-Abakanowicz, consulting engineer, the secretary of the committee, at 7 Rue du Louvre, Paris, who will furnish any further information required.

Ernst Thurnauer.

Paris, September 1, 1892.

THE SUCCESSFUL TRIAL TRIP OF THE UNION ELECTRIC COMPANY'S ELECTRIC LAUNCH "VASHTI."

ACCEPTING the invitation of the Union Electric Company to witness a trial trip of the "Vashti," a party of gentlemen representing the electrical and daily press, made a trip to Nyack by rail on Thursday last, Sept. 15. The party were driven to the boat-house of the Nyack Rowing Association, where the little craft was boarded. A delightful sail of nearly twenty miles around Tappan Zee was indulged in, which occupied about two hours. The behavior of the launch was everything that could be desired. Vibrations were almost imperceptible. She is a splendid little sea boat, as shown by her behavior when a "trough" was encountered in crossing the large bay from the picturesque headland, Hook Mountain, to Sing Sing, thence to Tarrytown and again across to Nyack. There was not the least "hitch" to mar the pleasure of the entire trip or to make the test anything but a success. Everything was perfectly new and untried, as the little vessel had been in the water but three days before this trial. Evidently storage batteries are "in it."

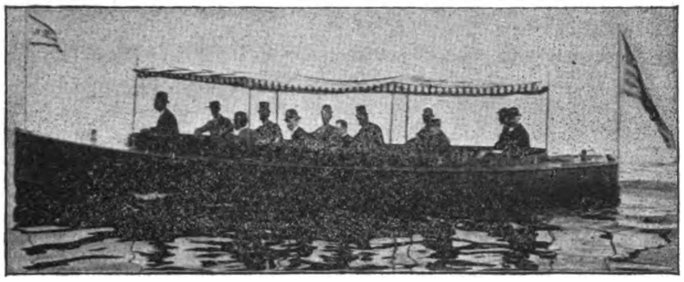

FIG. 1.—SIDE VIEW OF THE ELECTRIC LAUNCH "VASHTI."

After disembarking, the party were gracefully entertained at lunch by Mr. S. R. Bradley, Jr., secretary of the company. Suffice it to say, after the pleasant hours spent on the water, ample justice was done this latter portion of "the test."

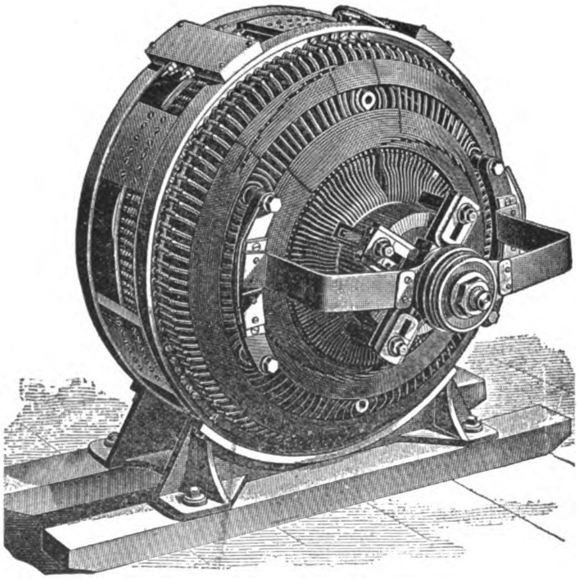

FIG. 3.—THE MAIN MOTOR.

THE "Vashti" is 30 feet long over all, with 6 foot 6 inch, beam, and has a draught of 2 feet of water. She can comfortably seat at least 26 persons. Her frames are of oak and she is planked with carefully selected cedar. She was built at the yards of Chas. L. Seabury & Co., of Nyack, under contract with Mr. S. R. Bradley, president of the Union Electric Co., of 45 Broadway, New York and is built from the same model as the steam launch of W. K. Vanderbilt, the "Alva." An almost incredible point is that although only having a length of 30 feet, this boat has a clear cockpit of some 23 feet.

Fig. 1 shows a full length view of the boat with Prof. Main at the wheel, and Fig. 2 shows also the current-controlling devices a description of which is here given. This controlling device is also the special design of Prof. Main, and is ingenious and simple and can be operated by a child. This portion of the apparatus is placed just under the forward deck, under the steering wheel, and where it is impossible for water to reach it. The person steering the boat operates this easily and at the same time. This device consists of a double-throw switch and rheostat with convenient wordings "ahead" and "back" on their proper sides of the dial. There are seven contacts on either side for increasing or decreasing speed. All this is on one shaft, and is manipulated by means of a small nickel-plated hand wheel. The voltmeter and amperemeter are placed one on each side of the rheostat dial. One switch cuts in one set or one-half the battery, while another throws in the whole 72 cells.

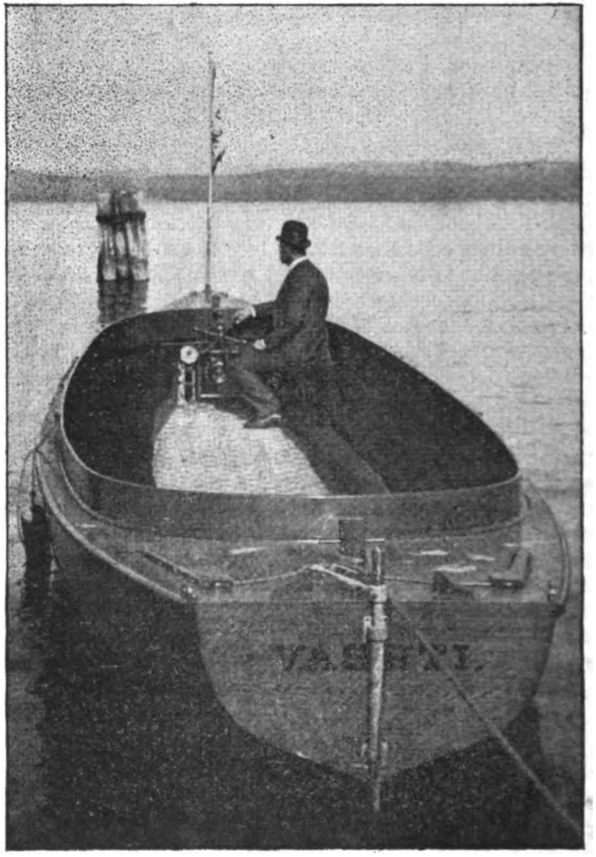

FIG. 2.—END ON VIEW OF ELECTRIC LAUNCH "VASHTI."

The motive power of the launch consists of an installation of 72 storage batteries (Main type), a cut of which appears in the advertising pages of this journal, the only difference being that in those used on the launch, the cell cases are of hard rubber. These cells are evenly distributed on either side of the keel of the boat, and immediately under her floorings on a false bottom or platform. This arrangement of what really constitutes the ballast of the boat is admirable, placing as it does all the weight below the water line and thereby making a wonderfully steady boat, as well as leaving at least 44 feet of locker room. The motor is also placed beneath the floor, and sits in a large copper jacket which protects it from any possible splashings or leakings. The motor Fig. 3, is specially constructed of the Main type with 5 h. p. capacity, manufactured by the Union Electric Works, with revolving brushes (carbon) and poles. A special device has been introduced by Prof. Main, by which the contact of the brushes on the commutator is neatly regulated. The brushes are held in a slot and a counter weight or compensator increases or decreases the brush contact as the centrifugal force increases or decreases. The motor and propeller shaft are direct coupled, the shaft thrust being a ball-bearing running in oil. The propeller is a three-flange wheel with 20 inch pitch. The weight of the motor is about 600 pounds and it has a very slow speed. At a speed of 400 revolutions the boat makes easily eight miles per hour.

THE SUBMARINE CABLE REQUIRED FOR LAKE HURON.

IN view of the great interest taken in the recent discussion in the columns of THE ELECTRICAL ENGINEER as to the proposed purchase of submarine cable by the United States Government for the use of the Signal Service on Lake Huron, we deem it worth while to print the specification, a copy of which has been courteously furnished us by Prof. Mark W. Harrington, Chief of the Weather Bureau. It will be seen that, as was suggested, the appropriation of $31,000 asked from Congress is intended to include the cost of laying the cable. The bids are to be opened at Washington at 11 a. m., Friday, September 30.

SPECIFICATIONS AND CONDITIONS FOR

furnishing and delivering or furnishing, delivering and laying, about six and one-half (6½) statute miles of one-conductor submarine telegraph cables. One piece to be laid from Thunder Bay Island to the main land, about 4 statute miles; and one piece from Middle Island to the main land, about 2½ statute miles. Said islands being located in Lake Huron, about 12 miles northeast and 15 miles east, respectively, from the city of Alpena, Mich.

SPECIFICATIONS.

1.-*Conductor.*—The conductor to be formed of a strand of seven copper wires, each No. 22 B. & S. gauge, of the best quality and manufacture, and of a conductivity not less than 96 per cent. pure copper. The resistance of the conductor to be not more than 12.20 ohms per statute mile (1,760 yards) at a temperature of 70 degrees Fahrenheit.

2.-*Insulation.*—The interstices in the conductor to be filled with Chatterton's compound, and the whole covered with three coatings of best gutta-percha, to be applied so as to be entirely homogeneous to a diameter of 0.26 inch, and give an insulation resistance of not less than 400 megohms per statute mile, after being submerged in water for 48 hours at a temperature of 70 degrees Fahrenheit.

3.-*Serving.*—The core to be served with three layers of best tarred jute, of proper thickness.

4.-*Armor.*—The served core to be armored with 12 No. 5, B. W. G., Best-Best galvanized iron wires, spirally laid.

CONDITIONS.

A sample is desired with each bid, if practicable.

Preference will be given to bids to furnish the cable laid, but bids will also be entertained for the cable delivered at Alpena, Mich.

Bids should state the cost per statute mile of cable delivered at Alpena, Mich., and, separately, the cost of laying the cable between the points named.

The cable is desired as soon as practicable, and each bidder must state the time within which it will be furnished.

The cable should have as few joints as practicable, and the bidder will specify whether the two sections will be delivered whole or in how many pieces.

The cable should be wound on reels of such construction and strength as to be used in laying it.

The cable is to be subject to such inspection and tests as the bureau may consider necessary, either before or after laying, or both; and if laid by the bidder, will be laid over such general course as may be indicated by an agent of the Weather Bureau, in the deepest water. The shore ends to be buried under ground from a point where the water is four feet deep to the foot of the cable pole, where it will be brought up, made fast to the pole and ready for connecting into a cable box. The cable will not be less than two feet under ground on shore, nor less than four feet from the surface in the water.

If laid by the bidder, an agent of the Weather Bureau will be present on the vessel and elsewhere, to see that the work is done according to the true intent and meaning of the contract.

All materials used to be of best quality, and all work to be done in the best manner and within the time specified by the accepted bidder.

The necessary instruments and batteries for testing the cables before and after laying must be provided by the contractor.

Patent Notes.

PROF. THOMSON'S ALTERNATING CURRENT TELEPHONE SYSTEM.

IN a patent just issued to Prof. Elihu Thomson, this well-known inventor describes a system of telephone in which alternating currents are employed in the primary of the induction coils to which the transmitter is connected instead of continuous currents, as now generally employed. In applying the alternating current for this purpose, Prof. Thomson employs such a low rate of alternation as not seriously to interfere with speech.

The alternations, generated by an alternator, are induced into the subscribers' lines and form the means for transmission from the subscribers' lines to other subscribers' lines, to which they may for the time being be connected through the exchange. The rate of alternations is as low as 32 vibrations per second, and even those below sixteen vibrations per second are available. These rates of vibration or alternation are so low that although the instruments are subjected to them they do not seriously interfere with speech, as the tone they produce is almost inaudible on account of the small volume of air set in motion by the diaphragms of the instrument.

By means of this system, all local batteries at the subscriber's end of the line are dispensed with, and the system is, as it were, a closed circuit system possessing great flexibility. The system also permits the working of the annunciators at the exchange by the subscriber momentarily opening the line by a switch, or, better, by the simple act of lifting the telephone from the hook, while the replacing of the telephone on the hook again signals the exchange that the use of the line is discontinued. The system also provides circuits, so that there shall not be any circuits actually grounded, as connections to earth through condensers may be made instead of returning through a continuous conductor or a metallic circuit connected to earth, such as is ordinarily employed.

Reports of Companies.

IMPORTANT ACTION OF THE WESTERN UNION CO. INCREASING CAPITAL STOCK.

THE WESTERN UNION TELEGRAPH COMPANY has declared a quarterly dividend of 1¼ per cent., payable Oct. 15. The board of directors have adopted resolutions recommended by the executive committee, authorizing and directing proper steps to be taken for an increase of $18,800,000 to the capital stock of the company, making the aggregate capital stock $100,000,000, to be issued at such time or times and for such lawful considerations as the board of directors may thereafter direct and determine. A special meeting of the stockholders will be held on October 25, to vote upon this proposition. The regular annual meeting of the stockholders will be held on October 12, and the transfer books for that event and for the payment of the dividend will be closed on Sept. 20. It is understood that $8,620,000 of the new stock will, if authorized, be used to pay the shareholders a scrip dividend of 10 per cent. to represent net earnings diverted from them and expended in making additions to the property. The remaining $5,600,000 will be held in the treasury of the company. For the quarter ending Sept. 30 the company reports partly estimated earnings as follows:

	1892.	1891.
Net revenue	$2,200,000	$2,000,000
Interest and sinking fund	242,960	242,388
Balance	$1,957,040	$1,757,612
Dividend	1,077,410	1,077,405
Surplus	$879,630	$680,207
Total surplus	14,455,757	12,097,948

From the quarterly reports issued by the company an approximate statement of the results for the year ending Sept. 30 shows:

	1892.	1891.
Net revenue	$7,398,545	$6,605,583
Interest and sinking fund	970 523	931,218
Balance	$6,428.022	$5,674,365
Dividends	4,309,637	4,309,606
Surplus	$2,118,385	$1,364,759

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

THE Institute will hold its first meeting of the season on Sept. 27, at 12 West Thirty-first street, when Mr. Charles Steinmetz will read a most important paper on "The Law of Hysteresis." The report on the election of officers will be brought up, and members will be invited to contribute notes of their electrical vacation experiences.

E. J. HALL, SR.

THE sudden death is announced of Mr. E. J. Hall, Sr., who has long been prominently and actively connected with telephone interests in Buffalo and Rochester. He had been ailing for some time past. Mr. E. J. Hall, Jr., the well known executive of the American Telegraph and Telephone Co., (Long Distance) in this city, is his son.

Literature.

The Law of Incorporated Companies Operating Under Municipal Franchises. By Allen Ripley Foote and Charles E. Everett. Cincinnati, *Robert Clarke & Co.*, 1892. Price, $10. (Advance sheets.)

THIS book embodying as it does the economic legislation of all the American States, so far as it relates to companies operating under municipal franchises, is a most timely, important and valuable publication. Just to what extent legislation is now occupied with questions of this nature is not well known, but it must be very considerable. In America it is of greater scope than in any other country for the reason that here, thanks to the primal conditions of Statehood, scientific home rule prevails, and each community settles for itself matters that elsewhere are heaped upon an overburdened Imperial legislature, which lets them drag along. The result of our system is that, while with greater freedom, we have an undue variety of treatment, the public will is more directly and immediately in control of the privileges that it confers. The precedent established thus in our federal system of government broadens down through all the methods of economic legislation, so that, not to put it too broadly, we will often find a New England community disposing in an hour of a question that in Old England will block action at Westminster for a whole session and even turn out a strong Administration.

But even where the principle of individual decision is most clearly seen, as in this country, it is evident that certain ideas and feelings may so permeate a nation as to be governing in even its most 'independent and widely scattered communities. It thus becomes necessary, or at least desirable, to ascertain just what the conditions prevalent in legislation are; whether different kinds of franchises are subject to different limitations or whether a uniformity of practice obtains; what return to the community is expected for favors granted; whether there is a growing jealousy of such corporations or whether they flourish under a benign sun of liberality. America is most certainly the best field in which to study the manifestations of the popular will towards companies operating under municipal franchises; and the book before us is in effect an analysis and summary of State and Municipal policy relating thereto.

Electrical investments are peculiarly susceptible to the influences of legislation for the reason that a very large number of electrical inventions are strictly public servitors. If we mention simply the telegraph, the telephone, the electric light and the electric railway, how large a sphere of industrial and inventive development is at once covered; and all these inventions can only be availed of under the operation of State laws and municipal franchises. Now, as we look around, do we find that electrical enterprises make greater headway in one State than another; and if so, is not the reason to be found in the more generous treatment by the State of those whom it invites to invest their capital, under its protection, in enterprises from which the mass of its citizens shall reap notable advantages? This is a vital question, and only with the aid of such a book as this can it be answered.

After all, the modern conception of the relation between the State and these local companies that supply water, electricity, gas, locomotion, etc., is the highest and best realization we yet have of the principle of co-operation. Every time that a corporation is formed to render some public service, under certain conditions that the State or municipality imposes, each and all of the citizens become partners in the enterprise, interested in its welfare and prosperity. It cannot well be otherwise, even though the citizen often enjoys in more senses than one an unearned increment. Sometimes—often perhaps—the corporation makes a bargain that is unreasonably profitable to its immediate stockholders; but not less frequently may be seen the development in wealth and prosperity of a community by a corporation that has not been given the slightest local encouragement and that has to struggle for years against small returns, when by a more restricted outlay at the start it might have made money very quickly. There has apparently been gaining ground an idea that these local services can best be rendered to a community by itself, on borrowed capital and with the aid of sundry new bureaus and departments; and the newer electrical enterprises have been a special point of attack by persons holding such opinions. Hence to-day we find a number of communities which instead of issuing franchises that bring a return, issue bonds that mean heavier taxation. On the whole, however, it may be doubted whether this economic heresy is winning many adherents; and the inference to be drawn from a study of this volume deepens the doubt. There do appear, nevertheless, two tendencies; one looking toward control; the other looking toward the exaction of a larger price for the franchise granted. The former process will probably continue. The State must be master and its supervision must keep pace with the growth of corporations in elements of power. The fact that it delegates to these corporations certain of the functions that the present condition of society requires the performance of, does not excuse it from vigilance on behalf of its citizens. But on the other hand, so long as it enjoys an active voice in the management of these quasi-public properties, the community is beginning to find out that it is better to go slow in making a company pay dearly for its franchise. It may be accepted as an axiom that the higher the price paid for the franchise, the lower will be the quality of the service rendered.

Many considerations of this nature, as well as others, are set forth by Mr. Foote in his thoughtful discussion of the principles involved. We do not at all points agree with him; at some, our disagreement is extreme; but in the main his work is very well done, and his masterly plea for a broad and liberal treatment by the public of itself as embraced in corporate forms, will stand. For the rest, it may be stated that Mr. Everett is an admirable editor of the legal part of the work, and that he has had splendid assistance from the forty-six attorneys who have prepared the digest of corporate legislation in each State. It is said that $20,000 has been spent on the preparation of the book. We can readily believe it, and we are equally ready to believe that everywhere the subscriptions for it will be liberal enough to fully indemnify and reward Mr. Foote, his publishers and his colaborers. The book is one that should be in the office of every local company, every mayor, every city clerk, and every lawyer who has to deal with questions of municipal franchise.

It remains to add that when complete, the work will be contained in two volumes of about 1,400 pages each. Delivery to subscribers will be made in October.

The Law of Electric Wires in Streets and Highways. By Edward Quinton Keasby, of the New Jersey Bar. Chicago, Ill. *Callaghan & Co.* 1892. 8vo. pp. 190 + xi. $3.50.

The author of this work, in his preface, claims to have undertaken nothing more than to collect and examine the reported decisions, with a view of ascertaining how the principles of the laws relating to streets and highways have been applied to the new and perplexing conditions which have arisen within the past few years, from the necessary use and occupancy of these thoroughfares of electric lines. He has not attempted, nor indeed would it have been useful for him to have attempted, to produce a treatise on the subject. The legal controversies relating to these matters have nearly all arisen within the past ten years, and there has been no little conflict, up to the present moment, between the decisions of different tribunals. To the mind of the layman it would almost appear as if nothing had been conclusively settled in reference to some of the matters principally in controversy, but Mr. Keasby, while for the most part very conservative in the expression of his own views, has sometimes felt justified in indicating the conclusions to which the reasoning of the courts appear to point. While therefore, the work, from a legal point of view can be regarded as little more than a digest of the reported decisions, it nevertheless appears to embody about all that could be said, or that it would be profitable to say, at the present moment.

Lord Coke has said: "Reason is the life of the law—nay, the common law itself is nothing else but reason; which is to be understood of an artificial perfection of reason gotten by long study, observation and experience, and not of every man's natural reason." In other words the broad and comprehensive principles of the common law, founded on reason, natural justice and enlightened public policy are adapted to practical use in particular cases by general usage, which evinces their fitness and convenience, and are then made precise and specific by judicial exposition. "The consequence of this state of law is," in the words of Chief Justice Shaw, "that when a new practice or a new course of business arises, the rights and duties of parties are not without a law to govern them; the general considerations of reason, justice and policy, which underlie the particular rules of the common law, will still apply modified and adapted by the same considerations, to the new circumstances. If these are such as to give rise to controversy and litigation, they soon, like previous cases, come to be settled by judicial exposition, and the principles thus settled soon come to have the effect of precise and practical rules." We find accordingly, that an examination of the cases which Mr. Keasby has industriously collected and annotated reveals much of interest as showing how the judicial mind has grappled with the various and oftentimes perplexing questions which have arisen.

"The rights in the streets," says Mr. Keasby, "are both public and private. They are opened for public use, and yet the title to the land, subject to this use, remains in private owners, or else the owners of adjoining lands have a right of property in having the road kept as a road for the public purposes to which it is devoted. The present discussion, therefore, involves the consideration of what are the proper uses of the street, and how far these are subserved by the various uses of electric wires, and also what are the public or private rights with respect to the streets and to the use of them for these purposes." The branch of the above inquiry as to public rights, relates mainly to the authority under which streets and highways may be occupied by poles and wires, while, in respect to private rights, it becomes necessary to ascertain whether the various uses of electric wires in the streets affect these rights, either as imposing a new burden upon the land or as trespassing upon the rights of abutting land owners in the street to such an extent that compensation must be made. Incidental to this branch of the inquiry are the frequently occurring controversies between the telephone companies and the electric lighting and railway companies, arising out of the interference of electric currents, due to the use by both, of the earth as a return conductor.

In the necessarily brief space at our disposal, we can only refer to some of the most important of these questions which have come before the courts for adjudication. It has been well settled that the use of the streets belongs solely to the public; that the legislature represents the public, and hence, that a municipality can have no control over the streets other than that which has been given to it by the legislature, either expressly or by implication. It follows from this that a municipality can have no power to grant exclusive franchises or permanent privileges. The legislature, however, within the limits prescribed by the constitution, may grant exclusive, indefinite, and irrevocable franchises for the use of the streets. In case the legislature has authorized the construction and operation of a street railway, and perhaps also the employment of electric motors for operating such railway, the question has frequently arisen as to how far the municipal authorities may permit, or may regulate, the construction of a system of overhead wires for supplying electricity? A number of cases involving this point have been decided, in which overhead wires had not been expressly authorized by the legislature, and in some cases not even by municipal ordinance. The trend of judicial opinion appears to be, that the municipality, by virtue of its power to regulate the use of the streets, may determine whether or not any particular structure is or is not in fact an obstruction to the free public use of the street. It has even been held in a case in California, that a municipality may prohibit the placing of electric wires over or across the roofs of buildings, on the ground that the practice is dangerous "both as being likely to originate fires and as interfering with the extinguishment of fires otherwise originated."

The greater number of controversies of late have arisen between the electrical companies and land owners, in consequence of the enormous multiplication, during the past few years, of overhead wires for various purposes. So long as electric lines were confined mainly to telegraphs along country roads, few such contentions arose, and it is therefore not surprising to find that although the telegraph has been in use for 50 years, scarcely a decision involving this question is reported prior to 1883. But with the daily increasing new uses of wires, the enormous increase in their numbers, and the introduction of the element of danger to life and property attending the use of powerful currents for electric lighting and other purposes, aided and abetted by a senseless newspaper clamor, a determined opposition to all overhead wires has been developed on the part of owners and occupiers of land, so that there have been many decisions within the past two years, as to whether an abutting owner may legally object to the erection of poles and wires in the street, especially for the purpose of propelling street cars. For a time the courts manifested a tendency to make the conclusion turn upon the question whether the fee of the land embraced in the street, was vested in the municipality or in the abutting owner. This aspect of the question however, appears to have been thoroughly threshed out and settled in the "elevated railroad cases" in New York, and the weight of opinion at the present time clearly is that the abutter, whether owner of the fee or not, has a right to light, air and free access to his property, which cannot be taken from him without compensation. There can be no doubt that the doctrine of all the decisions is to the effect that the adjacent owner has redress for any substantial obstruction of his right of access, or of interference with his free enjoyment of the use of the street. As to the right to plant poles without the land owner's consent, where there is no actual interference with access, or with light and air, there is still much difference of opinion. With the extension of the conveniences required by modern civilization there must necessarily be an enlargement of the uses to which the streets are put, and as Mr. Keasby points out, so long as these enlargements serve the public convenience, and do not diminish the actual use and enjoyment of the land owner, there would seem to be no reason on principle why the land owner should have a right to object, since in any event he could only be entitled to recover nominal and not actual damages. The real issue therefore, resolves itself into an inquiry whether the use of the electric cars, and of the poles and wires necessary to their operation in any particular case, does in fact interfere with the free use of the street in connection with the adjacent land, or diminish the value of such land by changing its relation to the street.

The most interesting as well as the most difficult phase of the whole controversy, is that which relates to the interference by electric light and railway currents with the ordinary use of the telephone. The telephone companies, being well provided with the sinews of war, have naturally enough resented the intrusion of both these newcomers with vigor, and not without effect. In the last-named instance the current has been applied to the legitimate purposes of the street railway, a prior occupant of the streets, and moreover, the electric railway, being used for the purposes of public travel, has in any case, as a matter of principle, a better claim of right to the use of the streets than the telephone wires. There has been much litigation on this subject in the inferior courts, but an examination of the decisions which have been collected by Mr. Keasby, shows that considerable difference of opinion still prevails as to the legal relations of the conflicting interests. It seems clear, however, that the courts are not disposed to exercise the power of injunction beyond what is necessary to avoid present injury to existing property, and it is by no means certain that it will be exercised even to that extent. It may be that the courts will ultimately take the ground that every one using electric force in the public streets must protect himself, by his own ingenuity, from interferences arising from the lawful uses of the same force by others. It is certain that the public convenience will demand that the thoroughfares shall be alike open to the use of all the electric currents that may be required, and as Mr. Keasby pertinently observes, "it seems likely that the settlement will be made through the ingenuity of inventors rather than by the efforts of lawyers and judges."

A considerable number of cases are reported growing out of the well-remembered conflicts between the Western Union and the American Union and Baltimore and Ohio Telegraph Companies, in reference to the exclusive grants of rights of way given to certain telegraph companies along railway lines. The case of *Pensacola Telegraph Co.* vs. *Western Union Telegraph Co.* arose under an act of the legislature of Florida purporting to give the former an exclusive right to erect telegraph lines in certain counties. The Supreme Court decided that this act was in conflict with the act of Congress of 1866, giving all telegraph companies under certain conditions, the right of way over all military or post roads in the United States. It appears from subsequent decisions that the real effect of this act is to deny any particular telegraph company the right to acquire any such easement in the lands of a railroad for telegraph facilities, as to exclude other companies from obtaining like privileges. Upon principle it would seem, therefore, to prohibit any railway company from making such an exclusive contract with one telegraph company as to debar itself from the right to make a similar contract with a rival company.

There are many other minor points of interest involved in the cases reported, reference to which must be omitted for lack of space. It is only necessary to add that the particular work which Mr. Keasby has undertaken to do, has been done conscientiously and intelligently. We can recall no decision, up to a very recent date, which has escaped his attention. Some compilation of this kind has become a necessity to all officers of corporations which have occasion to construct or use electric conductors in the public streets and highways. We can but express the hope that when the evolution of the subject has progressed far enough to render it possible to write a systematic treatise upon the law of electric conductors, that the work may fall to the lot of at least as accurate and careful an author as Mr. Keasby.

Letters to the Editor.

"CONTINUATOR," "PULSATOR," ETC.

It was with pleasure that I noticed the criticism of Mr. Tyler in the last issue of The Electrical Engineer, and while I, myself, would like to hear shorter and more appropriate names, it seems to me that the arguments or reasons given are not quite to the point. At present we understand by the words "continuous current generator" only a *dynamo which is capable of maintaining through an external circuit* an electric current, the impulses of which follow each other quick enough to be considered as an even flow. We do not understand by "continuous current generator" a dynamo which will originally generate continuous currents. It is well known that all commercial machines, built up to the present, are alternate current generators, with two or more contact terminals attached thereto, depending on the purpose for which they are required.

The same remarks apply to a pulsating current generator. An alternating current generator, or alternator, can be construed in the way indicated by Mr. Tyler, and from this standpoint the name "continuous current generator" would have been more appropriate for chemical batteries. It is well known to engineers that the names for the dynamo types under consideration are misleading and incorrect if construed in the way Mr. Tyler does. His objections would fall primarily upon the nature of the dynamo and upon the old names. The latter, in spite of their admitted weakness, are so well known that it would not be wise to change them so far as to lose their origin. It was not the intention to find names which could mean "that the apparatus, so called, *generate* the currents pulsated or continuated." It is the rule to name a device by the work it has to do, and not by the processes it has to perform to reach the final result, and this view justifies the old names. We speak of an arc light or incandescent light dynamo or generator, not because they generate the lights, but operate them in the external circuit; we speak of converters, transformers, secondary generators, because we take the external circuits always into consideration, and with the same right we can construe a continuous current generator or pulsating current generator, a dynamo adapted to maintain through an external circuit, respectively, a continuous current, or a pulsating current flow. Construed in this light, both the old and the proposed names are characteristic of the nature of the current used to operate devices.

The advantage in construing the generators in the light just named will be seen, as it overcomes the just criticisms raised. Mr. Tyler says: "These names will equally as well refer to purely mechanical or non-generating devices—and there are several—which are used to pulsate a continuous current, and to continuate a pulsating one."

These names cannot be construed in the light Mr. Tyler mentioned, but are characteristic and correct, if we consider the system to consist of the generator on one hand, and the external circuit on the other. The commutators or mechanical devices referred to by him are invariably located in the external circuit, while in a dynamo the external circuits begin at the brushes. The commutator, therefore, forms the terminals of the wires which constitute an element in the generator. A battery and a Ruhmkorff coil may serve as a comparison.

I hardly think that any one would call a "pulsator" a primary battery in connection with an interrupter. The interrupter has never the close connection with the battery, as a commutator to the armature winding; the difference is that the one forms part of the machine proper while the other forms part of the external circuit.

For mechanical devices, *separate* from the generator, we have the following names: Switch, pole changer, commutator; to which we could add "current dresser." For devices adapted to cause pulsations we have "vibrator" and "interrupter," to which we could add "fluctuator."

The objections raised by Mr. Tyler hold good only as long as a proper distinction is not made, or as long as a definition is not given. The less common names may be applied to devices not frequently used, such as "pole changer" or "current dresser," vibrator or fluctuator respectively, while the shortest ones, and especially those which easily disclose their origin, should be retained for the generators or more common devices, as for instance, *continuous* current gener*ator* or *continuator*, *pulsat*ing current gener*ator*, or *pulsator*.

LUDWIG GUTMANN.

CLEVELAND, OHIO, Sept. 3, 1892.

WHY UNIPOLAR DYNAMOS DON'T WORK.

MR. S. W. BALCH in his interesting article on "Twisting Magnetism," printed in THE ELECTRICAL ENGINEER of Sept. 14, seems to be at a loss for an explanation, why his machine did not yield any current whatever.

Unfortunately he has, in common with very many other inventors of unipolar dynamos overlooked a very important fact. It may perhaps save some future inventors in that field from disappointment and loss, if this fact is again pointed out with some emphasis, and in order to do this, I can do no better than to quote the following sentences from Silvanus Thompson's "Dynamo-Electric Machinery," viz: "It is, however, necessary that the moving conductor should, in its motion, so cut the magnetic lines as to alter the number of lines of force that pass through the circuit of which the moving conductor forms part. * * * If the coil be moved by a motion of translation to another part of the uniform field, as many lines of force will be left behind as are gained in advancing from its first to its second position, and there will be no current generated in the coil."

D. C. REUSCH.

NEW YORK CITY, Sept. 14, 1892.

Society and Club Notes.

ANNUAL MEETING OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

THE annual meeting of the American Electro-Therapeutic Association will be held in this city, at the Academy of Medicine, on October 4th, 5th and 6th. The president is Dr. William J. Morton, of New York; secretary, Dr. Horatio R. Bigelow, 1776 Chestnut street, Philadelphia. The New York committee of arrangements are Drs. Robert Newman and A. H. Goelet. The programme will consist of scientific papers and discussions, and reports of committees appointed last year to secure uniformity in the manufacture and use of certain instruments used in electrotherapeutics. Prof. E. J. Houston is also to contribute a paper on "Cataphoresis," and Mr. J. J. Carty will discuss electro-therapeutics from the standpoint of the electrician.

There will be an exhibition of batteries, instruments and appliances used in medical and surgical electricity. The New York Electric Club will give the association a reception on October 4.

Inventors' Record.

CLASSIFIED DIGEST OF ELECTRICAL PATENTS ISSUED SEPT. 6, 1892.

Accumulators:—

Storage Battery, P. Kennedy & C. J. Diss, Brooklyn, N. Y., 482,043. Filed Sept. 25, 1891.

Employs a non-conducting grid for holding the active material and conductors connecting the different sections.

Storage Battery, P. Kennedy & C. J. Diss, Brooklyn, N. Y., 482,044. Filed Sept. 25, 1891.

A structure for holding the active material composed of cohesive bitumen, resin, gum or gum-resin and a mineral non-conductor of electricity.

Alarms and Signals:—

Electric Fire and Burglar Alarm Connection, H. T. Wilson, Louisville, Ky., 481,989. Filed June 9, 1892.

Employs a spring blade bent into the form of a loop and filled with a melting composition normally holding the circuit open.

Train Signaling Apparatus, J. M. Henry, Wilmerding, Pa., & R. B. Wilson, Altoona, Pa., 482,126. Filed Dec. 23, 1891.

A signal between the cab of the engine and the cars of the train employing both electricity and compressed air or steam in its operation.

Electric Alarm Clock, J. McMillan & G. H. Taylor, Philadelphia, Pa., 482,133. Filed Mar. 26, 1891.

Feed Indicator for Boilers, A. Guasco & A. Chusin, Marseilles, France, 482,171. Filed Oct. 8, 1891.

Watchman's Electric Time Recorder, E. R. Heyser, Leon, Mex. 482,251. Filed Mar. 2, 1892.

Electric Annunciator, E. D. Moore, New York, N. Y., 482,263. Filed Feb. 18, 1892.

Electric Railway Signal, C. K. Hall, New Orleans, La., 482,306. Filed April 4, 1892.

A protection signal between individual cars in a train.

Conductors, Conduits and Insulators:—

Conduit System for Electric Railways, R. Lawrence, St. Joseph, Mo., 481,959. Filed Jan. 7, 1890.

A railway conduit having the trolley wire placed at one side in such a manner that the conduit may also be used for a cable system or other purposes.

Electrical Circuit and Cable, J. A. Barrett, Brooklyn, N. Y., 482,149. Filed Jan. 8, 1891.

Employs a single mesh of cord woven between and about two naked conductors.

Electric Conductor, J. A. Barrett, Brooklyn, N. Y., 482,150. Filed Jan. 8, 1891.

Claim 1 follows:

An electric conductor or group of conductors having a covering of paper, cloth or other flexible material provided with tucks extending transversely to the lines of flexture.

Electric Conductor, J. A. Barrett, Brooklyn N. Y., 482,151. Filed July 17, 1891.

Employs a plurality of independent circuits each consisting of a pair of conductors formed into a single oblong strand.

Electric Circuit and Cable, J. A. Barrett, Brooklyn, N. Y., 482,152. Filed Aug. 23, 1891.

Consists of a pair of flat conductors arranged edgewise with relation to each other.

Electrical Conductor, P. H. Holmes, Gardiner, Me., 482,177. Filed Jan. 2, 1892.

Claim 1 follows:

An electric conductor composed of particles of plumbago disposed in strata which lie in planes parallel with the direction of the current.

Means for Drawing Cables into Conduits, T. F. O'Connor, New York. N. Y., & J. W. Marsh, Pittsburgh, Pa.. 482,270. Filed Jan. 8, 1892.

Employs a series of drawing wires connected to the cable at different points along its length.

Electric Insulator, W. H. Clark, Brooklyn N. Y., 482,297. Filed May 21, 1891.

An insulator having a depression in its top for supporting the line wire and side projections for the tie wires.

Electric Cable, J. A. Barrett, Brooklyn, N. Y., 482,328. Filed Aug. 28, 1891.

Employs a core of hollow structure of paper or similar material upon which the conductors are secured at a distance from one another.

Dynamos and Motors:—

Armature for Dynamo-Electric Machines, J. Nebel, Charlton, 482,265. Filed Nov. 11, 1891.

An armature having not less than eight conducting bars, each bar connected not to the opposite bar but to the second, third or tenth before the opposite, and each brush touching two, three or ten commutator segments.

Galvanic and Thermo-Electric Batteries:—

Battery Connector, R. B. Knowles, Brooklyn, N. Y., 482,012. Filed Oct. 15, 1891.

A battery connector, having a screw-threaded projection provided with a shoulder for the purpose of making rigid contacts.

Heating:—

Electric Furnace Generator, E. Berliner, Washington, D. C., 481,999. Filed Aug. 31, 1887.

Employs an electromagnet having an axial bore and an armature acted upon by a heater, provision being made for intermittently passing a cooling fluid through the bore of the magnet against the armature.

Electrical Heater, J. V. Capek, New York, N. Y., 482,074. Filed Mar. 5, 1891.

Claim 4 follows:

The combination with a heating conductor and enclosing box of a cover therefor and a composition containing graphite and a metallic oxide between the conductor and the cover.

Lamps and Appurtenances:—

Ceiling Block for Incandescent Lamps, L. Stieringer, New York, N. Y., 482,104. Filed July 3, 1886.

Provides means for removing the weight of the lamp from the electric connection in the ceiling box.

Support for Electric Lamps, A. Wright, Providence, R. I., 482,112. Filed Mar. 23, 1892.

Electric Arc Lamp, J. T. Birch, Pittsburgh, Pa., 482,157. Filed Apr. 4, 1892.

Employs two hubs, each provided with radially arranged holders for carbon rods, a series of cam projections connected to the shafts carrying the hubs, and reciprocating dogs engaging said projections and rotating the shafts.

Electric Arc Lamp, J. E. Gaston, Sparta, Ill., 482,240. Filed May 31, 1892.

Employs a frame plate for the carbon carrying mechanism, having opposite guiding tracks projecting from opposite sides of the plate and tracks on one side of the frame plate arranged parallel with those on the opposite sides.

Electric Arc Lamp, J. F. Kester, Terre Haute, Ind., 482,253. Filed May 11, 1892.

Employs a clutch mechanism consisting of a friction block gripping the carbon holder and set in the arms of the collar surrounding the carbon holder, the whole being placed within a single armature frame pivoted at one point.

Measurement :—

Meter for Alternating Electric Currents, O. B. Shallenberger, Rochester, 481,975. Filed Oct. 31, 1888.

Employs a closed secondary conductor, consisting of continuous rings connected in parallel.

Induction Coil for Electric Meters, E. Thomson, Lynn, Mass., 482,209. Filed Mar. 5. 1889.

Has for its object to obtain when desired a larger proportionate registry for a small than for a large consumption of current.

Electric Meter, F. Teague, London, England, 482,324. Filed Nov. 17, 1891.

Employs an armature having a central mercury contact and an outer annular mercury trough adjustable to regulate the immersion of the armature.

Miscellaneous:—

Apparatus for Cutting Minerals, L. B. Atkinson and H. W. Ravenshaw, London, and F. Mori, Leeds, England, 481,921. Filed Aug. 18, 1891.

An electric coal cutter, employing an automatic rope feed receiving reciprocating movement from an eccentric rotated by the motor axis.

Apparatus for Electrically Purifying Water, L. T. Stanley, Brooklyn, N. Y., 481,979. Filed Feb. 11, 1890.

Power Transmitting Device, E. D. Weyburn, Chicago, Ill., 481,988. Filed Apr. 16, 1891.

A portable electric motor adapted to be moved along the side of a shop or factory and having power transmitting mechanism adapted to be applied in any portion of the work.

Rheostat, H. W. Lawrence, Denver, Col., 482,093. Filed Apr. 25, 1891.

A rheostat for regulating the brilliancy of incandescent lamps.

Automatic Battery Cut-Off, W. S. Richards, Natick, Mass., 482,136. Filed Jan. 8, 1891.

Employs a bell crank lever loosely engaged with the armature and having a terminal, and so arranged as to momentarily engage another terminal secured to the armature.

Electric Valve Controller, E. F. Roberts, Columbus, Ohio, 482,188. Filed Aug. 26, 1890.

Has for its object to automatically regulate the pressure and temperature in heating systems.

Telltale for Electrolytic Refineries, F. B. Badt, Chicago, Ill., 482,148. Filed May 16, 1892.

Electrical Gas Lighter, J. E. Hamilton, Chicago, Ill., 482,172. Filed March 11, 1892.

Electric Connector for Hose, C. F. Kellom, Delair, N. J., 482,181. Filed Dec. 11, 1891.

Magnetic Separator for Ore Concentrators, C. E. Seymour, Lake Geneva, Wis., 482,323. Filed Oct. 2, 1891.

Railways and Appliances :—

Automatic Trolley Disconnector, G. A. Kimball, Seattle, Wash., 481,956. Filed Nov. 21,1891.

Employs a pivoted trigger and a weight normally hung within a slot formed in the short arm of the trigger.

Trolley and Electric Railways, C. A. Adams and T. J. Thorp, Lincoln, Neb., 482,031. Filed Mar. 25, 1892.

Employs an internally screw-threaded sleeve screwed to the end of the pole and a lock knot bearing against the sleeve.

Trolley for Electric Railways, J. M. C. Tyner and S. S. Irving, Minneapolis, Minn., 482,325. Filed Nov. 30, 1891.

Claim 1 follows:

A trolley carrying a detent adapted to occupy a position over the trolley wire at a point in the rear of the trolley wheel.

Switches and Cut-Outs :—

Electrostatic Switch and Phase Indicator, A. U. Alcock, Melbourne, Victoria, 482,082. Filed May 26, 1891.

Claim 5 follows:

An electrostatic switch, consisting of the combination of a circuit closer, relatively movable plates of a condenser controlling said circuit closer and an indicating device controlled by said plate or plates.

Telegraph :—

Printing or Recording Telegraph, Z. T. Lillard and U. Erhard, Kansas City, Mo., 482,015. Filed Jan. 23, 1892.

A writing telegraph, in which each character of one instrument shall be in direct electrical connection with the like character of other instruments.

Combined Telegraph Key and Sounder, D. J. Ludwig, New York, N. Y., 482,129. Filed May 2, 1892

Employs a bifurcated frame and armature lever playing between the sides and the sounder magnet supported above the armature lever.

Electrically Adjusting Relay, W. S. Richards, Natick, Mass, 482,137. Filed Sept. 14, 1891.

Provides means whereby the tension of the spring is automatically adjusted by the strength of the current.

Telephones and Apparatus :—

Telephone Exchange Apparatus, A. S. Hibbard, New York, N. Y., 482,174. Filed June 2, 1892.

Employs a repeating coil, having one of its windings connected with the order circuit and an independent loop extending from the terminals of the receiving telephone and formed into a closed circuit with the other winding of the repeating coil.

ENTERPRISE ELECTRIC CO.

MR. W. C. MCKINLOCK, president and treasurer of the company, has just returned to Chicago from New York and pleasure resorts of the East. He also spent a short time in Bristol, R. I., on a business tour to the National India Rubber Company's factory, for which company the Enterprise Electric Co. has recently been appointed general Western agents.

Mr. W. F. Richardson, manager, has left for St. Louis to look after the business of the company at that place through the new branch house established lately there at No. 15 North 9th street.

The fall rush is fairly on, and the company have reason to be much encouraged thereby. The N-I-R-wire is popularizing itself because it is seamless, and by being manufactured of the purest and best of materials. The outlook is very flattering.

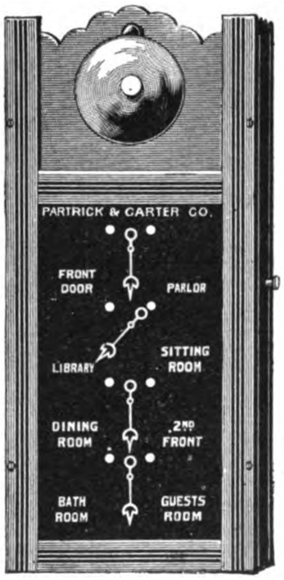
TRADE NOTES AND NOVELTIES

AND MECHANICAL DEPARTMENT.

Electricity will stand at least as much advertising as Soap, and make a larger return on the investment.

PARTRICK & CARTER'S NEW "SET-BACK" ANNUNCIATOR.

PARTRICK & CARTER Co., of Philadelphia, have just introduced to the notice of the trade a new automatic set-back annunciator, which bids fair to become very popular, and which the makers expect to supersede the old style trip annunciators in ordinary use. It is a well-recognized fact, they say, that the ordinary house annunciator does not fully answer the purpose for which it is designed. Servants and others will not trip or restore the drops, needles or other indicating mechanism, and hardly ever know from which room or locality the call proceeds, as there are sometimes from two to four pointers or drops registering on the dial. In this automatic system only one, and that the last call, remains pointing or indicating. Each new call resets the pointer that indicated the previous call, no attention to the annunciator other than observing the dial when the call comes in being required. The appearance of the automatic is the same as that of the "King" (one needle giving two indications) except that the resetting knob is dispensed with. All those who have had any practical experience with the ordinary annunciators which have to be tripped every time a call comes in, can appreciate this great improvement in the annunciator line, with its absolute certainty of receiving the last call only, and its freedom from complexity or liability to get out of order. This new annunciator is furnished from stock in all the leading varieties of wood cabinet. It is well made, like all the products of this house, and is very moderate in price.



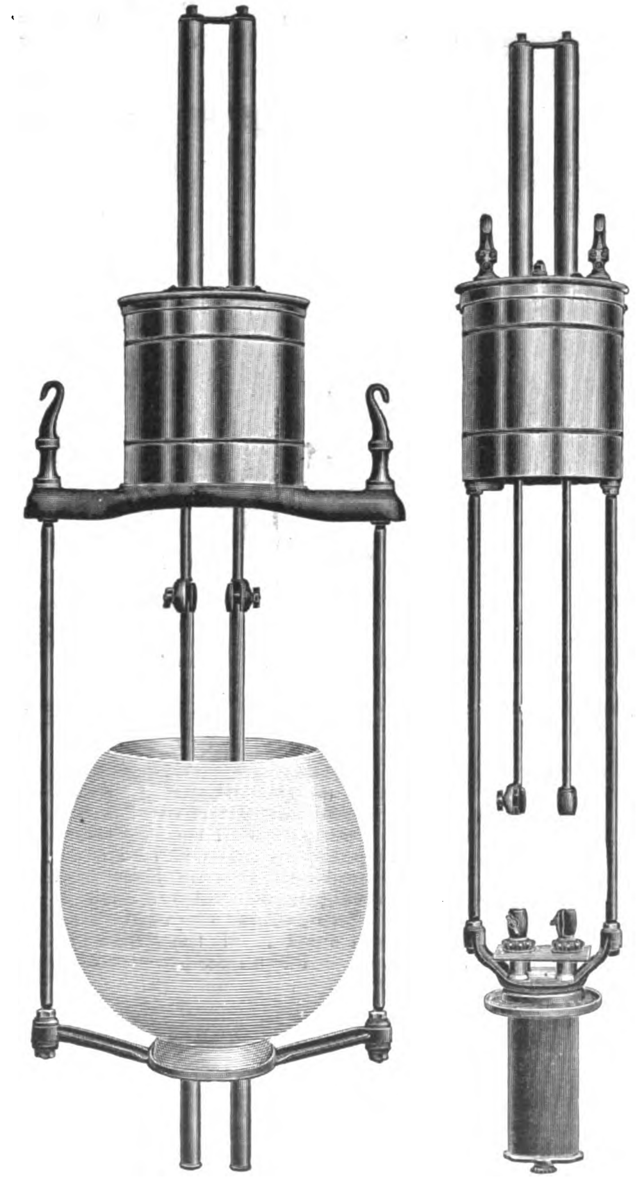
PARTRICK & CARTER'S NEW AUTOMATIC SET BACK ANNUNCIATOR.

THE D. & D. ELECTRIC MANUFACTURING COMPANY OF MINNEAPOLIS.

A NEAT and interesting catalogue of the dynamos and motors has been issued by the D. & D. Electric Manufacturing Company of 745-747 Washington avenue north, Minneapolis, Minn. The company are now making constant potential motors, incandescent dynamos, and power generators. Their type of machine is illustrated and described in this issue of THE ELECTRICAL ENGINEER. Besides giving a number of technical details as to their apparatus the company add the testimonials of a great many concerns that have had their dynamos and motors in use on all classes of work; and the reports are uniformly most favorable. Mr. Gilbert Donaldson is president and general manager of the company and Mr. Otis Humphrey is secretary and superintendent.

THE MONITOR DOUBLE ARC LAMPS OF THE WESTERN ELECTRIC CO.

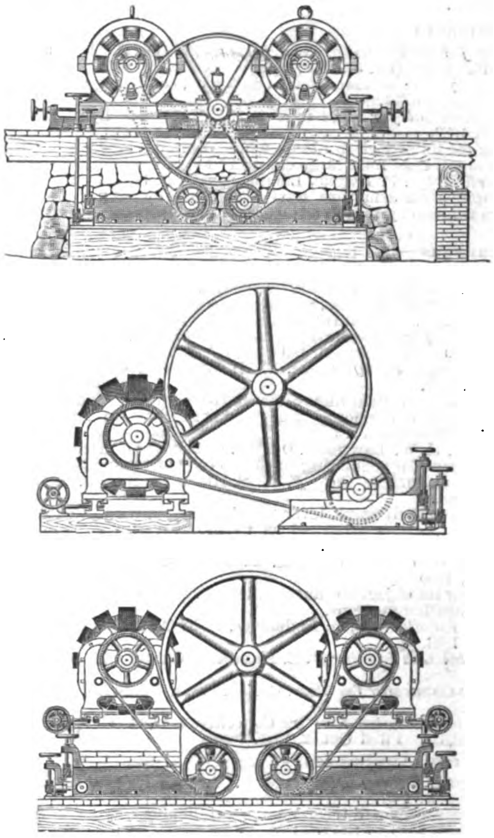
A HANDSOME new catalogue in stiff cloth boards has been issued by the Western Electric Co., of Chicago, New York, etc., devoted to its well-known and widely used arc lighting system. Illustrations and descriptions are given of the dynamos, lamps, switches, etc., and the pamphlet also includes some new apparatus which, while it has been successfully introduced, has not before been brought prominently to notice. Among these important novelties may be mentioned the "Monitor" double carbon arc lamp, which is here illustrated in Figs. 1 and 2, showing the wide frame style, and the narrow. These "Monitor" lamps are equipped with two independent regulating mechanisms, each of which controls the burning of a distinct pair of carbons. A simple automatic switching device serves to bring the second lamp mechanism into circuit and operation when the first mechanism has consumed its carbons. These lamps are usually supplied with half-inch carbons 12 inches long, but can easily be equipped to take carbons five-eighths inches in diameter, 14 inches long. They will burn two nights, or thirty hours, without retrimming. An interesting and valuable feature of economy with these lamps is that the adjustment of each lamp mechanism can be made without regard to its fellow; and it is claimed that proper adjustment is also much more easily secured than where the two feeding rods are regulated by one and the same mechanism. Another advantage claimed lies in the fact that in these double lamps no energy is wasted in holding up an idle but heavy carbon rod for several hours.



FIGS. 1 AND 2.—THE WESTERN ELECTRIC "MONITOR" DOUBLE CARBON LAMPS.

MODIFICATIONS OF THE EVANS FRICTION SYSTEM OF DRIVING DYNAMOS.

OUR readers are familiar with the Evans friction cone system, several times illustrated in these columns, of driving dynamos.



FIGS. 1, 2 AND 3.—APPLICATION OF EVANS' FRICTION CONE SYSTEM TO DYNAMO DRIVING.

We herewith illustrate a new method of application introduced by the Evans Friction Cone Co. of 85 Water street, Boston. The cuts, Figs. 1, 2 and 3, are so simple and plain that little explanation is needed. By this means, for example, 150 h. p. can be transmitted by the aid of an auxiliary pulley; two dynamos can be driven by one pulley; and one or both can be started and stopped while the driving pulley is running.

CLAYTON AIR COMPRESSOR WORKS.

WE have received from the Clayton Air Compressor Works, of 43 Dey street, New York, a copy of their handsome new catalogue No. 7, just issued. It is a large quarto of nearly 100 pages. It is the most complete one of its kind ever issued, and describes in detail the various styles of steam and belt-actuated air compressors for use in mining, tunneling, railway and bridge building, pumping natural gas, supplying pneumatic tubes, operating pneumatic riveters, tools and cranes, aerating water, elevating water, acids and other liquids, submarine work, operating oil fuel burners, refrigerating and ventilating, charging automatic sprinkler systems, stripping rubber hose in rubber factories, testing tinware, agitating liquids of all kinds, finishing silk ribbon, exhausting incandescent lamps, etc. It also illustrates and describes the new Clayton high pressure compressor, suitable for air or carbonic acid gas. The field of usefulness for compressed air is constantly broadening, and this catalogue shows several new designs representing the latest and most enlightened features of air compressor practice. It also contains testimonials, information and data of interest to users of compressed air, illustrations, tables and price lists, not only of the Clayton air compressors, but of the Clayton steam and belt-actuated vacuum pumps, of the Clayton fly-wheel steam pump, especially suitable for pumping coal tar, and also of air receivers, boilers, rock drills, smiths' tools, hose, couplings, etc. Copies of this catalogue, estimates and general information will be gladly furnished upon application.

THE NOVELTY ELECTRIC CO. of Philadelphia, have the contract for doing all the construction work on the new Masonic Temple at Camden, N. J.

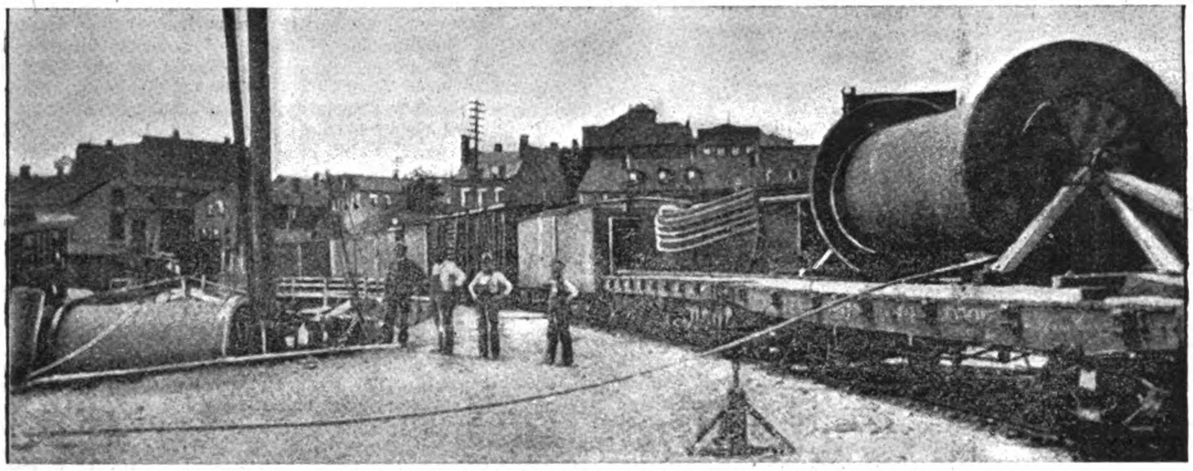
A THREE AND ONE-HALF MILE OKONITE CABLE FOR TELEPHONE WORK.

The submarine cables manufactured by the Okonite Company (Limited), 13 Park Row, New York, and so extensively used in the exacting applications of the leading telephone and telegraph corporations in the United States, are recognized as possessing exceptional merit for pliability, durability and efficiency. These results, so satisfactory to both the manufacturer and the purchaser, are due in part to the insulating properties of "Okonite," and in part to the extreme care exercised in the selection of all material, together with the close attention given during every stage of the manufacture of the cable, from the time it enters the factory at Passaic, N. J., as raw material, to the time it is shipped to its final destination as a finished production.

The Southern New England Telephone and Telegraph Company recently accomplished the laying of an "Okonite" submarine cable from a point on Pine Island near New London, Conn., across Long Island Sound to Fishers Island. This cable was three and one-half miles long, contained six copper conductors, weighed 50,000 lbs. and was in one length, without splice. It was transported from the factory at Passaic, N. J., on a "flat" car, on which was constructed a special reel, and laid from point to point without delay, accident or call for special help.

The entire management of transferring from the car, laying, etc., from start to finish was under the direction of Mr. E. B. Baker, superintendent Southern New England Telephone and Telegraph Co, ably assisted by Mr. R. D. Blish, the cable expert of the telephone company.

Our illustration, taken from a photograph, shows the cable after it arrived at New London, as it is being transferred from the reel on the "flat" car to the reel on the float, from which it was laid.



Unreeling Okonite Cable Crossing Long Island Sound to Fisher's Island.

The Southern New England Company, we are informed, has also laid a new length of cable between Pine Island and Eastern Point (on the mainland), thus insuring to the public a continuation of the prompt and reliable telephone service which they so zealously maintain.

THE PATTON MOTOR AND MANUFACTURING CO.

The above-named company have just completed a very handsome electric car of the well-known Patton system for Louisville, Ky., to be followed by nine more of the same style. The generating dynamo on the car takes the place of the fly wheel of the gas engine, being coupled directly on the shaft. The machine runs at a speed of twenty miles per hour, and under test pulled a freight train of eleven cars. One hundred cells of storage battery are used on this car, the standard number, however, which will be used in future being fifty, they simply being an adjunct to this system and not called upon to withstand the strains of a straight storage car. These batteries have been specially designed for great durability, combined with reasonable efficiency. The advantages of this system are that the generating plant is always furnishing the power for driving the car except under abnormal conditions of load, when the batteries assist, and the initial cost of the system is moderate.

The tests to which the Patton motor cars have been subjected have shown them, it is claimed, to be reliable and economical.

APPRECIATION IN THE SOUTH.

A reader in the South writes us: "I have noticed the growth of The Electrical Engineer with pleasure, and await its coming each week with considerable anticipation. I regard it as *the* paper for the profession. I wouldn't miss it for worlds."

NEW ENGLAND NOTES.

Jewell Belting Company, Hartford, Conn. The following is a partial list of the recent orders which this company has received for use on electric work: Jamestown Electric Street Railway Company, Jamestown, N. Y., two 36-inch double belts; Richmond Railway and Electric Company, Richmond, Va., one 56-inch double, one 36-inch double belts; Hartford Electric Light and Power Company, Hartford, Conn., one 60-inch 3-ply, one 44-inch double belts; Jersey City and Bergen Railroad Company, Jersey City, N J., three 27-inch double belts; North New York Electric Light Company, New York City, two 48-inch double belts; Chicago, Milwaukee and St. Paul Railroad Company, Milwaukee, Wis., one 56-inch double belt; Albany Railway Company, Albany, N. Y., one 48-inch double belt; Elizabeth Electric Light Company, Elizabeth, N. J., one 42-inch double belt; United Electric Company, Springfield, Mass, one 44-inch double belt. A recent visit to their factory in Hartford, showed every department full at work, and large electrical belts in every stage of construction. The Jewell belt has undoubtedly met with much favor amongst electrical men, and it is giving great satisfaction wherever used as evidenced by the large number of repeat orders which they receive. It is a distinct advantage to own one's tannery outright, as a much more careful selection of leather can be secured, and the company is well aware at all times of just what class of hides the leather is being produced from.

The Holyoke Machine Company, of Worcester, Mass., are furnishing the shafting, clutches and complete power transmission machinery for the following plants: Stamford Electric Light and Power Co., Stamford. Conn.: Mott Haven Electric Light Company, Mott Haven, N. Y.; Hudson Electric Light and Power Company, Hoboken, N. J.; Macon Electric Light Company, Macon, Ga., and the Suburban Electric Company, Elizabeth, N. J. They have also recently installed a number of their well-known Hercules turbines for electric work, which are giving excellent satisfaction, and are paying special attention to the governing properties of these wheels for electric railway work.

The Beacon Vacuum Pump and Electrical Company, Boston.—A syndicate of New York capitalists representing $5,000,000 are completing arrangements with this company, whereby they will have the right to establish lamp factories in England, Germany, France and Austria, in which the Beacon vacuum pump will be used, and the Beacon incandescent lamp manufactured. This lamp has attracted world-wide attention, and electricians are, it would seem, rapidly becoming convinced that exhaustion by metallic pumps is not only practicable but beneficial.

PHILADELPHIA NOTES.

Partrick & Carter Co.—The patrons of the Partrick & Carter Co. will soon be favored with the presence of the well-known salesman Mr. T. L. Townsend. who started last Wednesday on a tour covering nearly every State in the Union and a part of Canada; and is prepared to present many new novelties in electric bell supplies.

Francis, Nardi, Strang & Co., agents for the Merchantville (N. J.) Electric Light Co., are extending their plant through Dudley and Cramer Hill to Wrightsville, and from Cramer Hill to Pavonia. The above firm will open a store at Cramer Hill, where they will keep a full line of electrical supplies.

Mr. Charles E. White has the contract for installing a 50-arc light plant in the store of W. H. Wanamaker & Co., Twelfth and Market streets. The plant will be the American system, and a 60 h. p. Armington & Sims engine will be required to operate it.

KERITE IN THE ST. CLAIR TUNNEL.

The St. Clair Tunnel, near Detroit, owing to the dampness and gas, enabled the Great Western Telegraph Co. to fully test the claims made by Day's "Kerite" as to its being gas and damp proof. Their cables are exclusively used at the openings of the tunnel, and recent advices report perfect insulation.

RIES ELECTRIC SPECIELTY CO.

One would be surprised to see the enormous amount of shipments being made by the Ries Electric Specialty Co., of Baltimore, Md. Their regulating sockets are daily becoming more in demand, and large orders are being received from almost every portion of America and the Old World where the alternating current is used. This company are shortly going to increase their plant again so as to meet the rapidly growing demand for their specialties.

THE FALL CAMPAIGN.

Handsome steel engraved portraits of President Harrison and Mr. Cleveland are being sent out by Alexander, Barney & Chapin. They have gotten out a three-page folder, which, besides the portraits, gives the figures of the popular vote for President from 1824 to 1888, also a table of the electoral vote of each State at the present time, with blank columns headed "Cleveland" and "Harrison," so that political enthusiasts may have a choice to set down their prognostications for the coming election. Between the candidates is the "A. B. C." lamp, which shines for all.

NOTES FROM PEORIA, ILL.

The Fort Clark Street Railway Co. have just finished putting in a new engine and dynamo. The engine is a "Ball" of 180 h. p. This gives them a reserve of power, there being two other "Ideal" engines of 125 h. p. connected to two M. P. dynamos of Thomson-Houston manufacture.

The Rapid Transit Co. are progressing rapidly on their new line. The track is nearly finished and the poles are set. The trolley wire is not strung yet but soon will be. They will get their power from the Central R. R. plant.

Nicol Burr & Co., founders and general machinists, are putting in a 150-light generator to light their shops, etc. This is necessary as they intend to run nights to keep up with their orders.

The Local Edison Co.—There is considerable comment here on the delay of the city council in granting the Edison Co. a franchise for lighting and power. Also the Central Company, a company composed and backed by Peoria parties. The council wants to give a ten-year franchise, but the two companies won't accept one for less than twenty years. The Jenney Co. here are the only ones in the city. This company is controlled by the Gas Co., who have a monopoly and do not furnish all the lights that are ordered. It is almost an impossibility to get any incandescent lights at all.

NEW YORK NOTES.

Mr. C. J. Field, of the Field Engineering Co., is busily engaged in Philadelphia, putting in the first section of trolley road for the Philadelphia Traction Co. During a trip to this city last week he reported that rapid progress is being made. The Westinghouse Co. secured the first slice of the contract for motors, etc., and expect to secure all the rest on the same terms, as provided in the contract. The first power plant, to be put in by Mr. Field, will be of a temporary nature, as the Traction Company hopes in a year or two to have a magnificent power house, and probably more than one. Philadelphia—or at least one part of it—will soon be enjoying the blessings of the trolley system.

W. R. Fleming & Co., Mail & Express Building, this city, have just completed a plant for Hotel St. Lorenz in this city, that consists of two 60 h. p. Ideal engines, and are also installing in the Century Club, in this city, one 50 and one 60 h. p. Ideal engines. They have also recently taken several contracts for complete steam plants and are now erecting the following: Hotchkiss School Association, Lakeville, Conn., one complete plant of 70 h. p. Ideal engine and 90 h. p.. horizontal tubular boiler. Mount Vernon Construction Co., Alexandria, Va., complete boiler plant of 300 h. p. Municipal Electric Light Station, South Norwalk, Conn., complete plant of 100 h. p. Ideal engine and 125 h. p. horizontal tubular boiler.

Mr. I. P. Frink, of 551 Pearl street, New York, manufacturer of the well-known "Frink" reflectors, has recently made installations in the following churches: M. E. Church (South), Marshall, Mo.; Presbyterian Church, Washington, Ia.; First Congregational Church, Bay Shore, L. I.; M. E. Church, Stroudsburg, Pa.; Presbyterian Church, E. Stroudsburg, Pa.

The Electrical Engineering and Supply Co., of Syracuse N. Y., have issued a descriptive catalogue of 137 pages, profusely illustrated, and covering more than 450 different devices relating to electric lighting, railway and construction work. The book also contains a useful wiring table for 16 c. p. incandescent lamps of 50 and 110 volts.

The United States Projectile Co., of Brooklyn, N. Y., are so driven with work that they have placed the order with the Berlin Iron Bridge Co., of East Berlin, Conn., for an addition 240 feet long to their present building. The addition will be entirely of iron from the designs of the Berlin Company.

PHILADELPHIA NOTES.

Warren Webster & Co., 491 North Third street, Philadelphia, have issued a very neat, handsome and convincing pamphlet on the Williames vacuum system of steam heating which they control, and which they have been remarkably successful in introducing. It describes and illustrates the system and prints a number of testimonials which go to prove how valuable an adjunct the system is in the steam heating of any building, group of buildings, train of cars, etc. The pamphlet also contains information as to the patent litigation decided in favor of Warren Webster & Co.

Mr. Jno. A. Blattau, special traveler of the Ries Electric Specialty Co., of Baltimore, Md., says that the Ries regulating socket is making thousands of new consumers for the central stations, and that enterprising construction firms are reaping a harvest, particularly in wiring residences with this device.

WESTERN NOTES.

The Central Electric Company have taken the agency for "Machines for Painting Mouldings," recently illustrated in **The Electrical Engineer** and manufactured by the Standard Paint Company of New York City. These machines can be had from the Central Electric Company, or any of its branches; the Southern Electrical Supply Company, at St. Louis, Mo.; Gate City Electric Company at Kansas City, Mo., and the Western Electrical Supply Company at Omaha, Neb.

A Large Contract for Arcs.—Col. F. O. Richards, of the Standard Electric Company, of Chicago, has just closed contracts with the Cincinnati Edison Electric Company for fifty 50-light Standard dynamos for running 2,500 arc lamps of 2,000 c. p. each for street lighting. In addition to this they have already furnished two 50-light machines for commercial lighting. This is one of the largest contracts ever closed for arc lighting apparatus.

Decatur, Ill.—The Piatt Electric Co., 142 South Water Street, has bought the whole lighting business, etc., of R. F. Piatt, as well as the stock and business of the Decatur Manufacturing Co., electrical contractors, etc. Until further notice the business of the Piatt Electric Co. will be carried on by Mr. E. E. Gibson, secretary and treasurer, who has also been appointed purchasing agent.

The Electric Appliance Company are enjoying great activity in all lines of their rapidly increasing business.

Their pioneer efforts in the introduction of the Elkhart transformer are beginning to bear fruit, and they are in constant receipt of "second orders," which testify to the satisfaction which the "Elkhart" is giving.
